COLORIMETERS, CHROMOMETERS, or **CHROMATOMETERS.** Under this heading are included those instruments (*colorimeters*) which are used for determining the relative intensity of colour in solutions, and those (*chromatometers, tintometers*) which are used to obtain a numerical record of the hue and intensity of a colour.

Colorimetric measurements depend on obtaining equal intensity of colour in two columns of liquid, one of which contains a known amount of the substance to be estimated. This can be done either (*a*) by varying the *concentration* of one liquid, keeping the lengths of columns equal, or (*l*) by altering the length of one column, keeping the concentration the same.

The first method is used in Nessler's test, in Eggertz' method of estimating carbon in steel, and in the simple colorimeter of the U.S. Geological Survey (Bulletin 422). It is applicable to all colorimetric measurements. The second principle is adopted in most cases because it allows the repeated use of the standard solution and facilitates rapid work. In certain cases, however, *e.g.* in comparing manganese solutions, this method fails, as varying the length of column changes the *hue* as well as the *intensity* of the colour.

·The standard used may be of the same composition as the liquid under examination, or may be made of any suitable materials, but its colour must be identical in *quality* with that of the liquid tested, and its value per unit volume in terms of the substance estimated must be accurately known. Thus the permanent standards used in the estimation of combined carbon in steel are generally made of mixed solutions of *metallic salts*, and in the estimation of ammonia in water a solution coloured with *caramel* and a little *aniline red* has been used (Leeds, Chem. News, 37, 229).

Equality of tint having been obtained, the lengths of the columns are noted, and the comparison is repeated, using, preferably, a different length of column of the standard.

The relative strength of the solutions varies *inversely* as the lengths of the columns, so that

if 1 c.c. of the standard solution correspond with x parts by weight of the substance estimated, the weight of that substance in 1 c.c. of the test solution will be

$$\frac{\text{length of column of standard solution} \times x}{\text{length of column of test solution}}$$

If the strength of the standard differs by more than 10 p.c. from that of the test liquid, it is advisable to dilute one or other before comparison.

For the examination of precipitates, a solution of considerable suspensory power is prepared by dissolving 100 grams of gelatine, 100 grams glacial acetic acid, and 1 gram of salicylic acid (to prevent decomposition of the gelatine by keeping) in 1 litre of distilled water.

The solution is clarified with white of egg and filtered hot. For estimation of sulphuric acid, this solution is charged with barium chloride, and is added to a weak standard solution of sulphuric acid or a sulphate and to the solution to be tested, the two turbid liquids being then compared as above. By the use of other reagents, lime, zinc, and a large number of other substances may be estimated.

A useful colorimeter for general purposes, devised by Mills, is shown in Fig. 1. It consists of a glass jar closed above by a cap of which the length is sufficient to cover the top of the liquid. The cap is perforated in the middle and carries a short tube in which slides a glass rod bent as shown, and supporting, exactly at right angles to the axis of the jar, a flat circular opaque white disc. In the bottom of the jar are laid, one above another, a red and a green glass disc which form a black background to the white disc. When examining solutions of certain colours, a background of a colour other than black may be advantageous, and the white disc itself may be covered by a coloured plate. The white disc is lowered to the bottom of the jar by moving its rod, and the jar is filled to exactly 100 divisions with a standard liquid.

The white disc is raised until, on looking vertically down through the liquid at the disc, the depth of tint appears suitable. A second apparatus is then filled to 100 divisions with the liquid to be tested and its disc is adjusted until the colours of the columns of liquid in the two jars appear of equal intensity.

By placing on the white disc a small, black, hemispherical button, this instrument may be used for determining the strength of turbid solutions, such as milk, or for ascertaining the amount of a precipitate suspended in a liquid. Milk is diluted before examination with 99 parts of water, and is compared with a similarly diluted milk of known quality, the disc with the button

FIG. 1.

being adjusted in each tube as above until just invisible.

The slight alteration in the level of the liquid caused by the varying length of the sliding tube contained in the liquid when adjusting the height of the white disc is found by experiment, and a correction must be introduced into the calculation for variations of more than two or three divisions.

A very useful colorimeter, especially designed for the estimation of carbon in steel, but of course available for other purposes, has been introduced by Stead (Proc. Iron and Steel Inst. 1883, No. 1, 213). A similar, but more convenient apparatus, devised by Ridsdale (J Soc. Chem Ind 1886, 586) is shown in Fig. 2 Three glass tubes, each fitted below with a small,

FIG. 2.

opaque, white cylinder, are placed beneath a movable mirror, in a stand which may be turned to any position upon its weighted base. The central tube is removable and is closed below ; the outer tubes are drawn out and pass through indiarubber corks into ruby glass bottles, containing standard solutions of different strengths. Each bottle has a tube with a stopcock through which the liquid may be introduced or removed, and each is connected by a flexible tube with a syringe.

The liquid under examination is introduced into the central tube, and by working the syringes the standard solutions are raised in their tubes until the intensity of colour in each tube, as seen by looking into the mirror which is adjusted to reflect the light passing upwards through the tubes, is identical. Two distinct comparisons are thus simultaneously made, and, by noting the height of each column by means of the sliding pointer, the strength of the tested liquid may be ascertained from the formula already given. A very important advantage of this apparatus is that every part except the central tube is cleansed and recharged without disconnection.

Ridsdale (J. Soc. Chem. Ind. 1888, 70) has devised an apparatus for the examination of liquids of deeper tint than can be used in the foregoing apparatus. The central upper tube (Fig. 3) is sealed below, the upper side tubes are perforated at the bottom. Each tube contains a loose white opaque plug, and each is held at

FIG 3

any height by a movable jaw pressed against it by an indiarubber band.

The centre tube is charged with, say, 10 divisions of the standard solution, and the test liquid is run into one of the side tubes, whence it passes at once into the lower tube. When this is nearly filled, it is gradually raised to bring a portion of its contents into the upper

tube, until, on looking down vertically, the colours in the upper side tube and in the standard tube are of equal intensity. The calculation is made as already described. The lower tube beneath the standard tube must be raised with that of the side tube in order to equalise the effect of the double thickness of glass. When the solutions to be tested differ widely in tint, the standard tube may be perforated so that the length of its column may be readily adjusted.

Stokes' apparatus (Chem. Soc Proc 1887, 135) has two tubes placed vertically in a stand with a reflector below One tube is connected with a reservoir of the standard solution, by raising or lowering which the level of liquid in the tube can be altered

A similar arrangement is used in Le Docte's colorimeter (Eng. Pat 20667, 1898).

The Kennicott-Sargent colorimeter (Chem. Engineer, 1907, 213) differs from the above only in altering the level of the standard liquid by moving a glass plunger in a fixed cylindrical reservoir

Another arrangement, in which the standard liquid is forced into a graduated tube from a reservoir, is described by Gunsberg (Dingl poly. J. 228, 457).

The Nesslerising tubes adopted by Hehner (Chem. News, 33, 185) and recommended by Milne (J. Soc. Chem. Ind 1887, 33) are two cylinders of equal and perfectly uniform diameter, holding about 100 c.c Each is graduated from below, and at about the 30 c c. division has a glass stopcock.

The two cylinders are placed side by side on white paper, and to one of them is added 100 c c. of the liquid to be tested, followed by 2 c.c. of Nessler's solution To the other tube a suitable and known amount of standard solution of ammonium chloride is added, and the volume is made up to 100 c.c. with distilled water, after which 2 c.c. of Nessler's solution is added. The two liquids are looked at *vertically*, and the darker is allowed to slowly run off into a clean beaker, until their colours are equal The comparison may be repeated after filling up from the beaker. The mode of calculation is the same as in former cases.

A modified form of Eggertz tube has been described by Hogg (J. Soc. Chem. Ind 1895, 1022).

In a colorimeter devised by Leeds (Chem. News, 37, 229) comparison tubes are arranged in a rack, light being reflected through them by an inclined upper mirror, and again reflected to the eye of the observer from a mirror similarly placed beneath them. The standard liquid is contained in a bottle prism which is moved beneath one of the comparison tubes containing distilled water only until the colour observed is identical with that in the tube containing the test liquid. The strength of the test liquid is calculated from the thickness of liquid in that section of the prism which is interposed.

Gallenkamp's colorimeter (Chem. Zeit. Rep. 1891, 324) consists of two vertical troughs enclosed in a metal frame. That which contains the standard solution is wedge-shaped, while that for the test liquid is rectangular. An observation apparatus, moving vertically over a scale of 100 parts, has two slits at the same level, one

opposite each trough, the light from which is reflected and brought into one eyepiece. The observation consists in finding the thickness of the stratum of standard solution in the prism, which shows the same depth of colour as the test liquid.

White's apparatus differs from the above in having two wedge-shaped tanks, both movable with reference to two fixed slits through which the depth of colour is observed.

A colorimeter, described by Autenrieth and Koenigsberger (Chem Zentr. 1910. i. 2032) and recommended especially for the determination of hæmatine in blood, depends on comparison of the test liquid with a stable solution of similar hue contained in a wedge-shaped reservoir which is movable vertically beside the trough containing the test liquid. The movement of the wedge is measured on a millimetre scale, and the reading translated directly into percentages by reference to a plotted curve The two colours are observed through a Helmholtz ' Doppelplatte,' which obviates a dividing space in the field of view By substituting a suitable wedge, the instrument can also be used for the estimation of titanium, iron, chromium, iodine, ammonia, nitric acid, &c

Schreiner's colorimeter (J Amer Chem. Soc 1905, 1192) consists essentially of two parts : a wide flat - ended tube, 4 in. about 26 cm × 3 cm , graduated in millimetres, and the flat - ended immersion tube A, about 26 cm × 2 cm , which slides inside the wider tube

Two such pairs of tubes are mounted on a stand (Fig. 4), the inner tubes being fixed to the top of the camera while the outer tubes are held in brass clips which keep them in position, but permit their being moved up and down The length of the column of liquid enclosed between the ends of the outer and inner tubes can thus be adjusted at will Light,

Fig. 4.

reflected from a white surface D, passes through the two columns of liquid, and is then reflected at a mirror E to the observer's eyes at F. The axes of the tubes are inclined to one another so as to bring the images close together. Standard glass slides may be inserted at G in place of one of the wide tubes, the immersion tube being left in position.

Patterson has described (J. Soc. Chem. Ind. 1890, 36) a more complex apparatus employing
the same principle. In this case the adjustment of the concentric tubes is made by rack and pinion, and total reflection prisms are employed to bring the two images into one eyepiece. By substituting a direct-vision spectroscope for the eyepiece, the apparatus becomes a *spectrum absorptimeter*.

The simple and effective colorimeter devised by Steiger (J. Amer. Chem. Soc. 1908, 215) consists of two wooden boxes painted dead-black inside, one of which (Fig. 5A) is mounted on a

FIG. 5A.

stand and has a rectangular opening C in the base, while the second box (Fig. 5B) fits into the

FIG. 5B.

first, and has a rectangular opening, E, which coincides with C.

In the base of this box are two grooves in which slide two rectangular glass cells K, K, about 15 cm. long × 2·5 cm. wide × 5 cm. deep.

Fixed vertically over the opening E are two glass rods F, F, held in place by the springs R, each carrying at the lower end a small plane mirror, G, fixed at an angle of 45°. Light coming through the ground-glass A is reflected by a mirror, B, through the aperture E into the tank, where it is again reflected at the mirror G and passes through a column of liquid, the length of which can be altered by moving the tank backwards and forwards. When equality of colour is obtained, the lengths of the columns are read

off on millimetre scales engraved on the base of each tank. The reading is taken where the lower edge of the mirror touches the bottom of the tank.

Otto's *ozonometer* has two parallel tubes for gases or liquids, and employs wedges of coloured glass moving over a graduated scale as a means of measuring the depth of tint (Eng. Pat. 17524, 1898).

H. Krüss suggests (Zeitsch. anorg. Chem. 5, 325) the application to colorimeters of the Lummer-Brodhun double prism, which gives a field of view in which there is no visible line of separation between the two colours under observation. This condition gives maximum accuracy in matching the colours (*see also* Chem. Soc. Abstr. 1894, ii 158).

Andrieux (Compt. rend. 103, 281) describes an apparatus in which the *quality* and *intensity* of a colour are determined by comparison with a ray of polarised light.

An apparatus has been described by Meisling (Zeitsch. anal. Chem. 1904, 137), in which the hue is matched by the colour of a quartz plate in polarised light, and the intensity is measured by varying the length of the column of liquid.

An ingenious instrument, introduced by Mr. J. W. Lovibond, for the examination of liquids, powders, fabrics, &c., and known as the *tintometer*, is shown, partly in section, in Fig. 6. It

FIG. 6.

consists of a box, closed at one end by a ground glass plate, e, and separated into two divisions b, c. The box is carried by a stand, adjustable to any angle. A square glass cell, of known width, along the line g' g^2, containing the solution to be examined, is placed in one division, and glass plates h of similar colour (or, if necessary, of different colours, producing the proper tint in combination), and of known intensity, are placed in grooves in the other division, until, on looking through both tubes simultaneously through a single eyepiece, d, shaded to prevent access of side light to the eye, the appearance through the glass plates is identical with that through the solution.

The standard plates are specially prepared of various colours, and each is distinguished by a number indicating its *colour*, and another number showing the *intensity* of colour, i.e. the number of plates of that colour of unit intensity required to produce an intensity equal to that of the plate. The unit chosen by the inventor for each colour is an arbitrary one, but its actual value can be ascertained at any time by comparison with a standard solution of similar colour.

In some cases the glass plate e is wanting, and an adjustable plane glass mirror is used to reflect the light to the apparatus (Eng. Pat. 12867, 1886).

When the colour of a fabric is to be estimated, the fabric is stretched on a block placed in the division c, and a white fabric of *similar texture*, previously compared with a plate of pure *plaster*

of Paris, is placed in the division *b*. The standard plates are then inserted as above until the appearances through the eyepiece are identical. *Powders, sugars, &c.*, pressed in a small tray placed in the division *c*, may be similarly examined, a tray containing pure plaster of Paris being placed in the division *b* (J. Soc. Chem. Ind. 1888, 234).

For very delicate observations, the intensity of the light used may be found and noted, before commencing, by closing the division *c* and placing in the divisions *b* as many standard plates of *neutral tint* as serve to obstruct all the light.

The substitution of a movable wedge of coloured glass for the standard plates makes the apparatus available for ordinary colorimetric determinations (J. Soc. Chem Ind 1888, 234). An improved form of Lovibond's apparatus is binocular, and has a movable diaphragm. This makes it applicable to tests of colour vision (*ibid.* 1891, 489) (*see also* Lovibond, *ibid.* 1909, 500).

Procter has described (*ibid.* 1895, 123) a modified form of tintometer in which, by a system of mirrors, the colours to be compared are brought close together in the field of view, thus giving greater accuracy.

Sczepanik (Eng Pat. 22995, 1907) has patented an ingenious apparatus with which a numerical record of any colour can be obtained. Three strata of liquid of the three primary colours are superimposed. The thickness of each stratum can be measured and altered independently of the others, and thus any hue or intensity of colour can be matched.

Gardner and Dufton have introduced the ' Dalite ' lamp, which gives a light of the quality of daylight, and may be used for tintometric work (J. Soc. Chem. Ind. 1904, 598). This lamp is also of use in performing titrations by artificial light.

A useful device, introduced by Dupré (Analyst, 5, 123), may be mentioned under this heading. In the volumetric estimation of silver with potassium chromate as an indicator, especially when the solution is weak, it is somewhat difficult, on account of the original yellow colour of the solution, to observe the first tinge of red produced by the formation of the silver chromate. Dupré interposes, between the eye and the test liquid, a flat glass cell (of which the faces are about half an inch apart) containing a solution of potassium chromate of such strength as will neutralise the colour of the test liquid, which thus appears perfectly colourless, and in which the faintest appearance of red is readily visible. The cell filled with other liquid may be similarly adopted in many other titrations.

König (Proc. Amer. Phil. Soc. [18] 7, 29, 184, 208, 211) has devised a method for estimating metals by the intensity of the colour imparted by them to the borax bead. He dissolves a known weight of the oxide in a known weight of borax, grinds the bead until its faces are flat, coats it with Canada balsam to render its rough faces transparent, and places it in an apparatus where it is viewed by a lens of small power, while, by means of a rack, a glass prism whose colour is complementary to that under examination, is moved before it until such a thickness is interposed that the colour of the bead is extinguished.

A photochemical process for estimating differences in the intensity of a colour has been described by E. J. Mills and Buchanan (J. Soc. Chem. Ind. 1888, 309). It has been applied to the comparison of dyed goods. A number of discs of the tissues are photographed on one negative from which a number of positives on paper sensitised with silver, are copied. These are treated as usual, soaked for a considerable time in sodium thiosulphate to remove the whole of the unaltered silver salt, well washed, and dried. The disc photographs of each tissue are cut from a number of positives and each set is burned separately. The silver in the residue is dissolved and estimated volumetrically. The relative amount of silver found in the different sets of discs directly represents the relative intensity of the colours.

The following colorimetric process for the estimation of minute quantities of sulphur in iron, mineral waters, black ash, slag, &c., is due to Wiborgh (Chem. Zeit. 10, 92 ; Chem. News, 1886, 54, 158).

The divided metal, ore, &c , or the concentrated solution, is introduced into a small flask provided with an indiarubber cork, through which passes a stoppered funnel for introduction of acid, and a narrow-mouthed funnel ground at the top. A disc of white calico, which has been previously saturated with a solution of 5 grams crystallised *cadmium nitrate* (or, preferably, *cadmium acetate*) in 100 c c. of water and dried in a horizontal position on a cloth, is fixed between two indiarubber rings of the same interior diameters as the standard discs hereafter described, and the rings are firmly clamped over the funnel mouth. Dilute sulphuric acid is poured into the flask and heat is applied. In from 30 to 45 minutes the whole of the sulphur which is capable of conversion into sulphuretted hydrogen has passed off in that form and has been *wholly* absorbed by the cadmium salt on the calico. The disc is removed and compared with a set of standard discs, similarly prepared from iron containing a known amount of sulphur. The standard discs should not be exposed too freely to light. Arsenic, carbon, silicon, and copper do not appear to affect the determination. This method is so delicate that a disc will show a tinge of the yellow colour due to the cadmium sulphide when so small a quantity as the 1000th of a milligram of sulphur is present per square centimetre.

COLOUR AND CHEMICAL CONSTITUTION.

The object of this article is to give as concise a description as possible of the various rules which have been established, and the theories which have been proposed, with regard to the relation between colour and chemical constitution, particularly to the colour of dyes, with special reference to those rules which have proved of value in the preparation of dyes and which have served as guides for modifying the colour in a group of dyes.

Historical Outline.—The first synthetic dye (mauve) was produced by Sir W. H. Perkin in 1856. This branch of synthetic chemistry developed with great rapidity, and in the next twenty years the first members of many important groups of dyes had been prepared, *e.g.* fuchsine (1859), rosaniline blue (1860), and alkylated triphenylmethane dyes (1863–1866) ;

Bismarck brown (1864), chrysoidine (1876), and naphthol orange (1876) in the azo- group; Martius yellow (1864) in the nitro- group; Magdala red (1868) in the azine series; alizarin (1869) of the anthraquinone group; fluorescein and eosin (1874), representing the phthaleins, and Lauth's violet (1876), foreshadowing the thiazines. By this time sufficient material had been accumulated to allow the formulation of the well-known *Witt's Rule* (1876), according to which substances attained the potentiality of colour when their molecules contained certain atomic arrangements or groups, which Witt termed *chromophores*. The colour and dyeing properties were made manifest by the introduction of additional groups termed *auxochromes*.

Within the next three years additional triphenylmethane and azo- dyes were produced, deeper colour (red) being attained in the latter group by the use of naphthalene components in place of the benzene derivatives used in the earlier members, as *e.g.* in the Ponceaus (1878); and also by the introduction of an additional chromophore, as in Biebrich scarlet (1878). A consideration of the results now obtained, especially in the triphenylmethane and azo- groups, led to the enunciation of *Nietzki's Rule* (1879), which states that the colour of a dyestuff can be deepened by adding groups so as to increase its molecular weight, and that the deepening of colour produced is more or less proportional to the increase of molecular weight. (It should be noted that the term *depth* is used by colour-chemists in a very definite and limited way. In ordinary language the term depth of colour has at least two meanings. Blue and red are said to be deeper colours than yellow, and also one yellow is said to be deeper than another yellow if it is stronger or more intense, *i.e.* less admixed with white. Colour-chemists restrict the use of the term, and employ it for the first purpose only. Blue is deeper than red or yellow, and red is deeper than yellow. The ordinary colours arranged according to depth are: green, blue, violet, red, orange, yellow, *i.e.* the complements to the ordinary colours of the spectrum taken in order from the red to the violet end. This rule served for many years as a most valuable guide in extending the range of colours in many groups of dyes, especially in the azo- group, in which the deepest colours were now soon obtained (blue-black, 1882, Glaser). It may be said that this rule is still a valuable guide to the colour chemist.

In 1885 Liebermann and v. Kostanecki published the results of their investigations of the colour and dyeing properties of the hydroxy-derivatives of anthraquinone. Although these authors did not commit themselves to any very definite statement, yet their publication drew the attention of colour-chemists to the ease with which colour could be deepened by the multiplication of auxochrome groups in the molecule, provided these groups were suitably arranged. This general principle may be said to have been of equal value with Nietzki's Rule, and for many years the development of dye manufacture was almost entirely controlled by these two rules. Very interesting and ingenious methods were developed by Bohn and Schmidt in 1888 and 1890 for the multiplication of hydroxyl groups in the anthra-

quinone molecule with the result that a complete range of colours was soon available in this group of mordant dyes. The continued application of the same idea led somewhat later to the preparation of anthraquinone dyes containing both amino- and hydroxyl- groups, such as alizarin saphirol (1898), which combines the advantages of deep colour and fastness with brightness and clearness of tone. Liebermann and Kostanecki's Rule led at once to the careful study and production of dihydroxy-, amino-, hydroxy-, and diamino-naphthalene derivatives and their employment in the manufacture of azo- dyes. This general principle led to the production between the years 1887 and 1897 of an enormous number of azo- dyes of all colours.

In 1888 H. E. Armstrong put forward the best-known theory which has ever been formulated as to the cause of colour in organic compounds. This is known as the *Quinonoid Theory*. Its author pointed out that the chemical formulæ of the well-known dyestuffs either contained the *quinonoid* grouping or could be slightly modified or rearranged, in accordance with accepted ideas on tautomerism, so as to contain this grouping. More recent work has shown that the original quinonoid theory cannot stand. Modifications have been put forward by Baeyer (1907) and H. v. Liebig (1908), neither of which, however, is entirely satisfactory.

Of recent years it has come to be generally recognised that visible colour is only a special case of selective absorption. That some substances are coloured whilst others, nearly related, are colourless, must be regarded as more or less accidental, and due to a physiological cause rather than to any essential physical difference between them, viz. to the fact that the human eye can only detect selective absorption within a limited range of the spectrum. The problem of colour has thus resolved itself into two parts: (1) the cause of selective absorption; (2) the cause of the absorption lying within the limits of the visible spectrum.

As to the cause of selective absorption various theories have been put forward in recent years. We may mention Baly and Desch's theory, according to which absorption bands are due to dynamic isomerism (1904–1905), Stewart and Baly's theory of isotropesis as the cause of selective absorption (1906), Watson and Meek's theory that absorption in the visible spectrum and its neighbourhood is due to the reversal during tautomeric change of a conjugate chain of alternate double and single bonds (1915), the theory that absorption bands in the visible part of the spectrum are due to the vibration of electrons, and Baly's theory (1914) that absorption bands in the visible and ultra-violet parts of the spectrum are due to overtones or summation or difference tones derived from fundamental vibrations causing infra-red absorption bands (infra-red absorption bands have been attributed by most investigators to the vibrations of definite chemical radicals, Abney and Festing (1881), Julius (1888), Coblentz (1904–1905), and Weniger (1910)). In 1897 Pauer showed that under certain circumstances ordinary broad absorption bands are replaced by a large number of fine bands, recalling the lines in the emission spectra of substances examined in flames or under the

influence of the electric discharge. Hartley (1908) came to the conclusion that the ordinary broad absorption bands are formed by the fusion of these narrow bands. Various observers have shown the intimate connection between such fine absorption bands and the lines in the emission spectra of the same substances, *e.g.* Wullner (1863), Mitscherlich (1864), Salet (1872), Eder and Valenta (1899). And, finally, in certain cases (hydrogen and helium) the lines in the emission spectra have been deduced with great accuracy on the hypothesis that they are due to rotational vibration of electrons within the atoms.

The fact that so many different theories have been formulated makes it obvious that no final conclusion has been reached as to the cause of absorption bands in general.

As to the causes which bring the absorption bands into the visible spectrum and influence their positions within the visible spectrum, many investigators showed that Nietzki's rule was only a first approximation to the facts, and many exceptions to this rule were collected by Schütze (1892). Hewitt (1907) suggested that the chief oscillation frequency was less, and consequently the colour was deeper, the longer the conjugate chain of alternate double and single bonds in the molecule. The present writer pointed out in 1914 that those dyes of which the molecular formula can only be written in a quinonoid form have all a deep colour, whilst if the formula can be written either in a quinonoid or a non-quinonoid form, even great molecular complexity may fail to produce any great depth of colour. Watson and Meek (1915) showed that in several series the period of the absorption band is proportional to the length of the conjugate chain, which may be assumed to reverse during tautomeric change.
No explanation has yet been offered of the great effect on depth of colour which is so frequently produced by a multiplication of auxochromes. The relative position of the auxochromes has a great effect on the colour. Certain regularities in this respect have been pointed out by Kauffmann and Franck (1906), and Meek and Watson (1916).

It cannot be said that the theories which have been formulated since 1885 have proved of much service for the preparation of dyes. In the older group of dyes a complete range of colours had already been attained by assiduous experiment, guided by Nietzki's and Liebermann and Kostanecki's rules. It may perhaps be claimed that the quinonoid theory had some influence in the development of the azo-pyrazolone dyes. The present writer was able to apply one of the rules which he formulated to the production of deep-coloured dyes from the yellow flavones, and the work in this direction was perhaps of service for the recognition of the molecular structure of the colouring matters of flowers (anthocyanins). As to the new groups of valuable synthetic dyes which have been developed recently, the sulphide dyes, and the anthraquinone vat-dyes, the constitution of the former has been too little understood to allow of anything but empirical investigation, whilst in the latter group (the anthraquinone vat-dyes), our theories seem at present quite unable to explain the wealth of colour phenomena exhibited by the dyes already synthesised.

A short account is appended of some of the more important theories and rules above mentioned.

Witt's Rule.—This investigator pointed out (Ber. 1876, **9**, 522) that two things are required to give an organic substance colour and dyeing properties. The molecule must possess a certain grouping of atoms to give it the potentiality for colour, and it must also possess a salt-forming radical to bring out the colour and dyeing properties. The atomic groupings giving the potentiality of colour he termed *chromophores*, and molecules containing them were called *chromogens*. He specified the following chromophores and gave illustrations of chromogens containing them :—

Chromophores	Chromogens
NO_2	$C_6H_5NO_2$
$—N=N—$	$C_6H_5—N=N—C_6H_5$
$—CO—$	$C_6H_4\langle\begin{smallmatrix}CO\\CO\end{smallmatrix}\rangle C_6H_4$
$\langle\begin{smallmatrix}O\\C_6H_4(CO)_2\end{smallmatrix}$	$C_6H_4\langle\begin{smallmatrix}CO—C_6H_4\\CO—C_6H_4\end{smallmatrix}\rangle O$

It will be noticed that some of the chromogens are colourless, *e.g.* nitrobenzene and phenolphthalein, whilst others have a feeble colour, *e.g.* azobenzene and anthraquinone ; but none of the chromogens has any dyeing property. The colour is developed or strengthened by the introduction of salt-forming radicals into the chromogens. These radicals he therefore termed *auxochromes.* Hydroxyl, amino- and substituted amino- groups, *e.g.* $NHCH_3$, $N(CH_3)_2$, &c., are the principal auxochromes. Not all salt-forming groups can act as auxochromes, *e.g.* sulphonic and carboxyl groups are without this function. The following table shows how the chromogens already mentioned are converted into dyes by the introduction of auxochromes :—

Chromogen	Dye
$C_6H_5NO_2$	$C_6H_4(NO_2)OH$ Nitrophenol.
	$C_6H_4(NO_2)NH_2$ Nitraniline.
$C_6H_5—N=N—C_6H_5$	$C_6H_5—N=N—C_6H_4OH$ Benzene-azo-phenol.
	$C_6H_5—N=N—C_6H_4NH_2$ Aniline yellow.
$C_6H_4\langle\begin{smallmatrix}CO·C_6H_4\\CO·C_6H_4\end{smallmatrix}\rangle O$	$C_6H_4\langle\begin{smallmatrix}CO·C_6H_3·OH\\CO·C_6H_3·OH\end{smallmatrix}\rangle O$ Fluorescein.

## THE QUINONOID AND MODIFIED QUINONOID THEORIES.

In 1888 (Proc. Chem. Soc. 1888, 27–33). H. E. Armstrong pointed out that the chemical formulæ of the well-known dyestuffs either contained the *quinonoid* grouping or could be slightly modified or rearranged, in accordance with accepted ideas on tautomerism, so as to contain this grouping. The *quinonoid* grouping may be defined as a benzene nucleus to which

other atoms or groups are attached by double bonds in the *para-* or *ortho-* positions :

$$= \bigcirc = \quad \text{or} \quad =\bigcirc$$
Armstrong was probably much impressed by the recently discovered fact that benzene-azo-β-naphthol was identical with the phenyl hydrazone of β-naphthoquinone, so that there was as much justification for the formula
$$C_6H_5NH—N=\bigcirc\!\!\!\bigcirc \!\! O$$
as for the more usual one based on the formation of the substance from β-naphthol and a benzene-diazonium salt, viz. :

$$C_6H_5N=N—\bigcirc\!\!\!\bigcirc^{HO}$$
and if it were allowable to assume tautomerism to a quinonoid form in this case, it might be allowable in other cases, *e.g.* in the case of fluorescein :

$$HO\bigcirc\!\!\!\bigcirc\!\!\!\bigcirc OH \rightleftharpoons \bigcirc\!\!\!\bigcirc\!\!\!\bigcirc OH$$
$$\underset{\substack{| \\ C_6H_4\\ |\\ CO}}{C} \qquad \underset{\substack{|\\ C_6H_4\\ |\\ COOH}}{C}$$

whilst in the case of *p*-rosaniline it was quite consistent with experimental fact to suppose that on the conversion of the base into salts there was elimination of a molecule of water and formation of a substance with a quinonoid structure :

$$HO—C\!\!\!\underset{\diagdown C_6H_4NH_2}{\overset{\diagup C_6H_4NH_2}{—C_6H_4NH_2}}$$
$$\overset{HCl}{\Rightarrow} \quad \underset{\diagdown C_6H_4\cdot NH_2}{\overset{\diagup C_6H_4=NH\cdot HCl}{C_6H_4\cdot NH_2}} \quad +H_2O$$
In many cases the ordinary formula already contained the quinonoid structure.

The theory has been shown to be untenable. On the one hand, substances have been prepared which have a quinonoid structure, but are colourless, and on the other hand, coloured substances are known to which a quinonoid structure cannot be assigned.

Colourless Substances possessing a Quinonoid Structure.—Iminoquinone (I), diiminoquinone (II), quinonedimethylimine (colourless in crystalline form, yellow in solution) (III), diphenoquinone (exists in two modifications, one of which is colourless) (IV), and fuchsonimine (V); also the dimethyl ether (VI), the diacyl

derivatives (VII), and the anhydride (VIII) of phenanthraquinone dioxime :—

$$\underset{(I)}{\overset{O}{\underset{NH}{\bigcirc}}} \quad \underset{(II)}{\overset{NH}{\underset{NH}{\bigcirc}}} \quad \underset{(III)}{\overset{NCH_3}{\underset{NCH_3}{\bigcirc}}}$$

$$O=\bigcirc=\!\!\!-O \quad NH=C_6H_4=C\!\!<\!\!\overset{C_6H_5}{\underset{C_6H_5}{}}$$
$$(IV) \qquad\qquad (V)$$

$$\underset{(VI)}{\overset{MeON\;NOMe}{\bigcirc\!\!\!\bigcirc}} \qquad \underset{(VII)}{\overset{AcON\;NOAc}{\bigcirc\!\!\!\bigcirc}}$$

$$\underset{(VIII)}{\overset{\bigcirc\!\!\!\bigcirc}{\underset{\underset{O}{\overset{\|}{N\;\;N}}}{}}}$$

Coloured Substances to which a Quinonoid Structure cannot be assigned.—Nitroquinol dimethyl ether, the sulphate of *p*-trichlortriphenyl carbinol, the fulvenes, *e.g.* dimethylfulvene, and some fatty compounds, such as diacetyl, tertiary nitroso- compounds, *e.g. tert*-nitrosobutane, and dinitroparaffins.

Baeyer's Modification of the Quinonoid Theory.—It has already been mentioned that fuchsonimine is colourless. The introduction of a *para-* amino group into one of the phenyl groups causes the development of colour :

$$\underset{C_6H_5}{\overset{p\text{-}NH_2\cdot C_6H_4}{>}}C=\bigcirc=NH$$
This and similar facts led A. v. Baeyer to suggest that the cause of colour is an oscillation of the quinonoid condition between two or more benzene nuclei (Jour. Chem. Soc. Abs. 1907, i. 504). If we call the three benzene nuclei in the above compound A, B, and C, it will be seen that the oscillation of a hydrogen atom will allow A and B alternately to become quinonoid :

$$\underset{NH_2\diagdown B}{\overset{NH=\diagup A}{\bigcirc}}\!\!>\!\!C—\langle\;C\;\rangle$$

$$\underset{NH=\diagdown B}{\overset{NH_2\diagup A}{\bigcirc}}\!\!>\!\!C—\langle\;C\;\rangle$$

Baeyer suggested that this oscillation was the cause of the colour.

Many strongly-coloured substances are known in which such an oscillation is not possible. And necessarily all the arguments against the original quinonoid theory apply with still greater force against this modified quinonoid theory.

$$\overset{\|}{A}\quad\overset{\|}{A}\quad\overset{\|}{A}$$

H. v. Liebig's Theory that —A—A—A— is the Essential Organic Chromophore.—The fact that the fulvenes are coloured, although they do not contain the quinonoid structure, led H. v. Liebig to suggest that the essential cause of colour is the arrangement of linkages which is possessed both by quinonoid compounds and the fulvenes, viz. —A—A—A— (Annalen, 1908, 360, 128)   This theory explains the colour of nitroquinol dimethyl ether, which contains this arrangement of linkages :—

OMe
|
C
C   C—N
C
C
The theory will not explain the colour of the tertiary fatty nitroso- compounds; and, of course, the existence of colourless quinonoid compounds is as much an argument against this modification as against the original quinonoid theory

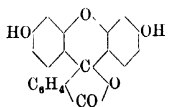
NIETZKI'S RULE   The colour of a dyestuff can be deepened by adding groups so as to increase its molecular weight, and the deepening of colour produced is, more or less, proportional to the increase of its molecular weight (Verhandl des Vereins zum Beförderung des Gewerbefleisses, 1879, 58, 231). This rule was probably formulated by Nietzki to summarise well-known facts in connection with the triphenylmethane group of dyes, but apparently was not based on any systematic investigation. The table on p. 349 shows that the rule applies to a considerable extent to other groups besides the triphenylmethane series.

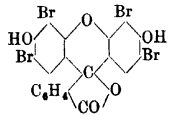
The rule was subjected to a careful examination by Schutze (Zeitsch physikal. Chem. 1892, 9, 109 et seq.), who pointed out many exceptions. He showed that in some cases, e g. on the addition of a nitro- group to indigo, the shade even becomes lighter instead of deeper, and he introduced the terms bathychrome and hypsochrome, the former being applied to those groups which produce a deepening of colour, and the latter to those having the contrary effect. Another example of a hypsochrome is the acetyl group. All dyestuffs containing hydroxyl- or amino-groups become much lighter in colour when completely acetylated.

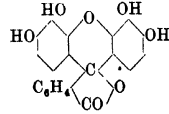
The following table is of interest, as showing that in some cases the molecular weight may be made very large without a deep colour being attained.

| Molecular formula	Mol wt.	Shade of dyeing
C_6H_5—N=N—C_6H_4OH	198	yellow
C_6H_5—N=N—C_6H_4—N=N $C_6H_3{}^{OH}_{COOH}$	346	brownish yellow
C_6H_5—N=N- C_6H_4—N=N—C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$	450	brownish yellow
C_6H_5—N=N—$C_8H_4{}^{OH}_{C_6H_5}$	274	orange
C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$ | C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$	482	yellow
(OH)(C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$ C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$ C_6H_4—N=N—$C_6H_3{}^{OH}_{COOH}$	752	yellow

HEWITT'S RULE   This investigator's researches on the colour of azo- compounds led him to the conclusion that the chief oscillation frequency is less, and consequently the colour is deeper, the longer the conjugate chain, i.e. the chain of alternate double and single bonds, in the molecule (Chem. Soc Trans. 1907, 91, 1251).

He noticed that in the case of many azo-dyes the introduction of a nitro- group into the benzene nucleus not containing auxochromes produced very pronounced deepening of colour in alkaline solution, e.g p-nitrobenzeneazophenol and p-nitrobenzeneazonaphthol have much deeper colours (crimson and violet) than benzeneazophenol and benzeneazonaphthol (orange and crimson respectively). He brought forward evidence in favour of the assumption that in alkaline solution these nitro- derivatives have an iso- nitroso structure, and in this form the nitro- derivatives have a much longer conjugate chain than the parent substances, e.g. :—






KO
      N=   =N—N=   =O
O

compared with :

      —NH—N=   =O
Sircar (Chem. Soc. Trans 1916, 109, 757, et seq.) showed that in very similar azo- compounds the length of the conjugate chain is not proportional to the depth of colour, e.g. 4-nitronaphthalene-1-azophenol only gives a red colour in alkaline solution, whilst p-nitrobenzene-azo-α-naphthol dissolves in the same solvent with a blue colour, whilst the two substances

| Name	Molecular formula	Mol. wt.	Shade of dyeing

have conjugate chains of the same length. He came to the conclusion that in azo- dyes the depth of colour is proportional to the length of the conjugate chain reckoned from the auxochrome to the azo- linkage.

WATSON'S RULE.—The present writer pointed out (Proc. Chem. Soc. 1913, 29, 348 ; Chem. Soc. Trans. 1914, 105, 759) that dyes which are quinonoid in all possible tautomeric forms have a deep colour, no matter how simple their structure or how small their molecular weight.

'In the following table there are placed opposite each other in the two columns dyes of very similar constitution which yet show remarkable differences in depth of colour :—

Hexahydroxybenzophenone
(Dyes yellow on alum and chrome)

$$C_6H_2(OH)_3 \cdot CO \cdot C_6H_2(OH)_3$$

Leather yellow
(Dyes yellow on leather)

$$C_6H_4 \cdot NH_2$$

$$C_6H_4 \begin{array}{c} C \\ | \\ N \end{array} C_6H_3 \cdot NH_2$$

4 4'-Diaminoazobenzene
(Yellow)

$$NH_2 \cdot C_6H_4 \cdot N : N \cdot C_6H_4 \cdot NH_2$$

Quercetin
(Yellow on alum. yellowish brown on chrome)

$$C_6H_2(OH)_2 \underset{CO}{\overset{C \cdot C_6H_2(OH)_2}{\diagup\diagdown}} C \cdot OH$$

Myricetin
(Dyes similar shades to quercetin)

$$C_6H_2(OH)_2 \underset{CO}{\overset{C \cdot C_6H_2(OH)_3}{\diagup\diagdown}} C \cdot OH$$

Anthracene blue W.R
(Dyes violet on alum, blue on chrome)

$$O : C_6H(OH)_2 \underset{OC}{\overset{C(OH)}{\diagup\diagdown}} C_6H(OH)_3$$

Magenta
(Dyes bluish red)

$$C_6H_4 \cdot NH_2$$

$$ClH_2N : C_6H_4 : C \cdot C_6H_4 \cdot NH_{2,}$$

Indamine
(Blue)

$$NH : C_6H_4 \cdot N \cdot C_6H_4 \cdot NH_2$$

Gallacetein
(Dyes violet on chrome.)

$$C_6H_2(OH)_2 \underset{\underset{CH_3}{C}}{\overset{C : C_6H_2(OH)_2 : O}{\diagup\diagdown}} CH$$

'The dyes in the right-hand column can only be represented by formulæ containing a quinonoid arrangement. Whatever tautomeric change they may be supposed to undergo their formulæ still contain the quinonoid arrange-

ment. Those on the left hand differ in that they can be represented by formulæ not containing this arrangement. They can, of course, be supposed to tautomerise into forms containing this quinonoid arrangement, but in all cases it is possible to represent them also in a non-quinonoid form.' 'A survey of all the better known dye-stuffs fully bears out this theory. The triphenylmethane dyes, the pyronines, benzeins, and fluorones, the indophenols, indamines, oxazines, thiazines, azines (safranines, &c.), all satisfy this requirement and exhibit deep colour, in many cases with little molecular complexity. Hæmatein and brazilein conform to this rule. They have almost the same molecular weight as the flavones, and there is considerable resemblance in their structure , but they conform to this rule, whilst the flavones do not, and consequently their colour is much deeper. The alizarin series, and also naphthazarin, illustrate the rule. On the other hand, the monoketonic dyes, e.g. the benzophenone and xanthone derivatives, the flavones and flavonols, ellagic acid, and the azo- dyes can be represented by non-quinonoid formulæ ; and many members of these groups, despite very considerable molecular complexity, have no great depth of colour.'

WATSON'S AND MEEK'S MODIFICATION OF HEWITT'S RULE.— In passing from one tautomeric form to another there is a reversal of the conjugate chain, so that double and single bands change places all along the conjugate chain In that group of substances which can only tautomerise from one quinonoid form to another the conjugate chain reversed is generally longer than in the other group of substances which can tautomerise from a quinonoid to a non-quinonoid form. An appreciation of this fact led to the formulation of a further modification of Hewitt's rule, viz. that the colour is deeper the longer the conjugate chain reversed during tautomeric change (Watson and Meek, Chem. Soc. Trans. 1915, 107, 1567). This rule was tested by measuring the wave-lengths of the maxima of the absorption bands of seven pairs of substances which were selected as being very similar in structure, but having conjugate chains of different lengths reversed during tautomerism. It was found that in each of these seven pairs the period of the vibration was proportional to the length of the conjugate chain reversed (see table, p. 352).

The reversal of the chain is shown in the following structural formulæ for 4 : 4'-tetramethyldiaminobenzhydrol (Michler's hydrol) and 4 : 4'-tetramethyldiaminobenzophenone (Michler's ketone) :—

$$-(CH_3)_2N \diagdown\diagup CH \diagdown\diagup N(CH_3)_2 \rightleftharpoons$$

$$(CH_3)_2N \diagdown\diagup CH \diagdown\diagup N(CH_3)_2 -$$

$$-(CH_3)_2N \diagdown\diagup \underset{OH}{C} - \diagdown\diagup N(CH_3)_2 \rightleftharpoons$$

$$-H(CH_3)_2N \diagdown\diagup \underset{\underset{O}{||}}{C} - \diagdown\diagup N(CH_3)_2$$

Name	Molecular formula	Shade of dyeing

EFFECT OF MULTIPLICATION OF AUXOCHROMES ON DEPTH OF COLOUR

Additional auxochromes frequently deepen the colour to a very great extent. This may be regarded as an example of Nietzki's rule, but the effect produced is generally much greater than we should expect from the very moderate weight of the additional auxochromes, e.g. from the first table given in the paragraph on Nietzki's rule, it will be observed that two hydroxyl groups added to fluorescein (producing gallein) deepen the colour much more than four bromine atoms (producing eosin), although their weight is much less. The table on page 351 illustrates the great effect of additional auxochromes

The relative positions of the auxochromes has a very great effect on the colour, e.g. there are two isomeric hexahydroxyanthraquinones, anthracene blue WR and rufigallol, one of which is blue and the other brown.

From a study of the polyhydroxyanthraquinones, Meek and Watson (Chem. Soc. Trans. 1916, 109, 557, et seq.) suggested the following rules as to the influence on the colour of the relative positions of the auxochromes :—

(a) Two hydroxyl groups in one benzene nucleus in the o- or p-position with respect to one another are necessary to produce a deep colour.

(b) The colour is still further deepened if both benzene nuclei contain pairs of hydroxyl groups in the o- or p-position to one another.

(c) Three hydroxyl groups in the 1 : 2 : 4-position in one benzene nucleus produce a deeper colour than a pair of hydroxyl groups in the o- or p-position.

(d) Three hydroxyl groups in the 1 : 2 : 3-position in one benzene nucleus produce a brown colour.

And these rules are apparently applicable to all groups of dyes, e.g. :—

(a) The hydroxy- derivatives of azobenzene dissolve in potash with the following colours :—

p-Hydroxyazobenzene	.	Yellow
o-Hydroxyazobenzene	.	Yellow
Benzeneazoresorcinol	.	Orange
Benzeneazocatechol .	.	Carmine
Benzeneazoquinol .	.	Blue
Benzeneazopyrogallol	.	Brick-red

(b) Fluorescein, quinolphthalein, and catecholphthalein dissolve in potash with a yellow colour ; hydroxyquinolphthalein gives a cherry-red, gallein a blue, and phloroglucinolphthalein an orange under the same conditions.

(c) The same rules are seen to apply to the pyranol dyes.					E. R. W.

COLUMBIA BLACK, -BLUE, -GREEN v. AZO- COLOURING MATTERS.

COLUMBIA YELLOW v. PRIMULINE AND ITS DERIVATIVES.

COLUMBIC ACID, COLUMBAMINE, and **COLUMBIN** v. CALUMBA.

COLUMBITE. A columbate (niobate) of iron, usually containing some manganese ('manganocolumbite') and tantalum, the general formula being $(Fe,Mn)(Cb,Ta)_2O_6$. With an increase in the amount of tantalum, there is a transition to the isomorphous species, *tantalite* (q.v.). The orthorhombic crystals are dark brown or black and opaque, and range in sp.gr. from 5·3 (columbite) to 7·3 (tantalite). It was in this mineral that C. Hatchett discovered, in 1802, the element columbium, so named because the specimen he examined came from America. Columbite is usually found as single crystals embedded in pegmatite or granite ; for example, at Haddam and Middletown in Connecticut, Chesterfield in Massachusetts, brilliant crystals in granite at Standish in Maine, large masses up to 2000 lbs. in granite veins in the Black Hills of South Dakota, and at several other American localities. At Ivigtut in Greenland it has been found in the cryolite deposit. Large crystals are found in the felspar quarries near Moss in Norway. Other localities are Rabenstein in Bavaria, Bushman Land in South Africa, Madagascar, &c.					L. J. S.

COLUMBIUM (*Niobium*). Sym. Cb. At. wt. 93·1 (Smith and van Haagen). Although this metal is still commonly termed niobium by the mineralogist and the metallurgist, the name columbium, which was given to it in 1802 by Hatchett, who first isolated it in the form of a new 'earth' (Cb_2O_5) from a mineral found in Connecticut, has been officially adopted by the chemist in English-speaking countries, and generally throughout the world, except perhaps in Germany.

Columbium is a member of a group of comparatively rare metals, including tantalum, tungsten, molybdenum, titanium, and uranium, commonly occurring together in minerals found in the oldest Plutonic rocks and especially in and around intrusions which traverse pegmatites and other extremely coarse-grained granite rocks. Monazite, and other minerals containing metals of the cerium group, zircons, cryolite, and fluorspar, and minerals containing lithium, cæsium, and rubidium, are often associated with these minerals, and are probably intimately connected with their genesis.

Although an extremely rare metal, columbium exists as the pentoxide in a considerable number of minerals, in some of which—such as pyrochlore and columbite—it may be regarded as the essential constituent, while, in others, although practically always present, its proportion varies from a mere trace up to an amount which justifies its being considered as the principal oxide.

Columbium occurs in minerals only as the pentoxide Cb_2O_5, in combination with a base, the columbium in the few minerals (such as wöhlerite) which contain silica, being present as a silico-columbate, and never as a silicate of columbium.

A list of thirty or forty minerals in which columbium is commonly found in association with tantalum might be given, but the principal will be given in the article TANTALUM, with which metal columbium invariably occurs in nature. From the technical point of view, the principal columbium minerals are those which consist essentially of columbates of iron, manganese, and lime, zirconia and metals of the cerium group being also usually present in, or at any rate intimately associated with, such minerals as contain lime.

The mineral richest in columbium is *pyrochlore*, a columbate of lime containing titanium, cerium, and thorium, together with other alkaline earths and alkali bases and some fluorine. The most important mineral, however, is the columbate of iron and manganese known as *columbite* or *niobite*, in which the Cb_2O_5 may even exceed 78 p.c., a condition nearly reached by certain specimens occurring in the cryolite of Arsukfiord (Greenland).

The columbium is always partly replaced by tantalum, the proportion of which may vary from a trace through all gradations, until the mineral merges into tantalite which is isomorphous with columbite, and which occurs in much larger quantity and furnishes the bulk of the tantalum of commerce and, as a by-product, of the columbium. These two minerals are found in alluvial deposits with cassiterite and wolfram, and in isolated masses left by the denudation of

intrusions in pegmatites, &c., at Greenbushes and elsewhere in Western Australia, in Colorado (Cañon City), Dakota (Black Hills), North Carolina and other districts of the United States, and in Sweden, Norway, Greenland, Madagascar, Rhodesia, and many other districts. They may be considered to possess the general formula $(FeMn)O(CbTa)_2O_5$, the relative proportions of ferrous and manganous oxides varying within extremely wide limits.

New deposits are constantly being discovered, and columbium, like many others of the rare metals for which a demand now exists, will doubtless be found to occur in much larger quantities than is generally believed.

Amounts, far in excess of present requirements, are obtainable as by-products from the preparation of the rare earths employed for incandescent mantles, from tin and wolfram ores, and from the heavy waste material obtained in the dressing of cryolite.

Metallic columbium may be prepared by passing a mixture of the vapour of the pentachloride and hydrogen through a red-hot tube (Roscoe); by electrolysis of the oxyfluoride; in a less pure condition, by heating the pentoxide with carbon in the electric furnace (Moissan); by the alumino-thermic process, and by the method of von Bolton, introduced with a view to the manufacture of metal filament lamps, before tantalum came into use. In this process, the pentoxide is mixed with paraffin and formed into threads which are heated *in vacuô* to a temperature of over 1900° by passage of an electric current.

By the alumino-thermic reaction, von Bolton has obtained columbium containing about 3 p.c. of aluminium which can be driven off with other impurities by prolonged heating *in vacuô* in the electric furnace. The purest columbium hitherto prepared in bulk is said to have been thus obtained. Like tantalum, it can also be obtained by reduction of the fluoride K_2CbF_7 with potassium, as a black powder from which the residual hydrogen may be expelled by shaping it into small cylinders and melting *in vacuô* in an electric furnace.

Although the most important use of tantalum is for manufacture of electric lamps, in which case it requires to be separated from columbium, the amount actually consumed for the purpose is extremely small. The standard tantalum lamp, introduced in 1904, contained only one twenty-thousandth of a pound of tantalum, and those now manufactured contain much less.

The method employed for the separation of columbium from tantalum in the preparation of the latter element for electric lamp filaments probably depends essentially upon a fractional crystallisation of the mixed double fluorides of potassium with tantalum, columbium, and titanium.

Metallic columbium melts at 1950°, and has a sp.gr. of 12·7, and an electrical resistance of 0·1870 ohm for a wire 1 metre long by 1 mm. diameter. It is less malleable or ductile than tantalum, but the rolled metal has a hardness greater than that of wrought iron, and may be welded at a red heat.

Although the powdered metal oxidises rapidly when heated in air, the rolled or cast

metal is but little affected, as a protective coating of oxide rapidly forms. It is practically unaffected by an acid except hydrofluoric acid, or by solution of the alkalis, but is rapidly attacked by fused alkalis or alkaline nitrates.

It combines with carbon when heated, and at dull redness rapidly absorbs hydrogen or nitrogen and becomes brittle, the hydride and nitride respectively being apparently formed.

It reacts violently when heated with sulphur or selenium, and forms the volatile pentachloride when heated to redness in chlorine.

It does not form an amalgam with mercury, but alloys with many other metals and in all proportions with iron.

The compounds of columbium have not yet been applied commercially, but the pentoxide, generally known as columbic acid, and the fluorides, especially the double fluoride with potassium $2KF \cdot CbF_5$ are of interest in connection with the preparation of the pure compounds or metal from minerals.

For methods of analysing columbites and tantalites, and of estimating columbium in presence of tantalum, see G. Chesneau (Compt. rend. 1909, 149, 1132; J. Soc. Chem. Ind. 1910, 29, 93), J. Moir (J Chem Met and Min. Soc. S. Africa, 1916, 16, 189; J. Soc Chem Ind. 1916, 35, 637), Giles (Chem. News, 1909, 99, 1), Simpson (Chem. News, 1909, 99, 243), Metzger and Taylor (Zeitsch. anorg Chem. 1909, 62, 383), Weiss and Landecker (Zeitsch. anorg. Chem. 1909, 64, 65), cf. Foote and Langley (Amer. J. Sci. 1910, [iv.] 30, 401), cf. Hauser and Lewite (Zeitsch angew. Chem. 1912, 25, 100), Meimberg (Zeitsch angew. Chem 1913, 26, 83), Meimberg and Wintzer (Zeitsch. angew. Chem. 1913, 26, 157), Levig (Analyst, 1915, 40, 204)

For a method of estimating columbium and tantalum based on the difference between the densities of the oxides of columbium (4·552) and tantalum (8·716), see Foote and Langley (Amer. J. Sci 1910, [iv.] 30, 393), see also Ruff and Schiller (Zeitsch. anorg. Chem 1911, 72, 329).   G. T. H.

COMPOUNDS OF COLUMBIUM.

Columbium dioxide CbO or Cb_2O_2, formed by heating potassium columbium oxyfluoride with sodium, is a white powder, which burns when heated in the air, forming the pentoxide. In chlorine it ignites, forming the oxychloride $CbOCl_3$. Is soluble in hydrochloric acid with evolution of hydrogen.

Columbium tetroxide CbO_2 or Cb_2O_4, a black powder, formed by heating the pentoxide in hydrogen, or with magnesium. Burns when heated in the air to redness.

Columbium pentoxide Cb_2O_5, a white infusible powder of sp.gr. 4·53–4·568 (4·8 Balke and Smith).

Columbic acid $HCbO_3$, a white powder formed by decomposing the oxychloride or pentachloride with water. Slightly soluble in hot hydrochloric acid. Yields the pentoxide when strongly heated. *Potassium hexacolumbate* $K_2Cb_6O_{16},6H_2O$, formed by fusing the pentoxide with potassium carbonate. Large monoclinic crystals, effloresing on exposure to dry air.

Other potassium columbates are $K_8Cb_6O_{19},13H_2O$; $2K_2Cb_4O_{11},11H_2O$; $K_4Cb_2O_7,11H_2O$. *Sodium columbate* $7Na_2O,6Cb_2O_5,32H_2O$ (Bedford, J. Amer. Chem. Soc. 1904, 26, 1235); *Sodium metacolumbate* $Na_2O,Cb_2O_5,7H_2O$ (Balke and Smith, J. Amer. Chem. Soc. 1908, 30, 1637). For the composition of other columbates, see Balke and Smith (l.c.).

Percolumbic acid $HCbO_4$, an amorphous yellow powder, obtained by treating columbic acid with hydrogen peroxide. Is decomposed on warming with sulphuric acid. *Potassium percolumbate* or *pyrocolumbate* $K_4Cb_2O_{11},3H_2O$, formed by mixing hydrogen peroxide with a solution of potassium columbate and adding alcohol. Decomposed by water. Yields hydrogen peroxide and ozone with concentrated sulphuric acid For other percolumbates, see Balke and Smith (l.c.).

For the hydrosols of columbic acid see Hauser and Lewike (Zeitsch. angew. Chem. 1912, 25, 100).

For the electrolytic reduction of columbic acid and its salts, see Ott (Zeitsch. Elektrochem. 1912, 18, 349).

When columbic acid is dissolved in concentrated sulphuric acid, the solution diluted, and then reduced with zinc, an indigo-blue solution is obtained which reduces a solution of copper sulphate to metallic copper; the solution is thus more strongly reducing than one containing tervalent titanium.

Columbium pentafluoride CbF_5, colourless, strongly refractive monoclinic prisms, $D^{18} 3·293$; m p 75·5° (corr.); b p. 217°–220°/760 mm. (corr.) Obtained by the action of fluorine on columbium. Very hygroscopic; readily soluble in water. Solution precipitates columbic acid on addition of ammonia or sodium hydroxide (Ruff and Schiller, Ber 1908, 42, 492).

Columbium oxyfluoride $CbOF_3$ forms double salts with other metallic fluorides, of which the alkaline salts have been investigated by Marignac.

Columbium trichloride $CbCl_3$, a non-volatile, non-deliquescent crystalline substance resembling iodine, forming long dichroic needles. Oxidised on exposure to air, and yielding columbium oxychloride $CbOCl_3$, and carbon monoxide when heated in carbon dioxide (Roscoe).

Columbium pentachloride $CbCl_5$, yellow needles, obtained by heating columbium pentoxide mixed with charcoal in a stream of chlorine. Also formed by heating the pentoxide with sulphur monochloride S_2Cl_2; or, together with the oxychloride, by heating the pentoxide with carbon tetrachloride; m.p. 194°; b.p. 240·5°; sp.gr. 2·73–2·77. Gives a normal vapour density. Soluble in carbon tetrachloride, chloroform, and alcohol. Its solution in hydrochloric acid gelatinises, and on addition of water, forms columbic acid. On reduction with sodium amalgam gives *chlorocolumbium chloride* $(Cb_6Cl_{12})Cl_2,7H_2O$, black, shining crystals, forming an olive-green powder, insoluble in cold water, but soluble in hot water to an olive-green solution. Only two of the chlorine atoms are ionic. When treated with the equivalent amount of sodium hydroxide, *chlorocolumbium hydroxide* $(Cb_6Cl_{12})(OH)_2,8H_2O$ is formed as a black microcrystalline precipitate, and

from this the *bromide* $(Cb_6Cl_{12})Br_2,7H_2O$ is obtained. The hydroxide is soluble in excess of sodium hydroxide, and from the solution excess of concentrated hydrochloric acid precipitates a brown powder $C_6H_{14},9H_2O$ (Harned, J. Amer. Chem. Soc. 1913, 35, 1078).

Reduction of a solution of columbium pentachloride at a platinum cathode gives a blue solution, which is of a colloidal character; with gold chloride it gives a magnificent purple liquid, from which, on boiling, a purple precipitate deposits. This precipitate is similar to purple of Cassius; it colours glass a violet-red (Stähler, Ber. 1914. 47, 841).

Columbium oxybromide $CbOBr_3$ and **pentabromide** $CbBr_5$ also exist, and an iodide has been formed (Barr, J. Amer. Chem. Soc. 1908, 30, 1668).

Columbium sulphides CbS_2 and Cb_2S_5, corresponding to the oxides, have been prepared (Biltz and Gonder, Ber. 1907, 40, 49, 63).

Columbium oxysulphide $CbOS_1$, a black crystalline powder formed by heating the pentoxide in the vapour of carbon disulphide mixed with carbon dioxide.

Columbium nitride Cb_3N_5. A yellow powder formed by heating columbium in nitrogen (Moissan, Compt. rend 1901, 133, 20; Muthman, Weiss and Reidelbauch, Annalen, 1907, 335, 58).

The spectrum of columbium contains thirty-one more or less complete groups of five lines showing wave-number differences equal to $720\cdot25$, $1027\cdot02$, $355\cdot19$, and $303\cdot29$ respectively (*cf.* Siegbahn and Froman, Ann. Physik. 1916, [iv.] 49, 611).

For arc spectrum of columbium, *see* Hildebrand (J. Amer. Chem. Soc. 1908, 30, 1672).

For the magnetic resolution of the spectrum lines of columbium, *see* Jack (Proc. Roy. Irish Acad. 1912, A, 30, 42).

CONDENSERS. A condenser is an apparatus in which the vapour of a liquid may be cooled down to a temperature below that at which it is converted into the liquid state under the prevailing pressure. The condensation of the vapour is usually effected by bringing it into contact with a cold surface, to which it imparts its heat, suitable arrangement being made for conveying away this heat from the cooling surface. Although air cooling is sometimes depended upon for this latter purpose, the arrangement usually adopted consists in causing a stream of cold liquid (water in the majority of cases) to circulate over the exterior of the condensing chamber. The following points should be considered in the designing of an efficient condenser :—

(*a*) The cooling surface must be made of material upon which the vapour has no chemical action, and should be capable of withstanding repeated variations of temperature without fracture.

(*b*) The area of cooling surface should be as great as possible, without making the apparatus unduly large and heavy.

(*c*) The material should preferably have a high specific heat, so that its rise in temperature may be kept within reasonable limits; and it should have a high thermal conductivity, in order that the heat it absorbs may be rapidly carried away.

(*d*) The design should be such as to admit of the condenser being readily cleansed.

It is not possible to obtain materials entirely satisfactory in each of the above respects, and so in practice the materials employed are those which combine cheapness with reasonable satisfaction in the foregoing particulars. For laboratory apparatus, the material commonly used is glass; metals (block tin, copper, &c.) are less often employed, except for constructing fairly large pieces of apparatus; of recent years, silica has found a limited use.

Condensers are used in two different kinds of operations : (1) for condensing vapours in distillation processes, in which case a still is attached to the upper end and a suitable receiver to the lower end; and (2) as 'reflux' apparatus in cases where it is necessary to boil a liquid for some time without sensible loss through evaporation; the vessel containing the boiling liquid is then attached to the lower end of the condenser and the condensed vapours flow back into the vessel. A number of condensers described below are specially designed for this purpose.

The simplest type of condenser is the familiar form devised by Weigel in 1771, but usually known as Liebig's condenser. It consists simply of a straight cylindrical glass tube, in which the vapour is condensed. The upper end is widened out slightly to facilitate connection with the still, and its lower end is cut off obliquely; a cylindrical glass jacket is slipped over the greater portion of the length of the tube, and through it, by appropriate entrance and exit tubes, cold water is circulated in an upward direction, so that the vapours passing down the inner condenser tube encounter a surface the temperature of which continuously falls in the direction of the receiver. This type of condenser admits of considerable variation and modification in the precise details of construction ; thus, with a view to exposing a large cooling surface, the portion of the condenser within the jacket is sometimes made of approximately rectangular section, thus

, being broadened considerably in one direction ; in other condensers the central portion carries a series of bulbs blown on it. Cooling surface is obtained in some condensers by replacing the central portion by a closely wound glass spiral, as in Fig. 1, the water-jacket being sealed on to the condenser proper. The modified Weigel condenser, shown in Fig. 2 (Chem. Zeit. 1902, 26, 633), is arranged for use with the two limbs *a* and *c* of the inner U-tube on the same level to prevent accumulation of liquid at *b*. The inner tube is fused into the outer tube at *d*.

FIG. 1.

Glass condensers with water-jackets sealed on are restricted in their use to the condensation

of the vapours of liquids of fairly low boiling-point (below 100°), since otherwise the glass joints are liable to crack. For liquids of moderately high boiling-point (140°–200°), it

FIG. 2.

usually suffices to employ merely the inner tube of a Weigel (Liebig) condenser (air condenser).

In the reflux condensers illustrated in Figs. 3 and 4 (J. Soc. Chem. Ind. 1897, 16, 979) the relative positions of the vapour and cooling stream of water are reversed, the water entering as shown by the arrows (at *a* in Fig. 3). A large area of exposed surface is obtained in these condensers, which, it will be observed, are of the 'double-surface' type, since, in addition to the inner water-cooled surface, condensation also occurs on the outer surface, which exposes an even larger area to the cooling action of the air.

Several vertical condensers have been devised by Friedrichs in which one of the two surfaces between which the vapours condense is constructed spirally (Zeitsch. angew. Chem. 1910, 23, 2425).

A number of extremely useful, compact condensers of the 'double-surface' type have been described. The vapours are condensed in the annular space between two surfaces, both of

FIG. 3.   FIG. 4   FIG. 5.

which are water-cooled, the design being such that one stream of water flows in succession over each. The efficiency of this cooling process is so great that these condensers can be made quite short; they are readily fixed in a vertical position and occupy little bench space.

In the Burgess condenser (J. Soc. Chem. Ind. 1905, 24, 1190), the tubes *a* and *c* (Fig. 5) are the cooling jackets, and *b* is the condensing tube proper. Cribb's condenser (Fig. 6) consists of

two concentric tubes joined together at the top; condensation is effected in the interior chamber thus formed. Water is conveyed into the inner tube by the tube *a*; overflowing, it passes round the exterior of the outer tube and flows away by the side tube *b*. The vapour is led in through the inlet tube *c*.

Another double-surface condenser of simple construction is illustrated in the article ANALYSIS (Vol I)

The condensers illustrated in Figs. 7 and 8

FIG. 6.   FIG. 7.   FIG. 8.

have the advantage of exposing four cooling surfaces to the vapour, and may be readily cleansed when necessary by removing the inner portions with the stopper (Chem. Zentr. 1908, ii 277).

An inquiry into the relative efficiency of laboratory reflux condensers made by Dover and Marden (J. Ind Eng. Chem 1916, 8, 834) showed that where a long condenser can be conveniently used, the Weigel is preferable, whilst the Friedrichs, or some modification of it, seems best where a short condenser must be used.

The condensers so far described are usually constructed of glass, but occasionally metals are employed. The use of *aluminium* for the inner tube of a Weigel condenser has been advocated by Norton (J. Amer. Chem. Soc. 1897, 19, 153). Many agricultural chemists, who have to deal with numerous ammonia distillations, prefer block-tin condensers; they are constructed like inverted **U**-tubes, one arm (the condenser arm) being much longer than the other and carrying a water-jacket if required, while the short arm is attached to the distilling flask. A convenient method of constructing a number of such condensers in series to be cooled by one stream of water is described in J. Amer. Chem. Soc. 1906, 28, 999.

A useful metallic condenser is the 'ball' type, used on the reflux principle in numerous experiments involving extractions with volatile solvents. Soxhlet's pattern is shown in Fig. 10, while the construction of a double-surface condenser of this pattern is sufficiently indicated in Fig. 9. Storch's metallic reflux condenser is

depicted and described in J. Soc. Chem. Ind. 1897, 16, 979.

The spiral (worm) type of condenser is frequently constructed of metal (copper) and enclosed in a metal tank which can be filled with cold water; these condensers find considerable use in small plants for preparing distilled water. For this latter purpose, a novel

Fig. 9.   Fig. 10.

form of condenser is described in Eng. Pat. 6916, 1905, which combines efficiency with extreme simplicity of construction. The condenser, which is placed vertically above the evaporating chamber, consists of two metallic truncated cones, the lower being open at the top, while the upper is closed by a dome-shaped lid. The outer surface of the upper cone is cooled by a continuous stream of cold water, and condensation is effected upon its inner surface. The condensed vapour collects in the annular space between the two cones, and the water is continuously run off into large earthenware jars. Special apparatus, devised for preparing pure distilled water (so-called 'conductivity water') on a laboratory scale are described by Bousfield (Chem. Soc. Trans. 1905, 87, 740); Golding (J. Soc. Chem. Ind. 1906, 25, 678), and by Hartley, Campbell, and Poole (Chem. Soc. Trans. 1908, 93, 428).

Condensers of various designs are described in J. pr. Chem. [2] 34, 427; [2] 49, 44; Compt. rend. 118, 478; Ber. 1892, 24, 3950; 1895, 28, 2388; J. Soc. Chem. Ind. 1899, 18, 707; Chem. Zeit. 1902, 26, 325; 1904, 28, 598, 686; 1905, 29, 809; 1910, 34, 116; Bull. Soc. chim. 1904, 31, 1116; Chem. Zentr. 1906, ii. 993; and reflux condensers in Chem. Zeit. 1896, 20, 462; 1904, 28, 598; Bull. Soc. chim. 1901, 25, 476; 1908, 3, 855; Zeitsch. anal. Chem. 1901, 40, 769; Chem. Zentr. 1906, ii. 993; Chem. News, 1907, 95, 52; and J. Soc. Chem. Ind. 1908, 27, 962.

CONDURANGO. The dried bark of *Marsdenia condurango* (Nichols) (*Gonolobus Condurango triana*, Reichenbach; family *Asclepiadaceæ*). It is obtained from a half-climbing or prostrate shrub of Ecuador. The bark comes into commerce in quills or quilled pieces, about 10 cm. long, and rarely exceeding 2 cm. in diameter; externally brown grey, roughened, with scale like warts; internally, greyish or pale brownish-white, striate; fracture short, granular or slightly fibrous in inner layer. Taste, somewhat bitter; odour of fresh bark, aromatic.

Kubler (Arch. Pharm. 1908, 246, 620) states that the principal constituents of the bark are dextrose, other usual components of plants, the glucoside *condurangin* and a polyhydric alcohol *conduritol*. *Condurangin* $C_{40}H_{60}O_{16}$ contains two methoxyl groups, is soluble in water, alcohol, and chloroform, insoluble in ether. Dilute sulphuric acid hydrolyses it to dextrose and an amorphous powder, containing several substances; alcoholic potash yields some cinnamic acid. *Conduritol* $C_6H_{10}O_4$ crystallises from hot alcohol in colourless prisms, and yields a tribenzoyl derivative, m.p. 142°-143°. According to Carrara (Gazz. chim. ital. 21, i. 204; 22, i. 236), commercial condurangin can be separated into two parts, one insoluble and the other soluble in water. The former is a white powder, $C_{20}H_{32}O_8$, m.p. 60°-61°; and the latter a yellow substance, $C_{18}H_{24}O_7$, m.p. 134°. Hager (Handbook, 1900) has further investigated these substances and named them *a*- and *b*-condurangin; *a*-condurangin gives a green colour with Froehde's reagent (conc. sulphuric acid and molybdic acid), *b*-condurangin does not. Carrara (*l.c.*) also isolated a yellow powder, $C_{30}H_{50}O_8$, which he named *condurangsterin*, m.p. 52°. Fluckiger has isolated a small quantity of an alkaloid having a strychnine-like action. Firbas (Pharm. J. 70, 417) treats the chloroform extract of the crude glucoside with a mixture of equal volumes of sulphuric acid, hydrochloric acid, and alcohol (Lafon's reaction). On warming, a green colour is produced, changing to bluish-green on the addition of a trace of ferric chloride. Certain other glucosides give this reaction, but they are not likely to be present in the bark.

Condurango has been employed for many years in South America as an alterative in the treatment of syphilis. It is used as a stomachic, and lessens gastric catarrh and relieves the vomiting and nausea which are usually associated with carcinoma of the stomach; it is also used to lessen the pain consequent upon gastric ailments. Condurango produces in large amounts incoordination of the muscles and convulsions, which may be followed by paralysis. Dose, 1 fluid drachm of the fluid extract of condurango, or 4 fluid drachms of the wine of condurango.

There are many other varieties of condurango and marodennas. The Guayaquil condurango has several peculiarities in the wood of the bark, and has not so many medullary rays. Mexican condurangos contain a strong collenchyma next to the bark, while nearer the pith is a layer of bast fibres containing large crystals of calcium oxalate (Chem. Zeit. 11, 1601; 12, 26).

CONDY'S FLUID *v.* MANGANESE.

CONESSINE or **WRIGHTINE** $C_{24}H_{40}N_2$ exists in the bark and seeds (0·6 p.c.) of *Wrightia antidysenterica* and in *Holarrhena africana* (A. DC.), *H. congolensis* (Stapf.), and *H. antidysenterica* (Wall.). Crystals, m.p. 122° (Polstorff, Ber. 1886, 19, 78, 1682; Warnecke, *ibid.* 1886, 19, 60; Arch. Pharm. 1888, [iii.] 26, 248, 281; Pyman, Chem. Soc. Trans. 1919, 163; Giemsa and Halberkann, Arch. Pharm. 1918, 256, 201; Ulrici, Arch. Pharm. 1918, 256, 57). Soluble in acetone, from which it separates in large colourless plates, efflorescing in air; m.p. 125° (corr.) [a]−1·90°.

CONGO BLUE, -BROWNS, -CORINTH, -FAST BLUE, -ORANGE, -REDS, -RUBINE, -SKY BLUE *v.* AZO- COLOURING MATTERS.

CONHYDRINE (*Conydrine*), **Coniceine.** *See* under *Coniine*, below.

CONIFERIN *v.* GLUCOSIDES.

**CONIINE AND THE ALKALOIDS OF HEM-
LOCK.**

Coniine $C_8H_{17}N$ is one of several poisonous, volatile alkaloids found in hemlock, *Conium maculatum* (Linn.) (0·2–0·9 p.c in the not quite ripe seeds). Hemlock (*Grande ciguë*, Fr.; *Scherling*, Ger.) is a tall biennial of the temperate regions of Europe, Asia, and America, and was the essential ingredient in the potion administered to condemned criminals by the Greeks. Besides coniine, hemlock contains N-*methyl-d-coniine*, N-*methyl-l-coniine*, γ-*coniceine*, *conhydrine*, and *pseudoconhydrine*

Preparation.—Coniine is most readily separated from the crushed, unripe hemlock seeds by digesting them with water made alkaline with sodium carbonate, to decompose the coniine malate, and distilling the mixture in a current of superheated steam. The distillate contains the coniine, together with much ammonia derived from the ammonium salts present in the seeds The liquid is neutralised with hydrochloric acid and evaporated to dryness. The dry residue is extracted with absolute alcohol, when most of the ammonium chloride remains undissolved, whilst the alkaloidal hydrochlorides go into solution. If ether is added to the alcoholic solution a further quantity of ammonium chloride is separated The residue left by the evaporation of the alcoholic solution is dissolved in cold water, ether added, and the coniine liberated by the addition of potash The ethereal layer is decanted, washed, dried with potassium carbonate and distilled at a low temperature, when the coniine remains as an oily liquid. It may be purified from the accompanying conhydrine by fractional distillation ; the coniine passes over first So prepared the coniine contains γ-coniceine from which it may be freed by conversion into the hydrochlorides and extracting these when dry with acetone, in which the γ-coniceine salt is soluble and the coniine salt insoluble. For the separation of the subsidiary alkaloids by benzoylation, *see* von Braun (Ber. 1905, 38, 3108).

Properties.—Colourless, alkaline liquid, having a remarkable, penetrating odour and a burning taste ; b.p. 166°–167°, m.p. - 2° ; rel. den. 0·8626 at 0°, dextrorotatory $[a]_D = + 13·79°$.

' Coniine is slightly soluble in cold water, but less so in hot water, so that a clear, cold solution becomes turbid when warmed. It dissolves about one-quarter of its own volume of water at the ordinary temperature. When boiled with water the alkaloid distils with the steam. Coniine mixes with alcohol in all proportions, and is also readily soluble in ether, but only sparingly so in chloroform or carbon disulphide. Exposed in the air it darkens and slowly resinifies. When administered internally coniine acts as a powerful poison. It is a monacidic base The ordinary salts are crystalline and soluble in water or alcohol. The hydrochloride B·HCl forms rhombic crystals and melts at 220°. The aurichloride B·HAuCl₄, m.p. 77°, forms minute yellow needles.

Reactions.– Coniine is a strong base, which

precipitates many metallic hydroxides from solutions of their salts.

It is a secondary amine. When oxidised with nitric acid it yields *normal butyric acid* among other products. When permanganate is used *a-pyridinecarboxylic acid (picolinic acid)* is obtained. On distillation with zinc-dust coniine is decomposed into hydrogen and *a-n-propylpyridine.*

Ladenburg has inferred from these and other reactions that coniine is α-propylpiperidine and has confirmed this by effecting the synthesis of the alkaloid by hydrogenating (with sodium in alcoholic solution) α-allylpyridine

$$C_5H_4N(C_3H_5)+8H=C_5H_{10}N(C_3H_7)$$
The liquid thus produced possesses all the chemical and physical properties of the natural alkaloid except one ; it is optically inactive (Ber. 1886, 19, 2579 ; 1906, 29, 2486). Ladenburg has also succeeded in resolving the inactive coniine into dextrorotatory and lævorotatory forms and has shown the dextro compound to be identical with the natural alkaloid. This was the first synthesis of a natural alkaloid.

The toxicological recognition is somewhat difficult ; in particular there are no reactions distinguishing it sharply from nicotine. Auric and platinic chlorides do not precipitate a 1 p c aqueous coniine solution, but do precipitate nicotine at much greater dilution. A trace of coniine evaporated in a desiccator with a drop of hydrochloric acid readily yields a crystalline hydrochloride, nicotine does not. Differences in odour, density, and solubility in water may also be used.

N-**Methyl**-*d*-**coniine** $C_8H_{16}(CH_3)N$ is stated to occur in hemlock (*v.* Planta and Kekulé, Annalen, 1854, 89, 150), and remains with γ-coniceine when this is separated from coniine by fractional crystallisation of the acid tartrates. It has been synthesised by methylating coniine with potassium methyl sulphate (Wolffenstein, Ber. 1894, 27, 2611 ; *cf.* Passon, *ibid.* 1891, 24, 1678). It is a colourless, oily liquid, b.p. 173°–174°, closely resembling coniine.

N-**Methyl**-*l*-**coniine** was obtained by Ahrens (*ibid.* 1902, 35, 1330) from residues accumulated in the preparation of coniine.

Coniceines. This name has been applied to a series of isomeric bases, $C_8H_{15}N$, obtained in various ways from the hemlock alkaloids. Only one of them γ-*coniceine* (2-propyl-Δ′-tetrahydropyridine) occurs in hemlock and was isolated from crude coniine obtained therefrom by Wolffenstein (Ber. 1895, 28, 302) ; occasionally as much as 70 p.c. of the crude alkaloid was γ-coniceine. This base was first prepared by Hofmann by the action of alkalis on bromoconiine. It strongly resembles coniine in odour and appearance, boils at 171°–172° under 746 mm. pressure, yields crystalline salts, and furnishes coniine on reduction. It has the constitution

γ-Coniceine.   Coniine.
Cf. Hofmann, Ber. 1885, 18, 16, 27, 112 ; Lellmann, Annalen, 1890, 259, 127 ; Löffler and

colleagues, Ber. 1909, **42**, 94, 107, 116, 124, 948, 3420; Gabriel, *ibid.* 1909, **42**, 4059.

Conhydrine $C_2H_{17}ON$, also found in hemlock, may be separated from coniine with which it occurs either by cooling- the concentrated ethereal solution of the two alkaloids, when the conhydrine crystallises out; or it may be obtained by distilling the crude coniine, when it remains behind in the retort, if the temperature has not exceeded 180°.

Conhydrine is a crystalline, basic substance, m.p. 121°, b.p. 226°, $[\alpha]_D + 10°$. On heating with phosphorus pentoxide, or with concentrated hydrochloric acid, it furnishes a mixture of α- and β-coniceines (*see* above). According to Willstätter it is 2 : β-hydroxy-propylpiperidine (Ber. 1901, **34**, 3166; *cf.*, however, Löffler and Tschunke, *ibid.* 1909, **42**, 929).

Pseudoconhydrine $C_8H_{17}ON$, which is also found in hemlock, closely resembles conhydrine. It is a crystalline, strongly basic substance, m.p. 105°–106°; b.p. 236°. It is a secondary base and forms crystalline salts (Ladenburg and Adam, Ber. 1891, **24**, 1671). Engler and Baur regard it as 2 : α-hydroxypropylpiperi-dine (*ibid.* 1894, **27**, 1777), and Löffler has suggested that it is 4-hydroxy-2-propylpiperi-dine (*ibid.* 1909, **42**, 116). (G. B.

COPPER. Sym. Cu. At. wt. 63·57. Melt-ing-point in air, 1062°; in reducing atmosphere, 1084°. Specific gravity : Roberts Austen (Int. Study of Met. 1910, 15) gives 8·217 as the sp.gr. of the molten metal. Copper, deposited by electrolysis from an acid solution of copper-sulphate and not subjected to any mechanical treatment, was found to have sp.gr. of 8·9544 at 15·5° in air (Watson, J. Soc. Chem. Ind. 2, 153).

Commercial · copper, prepared in the usual way, is never pure, and the examination of the fractured surface of a cast ingot of copper shows a minutely vesicular structure. On this account the density of such metal is less than the same sample of metal after it has been sub-jected to a compressing mechanical treatment, and varies from 8·2 to 8·6

Colour.—Copper has a characteristic red colour which, in a fractured surface of worked metal, may be described as salmon-red.

Lustre.—A smooth cut or polished surface shows a bright metallic lustre which, however, soon tarnishes.

Crystalline system.—Copper crystallises in the cubical system.

Ores of copper. The following minerals are those from which copper is extracted on a com-mercial scale : native copper, cuprite, mela-conite, malachite, azurite, chrysocolla, ataca-mite, chalcocite, bornite, chalcopyrite, fahl ore.

The importance of the several species in the above list as ores of copper varies very much with the locality. Thus, while native copper is the chief ore in the Lake Superior district of North America, and atacamite in one or two localities in Chile, they would in other localities, and generally, be looked upon as rather rare, especially so in the case of the last species men-tioned. So also in the case of malachite ; this species, as an ore of copper, is seldom met with except in small quantities in the upper and oxidised portions of some copper lodes ; yet in the case of the once celebrated Burra Burra mine in Australia, and at Nischne-Tagilsk in Russia, it formed the bulk of the ore produced, and is also the chief ore in the Tanganyika district, Africa.

Generally, in a copper-mining district, all the oxidised species mentioned above occur in varying proportions, but as depth is attained, and almost invariably at or about the level at which water is reached, the copper-bearing minerals change and the oxidised species give place to the richer sulphide species, and these finally to chalcopyrite intimately mixed with varying proportions of pyrite. The inter-mingling of the two species last mentioned is frequently so intimate that it is not easy to distinguish the component minerals or to separate them. Chalcopyrite thus diluted down, as it were, with one or more of the minerals—pyrite, pyrrotite, &c —forms the ore from which the greater proportion of the world's copper supply is derived and the bulk of the material treated at the smelting works generally. Such ore frequently contains appreciable quantities of gold and silver. The silver is frequently carried by intermixed fahl ore, but also, in many instances, by the pyritic mixture in which dis-tinct silver-bearing minerals are not observable.

As by far the larger proportion of ore pre-sented for metallurgical treatment is of the nature indicated above, viz. chalcopyrite mixed with varying quantities of the pyrite family of minerals, it will best serve the purpose of this article if the methods adopted for the extraction of copper from this material are first considered. The ores treated generally contain only small percentages of copper, frequently not more than 1 p.c.

The elimination of the several elements in the ore and the final production of the copper in the metallic state, are effected by two distinct series of chemical operations. One of these—the most important, because of its very general application—treats the ore by smelting, and

causes the necessary reactions to take place while the material is in a molten condition. The other—of limited application—treats the material in the wet condition, and causes the necessary reactions to take place in solutions.

These two distinctly different methods of procedure may be distinguished as (a) dry methods, and (b) wet methods.

Dry methods. The object which the smelter keeps in view in the first stages of the processes is to concentrate the copper contained in the ore in as small a quantity of material as may be economical. For this purpose, the product known as 'matte' or 'regulus' is universally selected. This consists of cuprous sulphide Cu_2S and iron sulphide FeS in varying proportions, together with sulphides of certain other metallic elements. The whole of the copper contained in the ore thus passes into the matte, while the silica combines with iron oxide and earthy bases, if present, and forms the slag. The slag separates easily from the matte, owing to its lower specific gravity, and is thrown away. Having thus concentrated the copper into regulus, or matte, the next stage of the process concerns itself with the decomposition of this matte in such manner as to eliminate the iron and sulphur and, as far as possible, other metallic elements which may be present and to yield the copper in the metallic state

The final process consists in refining the copper produced as above; or, in other words, removing, as far as practicable, the small quantities of such elements as may still be present in the product of the preceding operation which would injuriously affect the copper for manufacturing purposes

The treatment of the ore involves, therefore, three distinct operations :—

I. Smelting the ore with the production of matte and slag.

II. Treatment of the matte for the production of crude copper.

III. Refining.

The methods and the plant used for carrying out each of the three operations vary considerably, and the choice of any one depends upon local conditions, the nature of the ore as regards physical character, and the nature and quantity of the foreign elements present. It will not be possible within the limits of this article to study these considerations and the bearing they may have on the methods to be adopted; all that the space will allow of is a description of the methods as actually carried out under the most generally prevailing conditions.

I. *Smelting the ore with the production of matte and slag.*—The object of this process being the concentration of the copper in the matte, the chief considerations kept in view are the production of a matte as rich in copper, and a slag as poor in copper, as is practically and economically possible.

The grade of the matte to be produced having been decided upon, the smelter regulates this by suitably proportioning the sulphur in the ore to be treated so that there shall be sufficient to form Cu_2S with all the copper, and a further proportion to form FeS with the iron present in such quantity as will cause the matte to contain the desired percentage of copper. From these considerations it will be seen that the factor which regulates the grade of the matte is the quantity of sulphur present in the ore mixture smelted. With the class of ore under consideration, it invariably happens that the quantity of sulphur present is considerably in excess of requirements, and the production of the most suitable grade of matte necessitates the removal of this excess, which may be effected before the actual smelting of the ore is commenced. Under certain favourable conditions, however, it may be removed during the smelting process (see *Pyritic smelting*). This preliminary operation is designated 'calcining' or 'roasting.'

The process consists in subjecting the ore to a dull-red heat under oxidising conditions, so that the sulphur is caused to combine with oxygen derived from air admitted into contact with the ore with the production of sulphur dioxide, while the iron is also oxidised at the same time.

The method of carrying out this calcining process depends upon whether the ore is to be treated .

(a) In the rough—say in pieces from ¾ inch cube upwards ; or

(b) As fines or 'concentrates,' i.e. in which the particles are finely divided.

Under (a) : *The ore may be calcined by forming heaps of it in the open air* and starting the combustion by means of a small proportion of wood, the combustion being maintained by the sulphur present in the ore.

The ore may also be calcined in stalls more or less open. These consist of series of chambers in rows built back to back. The chambers are each bounded by three walls, viz back and two side walls, but are open in front and have no roofs. Small flues, opening out into the chambers, are built in the walls separating them, and these flues connect with a larger flue in the central division wall between the two rows, and these again connect with a chimney stack.

The ore is charged into these open chambers on to a layer of wood , when filled up, the wood is fired and combustion extends to the ore itself in the same way as in the case of the heaps. The gases produced in the operation are to a large extent led away by the flues in the walls above referred to. The annoyance caused by the escape of these gases at or near the ground level of the works—as is the case in open-heap roasting—is in this way to a large extent avoided.

The ore may be calcined in kilns.—These are similar to the stalls, but are generally built of much larger size, are closed in on all four sides, and are roofed over. They are provided with suitable openings in the roof through which the ore is introduced, and a doorway in the front wall (bricked up when the kiln is in operation) through which the calcined ore is removed. An outlet flue, connected to the roof or back wall, allows the gases to be conveyed to a chimney.

The ore may be calcined in 'burners.'—These are constructed and worked on very much the same lines as the 'burners' used for burning 'pyrites' at sulphuric acid works. In this plant, a number of closed cells or 'burners' are built in rows, back to back. Each cell is roofed in and connects at the back with a

central flue common to all the cells, by which the gases are led to the acid chambers. In the roof of each cell is an opening through which the ore can be charged from a hopper placed above. In this class of plant, the ore does not rest on the floor as it does in each of the cases previously considered, but upon a series of square bars suitably spaced. Below these bars is an enclosed space with suitable door through which the calcined ore is removed and by means of which the air supply is regulated.

In operating this plant, the cell having been brought up to a good red heat by the combustion of wood or other suitable fuel, ore in small quantities is gradually added as combustion proceeds, until the burner is full. At suitable intervals, a small quantity of the calcined ore is removed from the bottom of the burner and a corresponding fresh supply of ore is added through the opening in the roof. In this way, the operation of the burner is rendered continuous, and no fresh extraneous fuel is required after the first starting of the fire.

In all the methods of treatment described under (a), it is essential that proper care be taken to prevent the temperature reaching anything like melting-point. If the ore melts or sinters together, calcination is delayed owing to the reduced surface on which oxidation can take place. Further, in the case of such sintered or melted material, difficulties are created in working the process. In the case of heap roasting and also in the stalls and kilns, the formation of large masses of sintered or melted ore introduces undesirable irregularities in the air current through the mass of ore under treatment, and
FIGS. 1, 2, AND 3.

causes trouble when the ore is removed. In the burners, the formation of sintered masses of ore must be avoided, as such masses would have to be broken up in the burner with suitable tools before it could be made to pass out between the grate bars.

Under (b) : *The ore may be calcined in hand calciners or mechanical calciners.*—The former are not much used at the present time, as the necessary labour is effectually replaced by mechanical appliances. The hand calciner, which was universally used some years ago, consisted of a long flat bedded reverberatory furnace, with the usual fire box at one end and the outlet flue for the exit of the gases at the opposite end (Figs. 1, 2, and 3). The ore was dropped from a hopper through an opening in the roof on to the bed at the flue end of the furnace, where it was spread out by means of suitable tools worked by men at both sides of the furnace, operating through doors in the side walls.

The conditions in the furnace were intensely oxidising, and it was necessary to stir the ore frequently to prevent it sintering. In the process of stirring, the ore was turned over and moved towards the fire end, thus making room for a fresh charge from the feed hopper. This process of stirring and moving the ore forward towards the fire end was continued until the ore reached close up to the fire box, at which point it was discharged through openings in the bed of the furnace into vaults, or chambers, constructed below, from which—when sufficiently cool—it was removed. The labour required on these furnaces was very heavy and the output small, and, except in unimportant installations, they have given way to furnaces in which the

ore is stirred, moved forward, and discharged by mechanical means operated by power. It will be impossible within the limits of this article to describe the many furnaces of this type which have been introduced, and it will suffice to describe one or two which will serve as examples of the class of plant employed.

The McDougall furnace (Fig. 4).—This is very largely used, and consists of a series of flat circular superimposed firebrick hearths, enclosed in a brick-lined cylinder of steel plate. An iron shaft passes centrally up the cylinder through openings in the several hearths, and is

Brick   Pier

FIG 4

(From Gowland's Metallurgy. Charles Griffin & Co., Ltd)

caused to revolve by suitable gearing attached either to its upper or lower end. This shaft may be made hollow and cooled by air or water circulation.

One or more iron arms are attached to this shaft above each bed. The arms extend from the shaft to the periphery of the circular beds, and have attached to them a series of iron plates or ploughs set at a slight angle to the arm. The ore is fed from a hopper on to the top bed near the centre, and the angle of the ploughs is such that, as the arms revolve, they not only turn the ore over, but gradually move it from the centre to the edge of the bed. At one point in the edge of the bed is an opening through which the ore

falls on to the second bed. On this bed the ploughs are so set on the arms that the ore travels in the reverse direction and is drawn to the centre of the bed. Here it discharges on to the third bed ; and so on until it escapes at the bottom of the furnace. The openings through which the ore falls from one bed to the other also serve as flues through which the gases pass upwards through the furnace, finally escaping through a flue above the top bed.

Attached to the lowest bed is a fire box by which the furnace is heated up in order to start it ; but, after being once started, little or no fuel is required, as the oxidation of the ore provides sufficient heat throughout the apparatus.

The straight-hearth mechanical furnace.—This type of furnace passes under various distinctive names, according to the several methods adopted for operating the ploughs, and slight modifications in the construction. One such furnace consists of a flat bed about 100 feet long covered with an arch. At one end is the inlet for the ore, and at the opposite end is the outlet. At the ore inlet end is the flue for carrying off the gases, and at the opposite end, but to one side, is a fire box with the inlet to the furnace constructed in the roof of the latter. Other similar fire boxes—one or two in number—are placed at intervals along the length of the furnace. A channel is constructed in the side walls of the furnace and in these a rail is laid. A suitable carriage with wheels resting on the rails stretches from one side of the furnace to the other, and the bearings pass through slots in the two side walls and are carried by the wheels above referred to. To this carriage, suitable ploughs are attached in such manner that, in the course of its travel from one end of the furnace to the other, the ploughs turn the ore over and also move it forward. The carriage is moved by a pair of chains or ropes travelling in the channels formed in the side walls, and at the two ends of the furnace these chains or ropes are carried round wheels sufficiently large in diameter to lead them back under the furnace, thus making them continuous. One pair of these wheels is driven by suitable gearing, thus causing the pair of ropes or chains—and with them the carriage —to travel the whole length of the bed of the furnace, returning through the tunnel under the bed, where rails are laid for supporting the carriage. Two or more such carriages are attached to the ropes, or chains, at equal distances apart. The ore is fed mechanically on to the bed at intervals just as a carriage is about to enter, and the ore is spread, turned over, and moved forward gradually from one end of the furnace to the other. Each time a carriage emerges from the furnace, it draws with it a quantity of calcined ore. The carriage and its attached ploughs are cooled during the passage through the tunnel. The ends of the furnace are closed by light iron doors which hang down vertically and are automatically opened by the passage of the carriage and close themselves as soon as the carriage has passed.

There is yet another method of removing the excess sulphur which is sometimes used, known as ' pot roasting,' or ' blast roasting.' This method of calcining is advantageously applied to concentrates and fines, and, while it eliminates the sulphur, the heat attained is at the same

time sufficiently intense towards the end of the process to cause the ore to partially melt or sinter together, forming a mass which requires to be broken up before it can be treated in the smelting furnace. The process is carried out in a similar manner to that used in the treatment of lead ores, but is not very extensively used in the metallurgy of copper.

After the sulphur in the ore mixture has been reduced to the requisite amount, the ore is ready to be smelted. For this operation one of two distinctly different types of furnace are used ; these are :

    (1) Blast furnace.   (2) Reverberatory furnace.

The choice between these two methods of carrying on the smelting operation depends on a

FIG. 5.

variety of circumstances, all of which must have proper consideration, but the following are the chief points, viz. : If the ore is to be smelted in the state of fines or concentrates, it is unsuitable for blast-furnace treatment, while it is eminently suitable for the reverberatory furnace. On the other hand, rough ore is unsuitable for reverberatory-furnace smelting.

Blast-furnace smelting.—The furnace used may be built of brick, but is more generally, nowadays, constructed with water-cooled walls of steel plate (Fig. 5), each section of which is termed a jacket. In the smaller furnaces the horizontal section is circular, but in the ordinary sized and larger furnaces the section is always rectangular. As the working of this type of furnace is—as its name implies—dependent upon an air blast projected into the interior,

the width of the furnace is limited by the strength of the blast which is required to penetrate the charge from the sides to the centre of the furnace, while the length of the furnace is only limited by the capacity required. The increase in length is obtained by clamping together two or more of the jackets on each side, thus extending the longer axis of the furnace.

The jackets stand on a thick cast-iron plate carried on iron supports. In some cases these jackets are only used in the lower part of the furnace, all the upper part being constructed of brick, but the brickwork may, in certain cases, be advantageously replaced with a second tier of jackets, reaching up to the feed floor. Above the feed floor the furnace is continued in the form of a covered-in brick chamber with lifting doors at each side and an outlet in the roof of the chamber, connecting, by means of a suitable iron flue, to the general flue system of the works. Through the doors the charge, consisting of a proper mixture of ore—either raw and calcined, or partially calcined ore—is introduced. To this ore mixture there is also added such flux, either limestone or silicious material, and the necessary amount of coke as is required to form a suitable smelting mixture. As previously indicated, the object of this is to produce a matte of the desired grade and a slag which shall be as free from copper as possible and which shall be of such fusibility as to flow readily from the furnace. On the lower or working floor, the furnace is provided, either at the ends or sides, with one or more spouts through which the molten products of the smelting operation flow. Except in very large furnaces, only one such spout is used at a time, and if more than one is fitted, it is with the object of having one in reserve in case of a stoppage to the one in use.

The side jackets of the furnace are provided with circular openings (tuyères) passing from the outer to the inner surface. When the jackets are set up, these tuyères form a horizontal line of openings on each side of the furnace. The blast is brought down from the air main by light iron piping to the tuyères, and through these it passes to the interior of the furnace.

The blast, at a pressure of 10–42 oz. per square inch, is generated by a suitable blowing machine, which must be of the positive, and not the fan, type. A plentiful supply of water is circulated through all the jackets, and the overflow pipes from these, carrying away the hot water, discharge into sinks or launders.

The products of the smelting operation performed in this furnace flow out through the spout above described into the settler. In the case of small furnaces this is a square cast-iron vessel open at the top and mounted on wheels to allow of easy replacement. It is furnished with a cast-iron spout at its upper edge through which the slag overflows, and is provided with a tap hole near the bottom from which the matte is tapped from time to time. In the case of larger furnaces for this form of settler, there is substituted a circular tank, formed of steel plates lined with refractory material, placed permanently in position under the spout of the furnace. This form of settler may be 10 or more feet in diameter, and, like the smaller

pattern mentioned above, is provided with a slag spout near the top and a tap hole near the bottom.

In the settler, a thorough separation of the slag and matte takes place : the matte, having the higher specific gravity, falling to the bottom of the vessel and the lighter slag rising to the top, where it overflows through the spout into suitable pots provided for its removal to the slag dump. From time to time the matte is tapped off through the tap hole at the bottom of the settler. The working of this type of furnace proceeds continuously, fresh ore charges being dumped in at the top at short intervals, while a constant flow of slag and matte passes out through the spout.

Reverberatory-furnace smelting – The furnace used is essentially different both in construction and method of working from the one previously described. In the blast furnace, the fuel—coke —is burnt in contact with the materials to be smelted, and the intense heat required for the operation is obtained by urging the combustion of the fuel by means of an air blast In the reverberatory furnace the material to be smelted occupies one compartment of the furnace, while the fuel coal or wood—is burnt in another. The draught required for the combustion of the fuel is quite moderate, and is obtained by a chimney of suitable height and area. The use of pulverised coal has recently

been introduced in reverberatory furnace practice, with gratifying results, from a fuel economy point of view. The working bed of the furnace in plan is a parallelogram (Fig. 6) with rounded corners. At one end, and separated from it by a low partition, is the fire box, in which the fuel is consumed. At the opposite end is the outlet flue connecting with the chimney. A brick arch extends from the back wall of the fire box to the flue. This arches the furnace across from one side wall to side wall, and is constructed with a fall from the fire-box end to the flue end of the furnace. The partition, or bridge, as it is termed, to which reference is made above as separating the working bed from the fire box, reaches to such a height above the bed that an opening is left between its top surface and the roof of the furnace. Through this opening above the bridge, the flame from the burning fuel passes over the bed on its way to the outlet flue The side walls of the furnace are pierced with a number of openings used in working the furnace for spreading the ore charge, drawing off the slag, &c , and one opening is cut down to the lowest point of the bed for tapping the matte

The furnace walls and roof are constructed of highly refractory bricks with an outside casing of ordinary bricks, and the whole is bound together

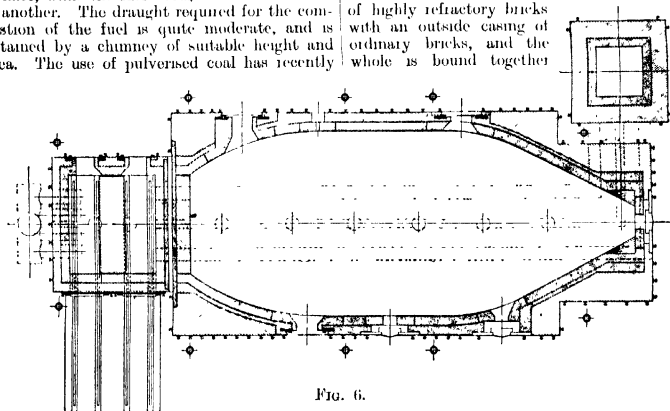

FIG. 6.

with steel girders placed vertically and tied together from one side to the other by iron tie rods. The working bottom is variously constructed. It may be formed of highly refractory bricks, or of silicious sand or crushed quartz.

The charging of this furnace takes place through one or more openings in the roof from hoppers supported above Assuming that the furnace is heated up to the required temperature, a charge of ore mixture is dropped from the hoppers above through the openings in the roof. This is then spread over the bed by means of suitable tools operated by men working through the side and front doors. When this operation is completed, the doors are closed and the fire attended to so as to raise the temperature of the furnace as rapidly as possible to full heat. The charge is occasionally stirred, if necessary, to remove any agglomerated masses from the bottom of the furnace, and

finally, a molten bath is obtained composed of two distinct layers—the matte forming the bottom layer, and the slag floating upon it. When this stage is reached, another charge may be dropped and treated in the same way ; and this may be repeated from time to time until the furnace is full of molten slag and matte. A side door and end door are opened and the slag allowed to run off, and towards the end, this is drawn off by means of tools handled by the furnace-men until nearly all the slag has been removed. The tap hole is then carefully opened, and this being at the bottom of the furnace, the matte flows through it and is led by a launder into a ladle or into moulds placed on the floor to receive it. When nearly all the matte has been run off, the tap hole is again closed and made secure, fresh charges are dropped in, and the operations repeated.

The slag may be received in ladles mounted

on wheels, and in these may be removed to the dump, run into a stream of water and thus granulated and removed ; or it may be run into sand moulds formed on the floor of the furnace house, and, when cool, broken up and removed to the dump.

The object attained in this operation in the reverberatory furnace is the same as with the blast furnace, viz. the production of the proper grade matte and a slag of easy fusibility reasonably free from copper.

Pyritic smelting.—This method of working secures in one operation what, in the preceding descriptions, is attained in two processes carried on in separate appliances. It has been shown that in order to produce a proper grade of matte from cupriferous iron pyrite, a certain proportion of sulphur must be oxidised to sulphur dioxide, and that, accompanying this action, a portion of the iron sulphide must also be oxidised. It has also been shown that, in ordinary working, this preliminary treatment and the actual smelting of the ore are carried out as two distinct operations. It has also been indicated that in the smelting operation proper, the high temperature necessary is obtained by the combustion of carbonaceous fuel. In pyritic smelting, the two processes referred to above are carried out as one operation in one furnace, and the high temperature necessary is derived from the rapid oxidation of the sulphur and iron (chiefly the latter) contained in the ore itself. While this method of working is of the highest importance from an economical point of view, it is of somewhat limited application, owing to the fact that comparatively few mines produce ore which—as regards its physical condition and chemical constitution—is suitable for this method of treatment.

The process is carried out in blast furnaces, and for its successful operation demands a larger volume of air per unit of time than the ordinary smelting process and an ore mixture in which the pyritic material is present in fairly large pieces. The silica must be, for the most part, free silica (quartz), and not combined with earthy bases as silicates. Under these circumstances the ore may be satisfactorily smelted, producing the required matte and slag with the consumption of but 1 to 3 p.c. of coke instead of 10 to 12 p.c. used in the ordinary method of smelting. A small amount of coke is found to be desirable in order to keep the charge open.

II. *Treatment of the matte for the production of crude copper.*—It has already been pointed out that matte consists of cuprous sulphide Cu_2S, with varying proportions of iron sulphide FeS, and the carrying out of the stage which is now to be considered involves the elimination of the sulphur and iron, while the copper is left in the metallic state. The process is carried out by different methods, the chief of which will now be considered. In all of those the operation is performed in two stages, although, in some cases, these follow one immediately after the other and in the same apparatus, while in others the stages are performed as two separate operations and in two or more separate furnaces. The first stage in each case consists in the removal of the FeS with the production of Cu_2S, and the second stage treats the Cu_2S with the production of metallic copper. The carrying out of the

first stage depends upon the fact that, when matte is exposed to oxidising conditions, the iron sulphide is the first of its constituents to be decomposed, the sulphur being oxidised to sulphur dioxide. The resulting iron oxide is then caused to combine with silica, forming a slag which can be removed from the residual cuprous sulphide.

The second stage in the process depends upon one or more of the reactions represented by the following equations :—

$$Cu_2S + 2Cu_2O = 6Cu + SO_2 ;$$
$$Cu_2S + 2CuO = 4Cu + SO_2 ;$$
$$Cu_2S + CuSO_4 = 3Cu + 2SO_2 ;$$
the first being the most important as representing the change which takes place in the largest proportion of the material. The reactions indicated are effected by bringing the several compounds together in a molten condition. The oxidised compounds may be added to the molten Cu_2S from outside sources or may be, and generally are, produced by the oxidation of a portion of the cuprous sulphide itself.

The reactions outlined above are, at the present day, almost always brought about by what is termed the 'converter process,' also named ' Bessemerising,' the former name derived from the designation of the vessel in which the operation is performed, viz. converter, and the latter from the name of the distinguished inventor, Sir Henry Bessemer, who had many years previously applied a similar method and plant to the production of steel from pig iron.

The converter consists essentially of a vessel formed of steel or iron plate, with a thick lining of either highly siliceous rock to which a small quantity of clay has been added, sufficient only to give the necessary coherence, or of basic material. The vessel is provided with a suitable aperture serving the purpose of a charging opening through which the matte to be operated upon is poured in a molten condition, also as an outlet through which the products of the operation are poured, as well as being an escape for the gases produced in the process. The vessel is supported on horizontal trunnions or on friction rollers, and is capable of being rotated by electric or by hydraulic power (Fig. 7). The form of the vessel is more or less cylindrical with the axis of the cylinder placed vertically or horizontally. In the case of the former, a shallow circular enclosed space, termed the air box, is attached on the outside at the bottom of the vessel. In the latter form, this air box takes the shape of a long rectangular box attached horizontally to the outside of the converter. From these boxes holes are led through the plates forming the casing of the converter, and are continued through the lining to the interior. Air, at a pressure of from 8 to 12 lbs. per square inch, is supplied to the air boxes as required, and the supply is controlled by suitable valves. Charging of the converter with matte is effected by means of a launder direct from the furnace, or settler, or by tapping these first into a steel ladle handled by an overhead crane which conveys it to the converter and pours it.

When an acid lining is used, the converter, having been lined and the lining dried by a slow fire, is placed upon the stand and connected up

to the air main A charge of molten matte is then poured in, the converter having been tilted into a suitable position for receiving it. The air being turned on, the converter is then tilted over so that the tuyères are brought beneath the surface of the matte, and the air,

being forced through the molten sulphides, causes a rapid oxidation of the constituents of the iron sulphide The sulphur is oxidised in this way to sulphur dioxide and the iron to oxide, which is immediately converted to silicate by combination with the silica of the lining. As

FIG. 7.

the oxidation proceeds, the temperature of the charge increases and the operation is continued until practically the whole of the iron sulphide has been decomposed, and the contents of the converter consist of cuprous sulphide and slag. The converter is now turned over and the slag run off into pots or moulds, and when this is done, it is again turned into the blowing position, when the second stage of the oxidation is commenced. The passage of the air through the molten cuprous sulphide brings about the oxidation of a part of that material to cuprous oxide, which immediately reacts upon unaltered cuprous sulphide with the production, of an equivalent quantity of metallic copper, in accordance with the reactions already given. This action continues until all the cuprous sulphide has been decomposed and the contents of the converter consist of metallic copper ; any small quantity of slag which may be on the surface is removed by turning down the vessel and skimming off. The metallic copper is then poured by tilting the converter. As the slags produced in the operation contain a certain amount of copper they are resmelted in the furnace in which the matte was produced in the first place. As soon as the copper has been poured, the converter is ready to receive another charge, and the operations are repeated. When several charges, generally 5 to 10, have been put through (the number depending upon the nature of the material of which the lining is formed and

the care exercised in ramming it into place), the lining becomes too thin for further use ; the converter is therefore removed to the relining department by means of the crane, the old lining is taken out and a fresh one put in, when, after drying, it is again ready for use.

Owing to the frequency of this relining necessary in the acid converters, basic lined converters have been introduced, magnesite bricks being used for this purpose. The silica which is necessary to flux off the oxide of iron formed by the oxidation of the iron sulphide in the matte, is charged into the converter in the form of dried silicious ore. Very large basic lined converters are now being used and the method of working varies somewhat from that used in the case of acid lined converters. The copper from a previous charge having been poured, 30 to 40 tons of matte may be poured into the converter followed by about 3 tons of silicious ore which may itself be cupriferous. The blast is then put on and the converter slowly turned until the tuyères are below the level of the matte. For the first few minutes a blast pressure of only 5 lbs is used, and after the matte and silica have thoroughly intermingled, the blast pressure is increased to about 12 lbs. per square inch. When the silica has been fluxed by the iron oxide, the converter is turned down and the slag poured off. A further charge of 6 to 7 tons of matte and sufficient silicious ore are now added and the blow is resumed. This removal of slag and additions of matte and ore are continued until sufficient white metal or cuprous sulphide has accumulated in the converter to be blown to metal in the usual way.

Another method for the production of metallic copper from the matte is conducted entirely in reverberatory furnaces, and is sometimes employed where the output does not justify the more expensive converter plant previously described. In this method of working, the first stage, viz. the removal of the iron sulphide of the matte by oxidation of its constituent elements, is effected by smelting the material with a proper proportion of calcined matte together with silica sufficient to form a silicate of iron slag with the iron oxide ; or the matte may be smelted with oxidised copper ore, silica being also present. In either case, the result is that the iron sulphide is decomposed, the sulphur passing from the furnace as sulphur dioxide, and the iron forming, with the added silica, a slag, which is removed. The contents of the furnace at this stage consist chiefly of cuprous sulphide, Cu_2S. Currents of heated air are directed over the surface of the molten bath, with the resulting formation of cuprous oxide and the concurrent reaction between this and the unchanged cuprous sulphide results in the production of metallic copper, in accordance with the equations previously set out. When this reaction has extended to the whole contents of the furnace, the heat is raised and the metallic copper is tapped out into moulds.

III. *Refining.*—The method of treatment to be adopted in this operation depends upon whether (a) the copper is practically free from gold and silver and from deleterious elements ; (b) the copper contains appreciable quantities of gold and silver, or contains undue quantities of deleterious elements.

If the metallic copper produced by the operations previously described under I. and II. comes under the description (a) above, it can be refined by furnace treatment only; if it comes under (b) it must be refined electrolytically in order to recover the gold and silver or to obtain it free from the impurities.

Under (a), the furnace employed is of the reverberatory type, and the removal of the impurities is effected by slowly melting the pigs of copper under highly oxidising conditions, and maintaining the bath of molten copper under this condition until the impurities are oxidised and removed, either by volatilisation or by passing as oxides into the copper silicate slag formed. The oxidation of the impurities is facilitated by the fact that metallic copper has the property of dissolving a small proportion of cuprous oxide, which compound is brought into contact with the elements to be oxidised under the very favourable condition of fluidity.

· The oxidising condition of the bath of molten copper is maintained until the impurities are removed, as far as practicable, and the copper contains a maximum quantity of dissolved cuprous oxide. In this condition the metal is said to be 'dry.' After removal of the slag, the next stage consists in reducing the greater portion of the dissolved cuprous oxide, which is effected by depressing poles of green wood below the surface of the bath of metal, when considerable agitation takes place and the cuprous oxide is subjected to the reducing action of the gases given off by the pole.

The process is continued until only a small quantity of cuprous oxide remains, and the copper attains the physical condition known as 'tough pitch,' when it is ladled out into moulds of any required shape.

Under (b), the copper is refined electrolytically. This process depends for its operation upon the fact that if an electric current is caused to pass through a solution of copper sulphate, the copper in the solution is deposited at the cathode, while the acid is set free at the anode. If the anode is composed of metallic copper, then the acid set free on its surface immediately dissolves an equivalent portion of copper which passes into solution, and is, in turn, deposited at the cathode, and the process thus becomes continuous so long as the current passes and there is copper at the anode to be dissolved. Assuming that the solution of copper sulphate is properly made up and maintained, and the voltage and current are suitably adjusted, then only copper will be deposited at the cathode, while the gold and silver and all the impurities contained in the copper anodes will either remain as insoluble slime, collected at the bottom of the vessel in which the operation is conducted, or will pass into the electrolyte. Gold, silver, and lead pass entirely into the insoluble slime ; other elements, such as iron and nickel, pass wholly into the solution, and others again are to be found partly in the slime and partly in the electrolyte. The cathode surface is, to start with, a very thin sheet of electro-deposited copper, and when—as the result of the operation—sufficient copper has accumulated upon its surfaces, it is removed from the bath and is ready for melting and casting into any required shape. In practice, a number of anode plates are hung in a lead-lined wooden tank, and are suitably connected to the positive lead. Alternating with these anode plates are hung the cathode sheets, connected in parallel with the negative lead. A large number of tanks are connected in series, and the current is passed through the whole set of tanks. The electrolyte is caused to circulate through the whole series, and, after it has been in use for some time, a certain proportion must be removed regularly for purification. A quantity of anode copper remains undissolved, and when the tank is to be cleaned, this is taken out for remelting into anodes, the solution is run off, and the slime is removed. This latter is washed and dried, any large particles of copper removed by sieving, and the fine slime is then treated for the recovery of any silver or gold which it may contain.

Copper flue dust. A considerable amount of copper may be carried forward in the waste gases from the furnaces and precautions are now taken to recover it. In modern well arranged plants, capacious flues and dust chambers are provided between the furnaces and the chimney for the deposition of the fine particles of ore carried forward, and for the condensation of copper fume, which is frequently arsenical. The Cottrell process of electrostatic precipitation of dust is sometimes used. The dust obtained is collected from time to time and retreated in reverberatory furnaces or is briquetted and smelted in blast furnaces.

Wet methods. Until recently these had a very limited application in the extraction of copper, but within the last few years have made remarkable strides, and extensive plants are now in operation in which new methods or modifications of the older methods are being used. The wet extraction of copper consists of leaching the ore either in its natural condition or after roasting and in a suitable state of subdivision, with a suitable solvent, in vats fitted with false bottoms and precipitating the copper from the solution thus obtained by suitable means.

Wet methods are specially suitable for the treatment of low grade oxidised ore and for oxidised tailings, but have also been successfully applied to the treatment of material containing the copper as sulphide. The most widely used method consists in leaching the ore with dilute sulphuric acid and recovering the copper from the solution by electrolysis or by precipitation on metallic iron. This method can be applied directly to oxidised ores, but in the case of sulphide ores a preliminary roast, in order to render the copper soluble in the acid, is frequently necessary.

At Rio Tinto the massive cupriferous pyrites is treated without roasting, large heaps of the mineral being allowed to oxidise slowly under the action of air and moisture, and the copper sulphate thus formed is washed out and precipitated on metallic iron. In some cases in which sulphuric acid leaching is followed by electrolytic deposition of the copper, the regeneration of sulphuric acid in the precipitation plant yields a solvent suitable for further leaching operations.

Another method used consists in roasting the cupriferous sulphide material with salt. Soluble copper salts are thus formed which may be recovered by solution and precipitation of the

copper on iron. A modification of this process is also used whereby silver is recovered with the copper.

Other processes are sometimes used in which sulphurous acid, ferric sulphate, ferrous chloride and ammonia are used as solvents.   C. O. B.

COMPOUNDS OF COPPER.

Oxides. Five oxides of copper are said to be known: the quadrantoxide Cu_4O, the trientoxide Cu_3O, the sub- or hemi-oxide Cu_2O, the monoxide CuO, and the peroxide CuO_2. Other oxides have been described, but their existence is not proved.

Copper quadrantoxide is stated to be formed by adding a solution of copper sulphate to a cooled dilute solution of stannous chloride in caustic potash (Rose, Pogg. Ann. 1861, 120, 1). It is an olive-green powder, which rapidly absorbs oxygen from the air. According to Moser (Zeitsch. anorg. Chem. 1909, 64, 200), this product is really a mixture of cuprous oxide and copper.

Copper trientoxide is obtained as a hard yellowish mass by heating cupric oxide at $1500°–2000°$. It is unaffected by any acid except hydrofluoric (Bailey and Hopkins, Chem Soc. Trans. 1896, 269).

Copper suboxide, or hemioxide, red oxide of copper, cuprous oxide Cu_2O, occurs native as *cuprite* or red copper ore, and as *chalcotrichite*.

It may be prepared (1) by heating finely divided copper in air below a red heat; (2) by gently heating a mixture of 5 parts cuprous chloride and 3 parts sodium carbonate in a covered crucible, and separating the oxide by lixiviation; (3) by reduction of an alkaline solution of a copper salt by sugar or certain other organic bodies, as in Barreswil's (Fehling's) solution; (4) by heating in a covered crucible a mixture of 5 parts copper monoxide and 4 parts copper filings; (5) by the electrolysis of copper sulphate solutions under certain conditions (Miller, J. Phys. Chem. 1909, 256; Gillett, *ibid.* 1909, 332); (6) by heating cupric oxide in sulphur dioxide and treating the product with water, when cupric sulphate is dissolved and the cuprous oxide remains: $3CuO + SO_2 = Cu_2O + CuSO_4$ (Hammick, Chem. Soc. Trans. 1917, 111, 384).

This oxide is decomposed by most acids into a cupric salt and copper; hydrochloric acid, however, converts it into cuprous chloride

Cuprous oxide fuses at a bright-red heat. It dissolves in metallic copper and renders it brittle or 'dry' when present in quantity. As much as 4·6 p.c. has been found by Abel in very dry copper, and, according to Watson (J Soc. Chem. Ind. 1883, 154), from 1 to $2\frac{1}{2}$ p.c. is present in ordinarily good copper

It is largely used in the manufacture of *ruby glass*, and for the production of a red glaze on pottery (Louth and Dutailly, Mon. Ceram. et Verr. 19, 237), and, together with the black oxide, forms one of the so-called *copper paints* used for painting ships' bottoms.

A yellow form of the oxide is produced by the action of alkali on cuprous chloride, or better by the reduction of a cupric salt by means of hydroxylamine in presence of alkali. It can also be prepared electrolytically, using an alkali sulphate as the electrolyte and an anode of pure

copper. It may also be obtained by the reduction of Barreswil's (Fehling's) solution in presence of a deficit of tartrate. The yellow precipitate thus formed is not a definite hydrate, but is a colloidal form of the oxide with an indefinite amount of water (Gröger, Chem. Zeit. Rep. 1902, 197). It quickly changes to an orange or brick-red colour and can then be dried unchanged. The dried product contains from 2–3 p.c. of adsorbed water. At a low red heat it loses this water and changes into the red crystalline form. The yellow cuprous oxide is to be regarded as a primary metastable form, the red crystalline form being the stable one. It is a powerful reducing agent, especially in ammoniacal solution. This solution, which is colourless, immediately becomes blue from the formation of the monoxide on exposure to the atmosphere, and thus forms a delicate test for oxygen. The hydrated oxide dissolves in a concentrated solution of magnesium chloride.

This oxide is produced in Hoepfner's process for extracting copper from ores, &c., with cupric chloride solution. Cuprous chloride is formed and treated with alkali to obtain cuprous oxide (J. Soc. Chem. Ind. 1893, 932; Eng. Pat. 18900, 1892).

Copper monoxide, cupric oxide, black oxide of copper, 'copper oxide' CuO, occurs as *melaconite* or *black copper*, especially at Lake Superior.

It may be prepared by heating the nitrate or carbonate to dull redness or the sulphate to intense redness. The decomposition of the sulphate is the basis of Adcock's process for the preparation of the oxide direct from the natural carbonate or sulphate (Eng Pat. 11678, 1900). The copper oxide used for organic analysis, &c., may be prepared by moistening copper scale (the mixture of suboxide and black oxide obtained while working copper sheet, &c.) with nitric acid, and igniting.

An electrolytic method of preparing the oxide has been described by Miller (J. physikal. Chem. 1909, 256); and by Luckow (Zeitsch. Elektrochem. 1897, 482).

Copper oxide is a black powder which agglomerates when heated, and fuses at the melting-point of copper, forming cuprous oxide, or Cu_3O, according to the temperature. It can be made to crystallise in regular tetrahedra. It is slightly hygroscopic, especially when in powder. When heated with organic substances or certain gases, it is reduced to metal. The metal produced by reduction in hydrogen always contains that gas, but if the oxide be reduced in formic acid vapour, the metal is quite free from hydrogen and is suitable for organic analysis (Weyl, Ber. 15, 1138).

It dissolves in acids with formation of cupric salts. In oils, &c., it is soluble to some extent; it is for this reason that copper cooking vessels require such constant cleansing.

. Copper oxide is used in ultimate organic analysis; to make green and blue glass and glazes, and to some extent as a pigment. It has also been used as one electrode of a galvanic cell (v. Lelande and Chaperon, Bull. Soc. chim. [2] 49, 173).

Cupric hydroxide $CuO·H_2O$ may be prepared by precipitating a solution of a copper salt by addition of alkali and washing rapidly.

When heated with water, it becomes black and amorphous.

A colloidal form of the oxide has been obtained by Paal and Leuze (Ber. 1906, 1545), which gives blue-violet solutions, and when dry retains its solubility indefinitely.

The hydroxide is used as a blue pigment by paper stainers, but becomes green on exposure. It corresponds closely with certain of the highly basic carbonates sold as *verditers.* According to Dumas, it is best prepared as follows : 6 parts of copper sulphate are dissolved in water and mixed with a solution of 3 parts of calcium chloride. The clear liquid is decanted from the precipitated calcium sulphate and is mixed with 1½ parts of lime made into a cream with water. The greenish precipitate is collected, washed, and mixed with one-fourth its weight of slaked lime and as much pearl ash, and to render the colour more permanent, one-fourth its weight of ammonium chloride and one-half its weight of copper sulphate are usually added.

The hydrated oxide dissolves in ammonia, the saturated solution in strong ammonia being known as 'Schweitzer's reagent,' or *cuprammonium.* This solution has the property of gradually dissolving *cellulose* with formation of a viscid solution which is used for the preparation of the 'Willesden papers,' and for the production of 'artificial silk' on the large scale. This process consists in injecting the copper-cellulose solution into strong solutions of alkali or acid. In either case, coagulation takes place with formation of a fibre of cellulose corresponding in thickness to the diameter of the jet.

An aqueous solution of sodium hydroxide of sp.gr. 1·345 1·370, or of potassium hydroxide of sp.gr. 1·453–1 498, will dissolve 0 78 grm. of cupric hydroxide in 100 c.c giving a bright blue solution which yields no precipitate when boiled. If a more dilute alkali solution be used the solution is not stable when further diluted and subsequently boiled (Justen-Mueller, Compt. rend. 1918, 167, 779).

Cuprammonium solutions are prepared on the large scale by the joint action of oxygen and ammonia on metallic copper at temperatures near 0° (Schaefer, U S. Pat. 884298, 1908 ; Bronnert, Frémery, and Urban, Eng. Pat. 1763, 1900 ; Lecœur, Fr. Pat 374277, 1906).

Bellot has patented a continuous process of manufacture, using a series of closed vessels (Fr. Pat. 335207, 1903).

The solution should be purified by dialysis, as the presence of crystalline salt favours its decomposition (Lecœur, Fr. Pat. 362986, 1906). Addition of 1–2 p.c. of polyhydric alcohols, carbohydrates, gum, &c., to cuprammonium solutions increases their stability and prevents the deposition of cupric hydroxide (Friedrich, Eng. Pat. 4104, 1909), and the presence of such substances facilitates manufacture of the solution, making it possible to employ copper concentrations up to 5 p.c. without cooling (Fr. Pat. 399911, 1909).

Chattaway has shown (Proc. Roy. Soc. 1908, 80, A, 88) that by the reduction of a cuprammonium solution with aromatic hydrazines, copper mirrors can be deposited on glass.

Dawson states that a solution of cupric hydroxide in ammonia contains copper as the base $Cu(NH_3)_4 (OH)_2$ (Zeitsch. physikal. Chem. 69, 110). (For a general discussion of the constitution of cuprammonium salts, *see* Horn and Taylor (Amer. Chem. J. 1904, 253), and Horn (*ibid.* 1907, 475).)

Copper dioxide, copper peroxide CuO_2, is obtained by the action of hydrogen peroxide on cupric hydroxide in neutral solution at 0° (Kruss, Ber. 1884, 17, 2593 ; Moser, Zeitsch. anorg. Chem. 1907, 54, 121). The crystalline precipitate is washed with water, alcohol, and ether at 0°, and dried *in vacuô*. It has a yellowish-brown colour, and decomposes at 180°, forming cupric oxide.

SALTS. Two series of copper salts are known, *cuprous* and *cupric.* The former are mostly insoluble in water, and are of but little commercial importance. They act as powerful reducing agents and readily pass into the cupric condition. Cupric salts are mostly soluble, and are of wide application.

Cuprous chloride Cu_2Cl_2 may be prepared, amongst other methods, by boiling cupric chloride with hydrochloric acid and copper turnings. On addition of water it is precipitated in white crystals.

Zulcoga has suggested (Rev. Chim. Ind. 1900, 107) that the cuprous chloride solution used in the extraction of silver from its ores should be prepared by mixing solutions of cupric sulphate and of cupric sulphate and sodium chloride.

Cuprous chloride melts below a red heat into a yellow transparent mass. The dry crystals become yellowish on exposure to light ; if moist, they acquire a dirty-violet tinge. Plates of copper coated with this chloride by the action of chlorine will take photographic impressions, but cannot be made to withstand exposure to light (e Carlemann, J. pr. Chem. 63, 475 ; and Priwoznik, Dingl poly. J. 221, 38).

Cuprous chloride combines with ammonia to form three compounds

$Cu_2Cl_2 \cdot NH_3$, $Cu_2Cl_2 \cdot 3NH_3$, $Cu_2Cl_2 \cdot 6NH_3$
Cuprous bromide and iodide form compounds analogous to the last two (Lloyd, J. Phys. Chem. 1908, 398).

The hydrochloric acid solution, when exposed to air, absorbs oxygen and acquires a brown colour, subsequently depositing a pale bluish-green insoluble copper oxychloride

$$CuCl_2 \cdot 3CuO, 4H_2O$$
An identical substance used as a pigment, and known as *Brunswick green*, is prepared by boiling a solution of copper sulphate with a small quantity of bleaching powder solution ; or by moistening copper turnings with free exposure to air. It occurs in nature as *atacamite.*

The use of the oxychloride in preference to the sulphate for destroying mould on vines, &c., is recommended. 200–250 grams per litre of water are employed (Deletrez, J. Soc. Chem. Ind. 1909, 438).

When a solution of cuprous chloride in potassium chloride, acidified with hydrochloric acid, is treated with acetylene, a yellow precipitate of $Cu_2Cl_2 \cdot C_2H_2$ is formed. Other compounds containing copper oxide or potassium chloride can be obtained by varying the conditions (Chavastelon, Compt. rend. 132, 1489).

Acetylene reacts with solutions of cuprous

chloride in ammonia to form a blood-red precipitate of *cuprous acetylide*, which, on dehydration, has the formula Cu_2C_2, and is highly explosive . (Scheiber, Ber. 1908, 3816). Its decomposition by acids has been used as a means of preparing pure acetylene. A colloidal solution of copper acetylide has been prepared by Küspert (Zeitsch. anorg. Chem. 34, 453) (*v.* ACETYLENE).

Cuprous bromide Cu_2Br_2 is obtained by the union of its elements or by boiling a solution of cupric bromide with copper, and forms a brown crystalline mass.

Cuprous iodide is the only known iodide of copper, and is obtained as a white precipitate by adding potassium iodide to a solution of copper sulphate containing ferrous sulphate or sulphurous acid. It has a sp gr. 5 653 at 15° (Spring, Rec. trav. chim. 1901, 79), melts without decomposition at 628°, and is practically insoluble in water.

Cuprous sulphite Cu_2SO_3,H_2O is obtained in microscopic nacreous plates by passing sulphur dioxide into a hot solution of cuprous acetate in acetic acid. It forms double salts with the alkali sulphites. *Cupro-cupric sulphate* $Cu_2SO_4 \cdot Cu_2SO_3,2H_2O$ is a red microcrystalline powder.

Cuprous sulphate Cu_2SO_4 can be prepared by the action of dry dimethyl sulphate on dry powdered cuprous oxide (Recoura, Compt. rend. 148, 1909, 1105). A compound of cuprous sulphate and carbon monoxide $Cu_2SO_4 \cdot 2CO,H_2O$ has been obtained by Joannis (*ibid.* 1903, 615), by reducing cuprammonium sulphate with hydroxylamine. Péchard has made ammonio-cuprous sulphate $Cu_2SO_4 \cdot 4NH_3$ (*ibid.* 1903, 504).

Cuprous sulphide Cu_2S occurs as *chalcocite* or *copper glance*. It may be prepared by heating copper to redness in sulphur vapour, or by heating a mixture of copper and sulphur It melts at $1130° \cdot D_4^{25°}$ 5 785. It is dimorphous, and has an inversion temperature at 91°.

Cupric chloride $CuCl_2$ may be prepared as a fused, liver-coloured, anhydrous mass by heating copper in excess of chlorine. In solution it may be prepared by dissolving the oxide in hydrochloric acid. It crystallises in grass-green prisms or needles containing 2 molecules of water. They become pale-blue when dried *in vacuó.* The anhydrous salt is obtained on gradual addition of a large excess of conc. sulphuric acid to a solution of the chloride (Viard, Compt. rend. 1902, 135, 168).

° Cupric chloride is very deliquescent, and is soluble in alcohol. When a small quantity of potash is added to the aqueous solution, a pale-blue basic oxychloride $2CuO \cdot CuCl_2, 4H_2O$ is precipitated. It turns to a black anhydrous powder when heated, but again becomes green with absorption of 3 molecules of water when moistened. It is an intermediate product in the manufacture of *verditer* (*v.* Copper carbonates).

Cupric chloride is used in calico printing, in the manufacture of *methyl violet*, and for the oxidation of *Cutch colours.*

Green has shown that the chloride is a very effective disinfectant (Zeitsch. fur Hygiene), 1893, 495).

When cupric chloride solution is mixed with excess of potassium thiocyanate solution, *cupric thiocyanate* $Cu(CNS)_2$ is produced. This is

slowly acted on by water and is ultimately reduced to *cuprous thiocyanate* CuCNS with formation of carbon dioxide, ammonia, carbamide, hydrogen cyanide, thiocyanic and sulphuric acids (Philip and Bramley, Chem. Soc. Trans. 1916, 109, 597).

Cupric bromide $CuBr_2$ is obtained by dissolving cupric oxide in hydrobromic acid and evaporating *in vacuó.* It is dark-coloured, very deliquescent, and, when heated, decomposes into cuprous bromide and bromine. It is used as an intensifier in photography, and for that purpose is made by dissolving in water a mixture of anhydrous copper sulphate and potassium bromide (Akt. Ges. f. Anilinfabr. D R. P. 201168, 1907).

Cupric sulphate, *Blue vitriol* $CuSO_4, 5H_2O$, occurs naturally at Copaquire, Chile, the rock containing over 12 p c of the hydrated salt (Walker, Eng. and Min. J. 1903, 710). This salt may be prepared by dissolving copper or its oxide in sulphuric acid.

It is prepared on the large scale from metallic copper in the following way : Old copper plates from the sheathing of ships, &c , are heated to strong redness in a reverberatory furnace, and an excess of sulphur is thrown in and the doors are closed. When combination is complete, the doors are reopened and the heat is raised to dull redness to oxidise the sulphide into sulphate. The mass, while hot, is thrown into dilute sulphuric acid, allowed to settle, the solution decanted, concentrated, and crystallised. The sulphate so produced is of considerable purity. *Coarse copper* and *copper glance* or other sulphurous copper ores are similarly treated. Pauffin and Couvert have patented a process for the direct manufacture of the sulphate from the metal (Fr. Pat. 399413, 1909). (*See* also Walker, U.S. Pat. 788862, 1905).

.When much iron is present, as in most copper ores and especially in copper pyrites, it would be impossible to separate the copper and ferrous sulphates by crystallisation, because, although copper sulphate crystallises normally with 5 molecules of water, it forms, in presence of ferrous sulphate, crystals isomorphous with that salt and containing 7 molecules of water. By carefully adjusting the temperature at which the sulphide is roasted, however, the iron salt may be converted into the oxide while the copper sulphate remains almost unaffected. The iron may be removed by heating the solution of the sulphates to 180° in a copper boiler under pressure. Ferrous sulphate crystallises out and is filtered off (Gin, Fr. Pat. 328800, 1903). The iron may be oxidised and thus separated from the copper by boiling the solution with a little nitric acid. It may also be precipitated as oxide by boiling with copper oxide, or by boiling with lead peroxide with subsequent addition of a little barium carbonate.

Crude copper or the ore may be roasted in air, and then treated with sulphur dioxide to form the sulphate (Gin, Zeitsch. angew. Chem. 1903, 566 ; Eng. Pat. 5230, 1903).

Darier has patented a process in which cupric chloride is formed by the action of chlorine and water on the metal, and is then decomposed by sulphuric acid, with formation of the sulphate and regeneration of hydrochloric acid (Fr. Pat. 350421, 1904).

When the sulphate is required for purposes

where the presence of iron is not injurious, such liquors, or the mother liquors from which the purer salt has been separated, may be at once crystallised out, with the formation of crystals containing both iron and copper. Much of the 'agricultural copper sulphate' is of this class. The 'Salzburg vitriol,' prepared at Buxweiler, also contains both iron and copper. According to Lefort (Compt. rend. 26, 185), it consists of $CuSO_4\cdot3FeSO_4,28H_2O$. 'Cyprian vitriol,' prepared at Chessy from zinciferous copper ores, forms blue rhombic prisms, which contain according to Lefort, $CuSO_4\cdot3ZnSO_4,28H_2O$.

The copper may be separated from the ferrous mother liquors by placing them in vats containing iron plates upon which the copper is slowly deposited.

Apparatus for the solution of copper oxide in sulphuric acid upon a large scale has been described by Coste (Fr. Pat. 392617, 1908). If copper be known to contain silver or gold, as is the case with that from the Harz, it is treated with sulphuric acid diluted with its own volume of water, the copper being thus dissolved while the silver and gold are unattacked.

Argentiferous copper ores are roasted in a reverberatory furnace, and added in small charges to sulphuric acid and digested until the solution contains but little free acid. The solution is then decanted from the precipitated lead and gold, and is concentrated and run into lead-lined tanks containing plates of copper, upon which all the silver and part of the antimony and arsenic are deposited, while the greater proportion of the bismuth is precipitated as a basic sulphate, and the iron is reduced to the ferrous condition. The liquor is then crystallised, the mother liquors being used for treating a fresh quantity of ore. Copper sulphate is obtained of great purity and in considerable quantity in the refining of silver by precipitating it upon plates of copper from its solution as sulphate (v. SILVER).

An electrolytic process for the production of the sulphate consists in using a solution of sodium sulphate and copper electrodes, a current of carbon dioxide being passed through the liquid. Copper is dissolved from the anode as sulphate, while sodium carbonate is produced at the cathode. These react, regenerating sodium sulphate and precipitating copper carbonate, which is collected and dissolved in sulphuric acid (Kroupa, J. Soc. Chem. Ind. 1906, 78).

Palas and Cotta have also described electrolytic processes for the production of the salt (Eng. Pat. 9806, 1899, and 17485, 1900).

The electrolytic production of the sulphate from 'cement copper waters' has been described by Rambaldini (Chem. Zentr. 1909, i. 1675).

It is stated that copper sulphate is sometimes adulterated with ferrous sulphate and Prussian blue to the extent of 90 p.c. (J. Soc. Chem. Ind. 1900, 84).

Copper sulphate crystallises in large transparent blue, doubly oblique rhombic prisms of sp.gr. 2·28, of the formula $CuSO_4,5H_2O$. According to Poggiale, their solubility in 100 parts of water is :

10°C.	20°	30°	40°	50°
36·59	42·31	48·81	56·9	65·83
70°	80°	90°	100°	
94·60	118·0	156·44	203·32	

When heated, it loses 2 molecules of water at 30°, 2 more at 93°-98°, and at 232° becomes anhydrous, white, and hygroscopic, and combines with water with considerable evolution of heat. At 341° the anhydrous salt begins to decompose (Wanjukow, Chem. Zentr. 1909, ii. 1124). The sp.gr. of the anhydrous salt is 3·606 (Thorpe and Watts). It combines with water in alcohol and other organic liquids with production of a blue colour, and may be used for ascertaining the presence of water in those substances, but the test is not delicate. The anhydrous salt is also soluble in anhydrous methyl alcohol, and produces a bluish-green solution (Klepl, J. pr. Chem. 1882, 25, 526).

Copper sulphate absorbs hydrogen chloride with evolution of heat, forming cupric chloride and liberating sulphuric acid. It is therefore used to remove hydrogen chloride from such gases as chlorine or carbon monoxide. A similar reaction occurs in solution.

When mixed in solution with molecular proportions of potassium and other sulphates, it produces well-defined, crystalline double sulphates. Several basic sulphates are known.

The sulphate is the most important of the copper salts. It is largely used in calico printing, principally in connection with potassium dichromate or iron mordants ; in black dyeing with logwood ; directly or indirectly for the preparation of most pigments containing copper ; and to prevent rot in timber. In agriculture the crude sulphate containing ferrous sulphate is used to a considerable extent to prevent smut in seeds. The seeds are soaked for some hours in a weak solution of the sulphate, and are sown within 24 hours.

A 10-20 p.c. solution of copper sulphate, preferably mixed with lime, is applied to vines with great benefit. A small quantity is found in the vines and must, but the tannin and sulphur introduced before fermentation appear to remove it in most cases.

Karsten has stated (v. J. Soc. Chem. Ind. 1896, 367) that attacks of illness resembling dysentery have been caused by a wine which contained copper in such quantity as to form a visible deposit on steel in 12 hours. Its presence was due to spraying the vines with a copper salt.

An effective wash for vines is prepared by boiling 25 parts of sodium carbonate and 25 parts of resin in 100 parts of water, and then diluting and adding copper sulphate (J. Soc. Chem. Ind. 1899, 155).

Copper sulphate is used in preparing copper ferrocyanide, a solution of which, in potassium citrate solution, is used as a toning-bath for photographs (Ferguson's Copper Toning, ibid. 1900, 465).

Copper sulphate is also used in dyeing to make diazo- colours permanent to light. The dyed fabric may be treated with the salt (Graebling, ibid. 1905, 797), or it may be added to the diazotising bath (Grossmann, Färber-Zeit. 9, 328).

Cupro-tetrammonium thiosulphate CuS_2O_3 $(NH_3)_4$, has been proposed as an ingredient of detonator compositions, which although less sensitive are alleged to possess advantages over mercury fulminate compositions, as being cheaper, less unhealthy, simpler, and less dangerous to manufacture. The thiosulphate is

made by adding excess of strong ammonia solution to a hot saturated solution of copper sulphate, and thereafter adding an equivalent amount of sodium thiosulphate, dissolved in hot water. The salt separates out as the solution cools; it is washed with a weak solution of ammonia, and dried at a temperature not exceeding 50°. The violet-blue crystals are slightly soluble in water, not hygroscopic, insensitive to light, and very stable. Compositions suitable for various purposes are made by mixing with potassium chlorate, powdered glass, antimony trisulphide and lead thiosulphate (Herz, Zeitsch. ges. Schiess. u. Sprengstoffw. 1912, 7, 284; J. Soc. Chem. Ind. 1912, 31, 903)

Potassium copper nitrite $K_2Cu(NO_2)_4$ is obtained by mixing cold saturated solutions of copper sulphate and potassium nitrite, adding methyl alcohol, filtering, and adding ethyl acetate to the clear, green filtrate when long crystals of the salt separate. *Rubidium copper nitrite* of similar composition may be obtained in like manner (Kurtenacker, Zeitsch. anorg. Chem. 1913, 82, 204). *Basic copper nitrites* $3Cu(OH)_2 \cdot Cu(NO_2)_2$ and $2Cu(OH)_2 \cdot Cu(NO_2)_2$ are also known.

Cupric nitrate $Cu(NO_3)_2$ may be prepared by dissolving copper or the oxide or carbonate in nitric acid. The solution at temperatures above 20° deposits dark-blue crystals containing 3 molecules of water, which melt at 114·5° and boil at 170° with evolution of nitric acid and formation of a green basic salt. This basic salt may also be prepared by boiling the solution of the nitrate with copper or copper hydrate, or with a little alkali (v. also *Copper carbonates* for an application of the basic nitrate).

The anhydrous salt may be obtained by the action of nitric anhydride on the hydrated salt. It is a white, deliquescent powder, decomposing at 155°–160° (Guntz and Martin, Bull. Soc. chim. 1909, 5, 1004).

Copper nitrate is used to a slight extent in dyeing and calico printing, and a solution, prepared by mixing solutions of copper sulphate and calcium nitrate, is used in viticulture (Gouthière et Cie and P. Ducancel, Fr Pat. 395806, 1908)

Cupric sulphide CuS occurs as *covelite* or indigo copper in blue flexible plates, in Vesuvian lava, in Chile, and in the copper-mines of Mansfeld. It may be prepared by heating cuprous sulphide with sulphur at a temperature not above the boiling-point of sulphur; by digesting cuprous sulphide with cold strong nitric acid; or by precipitating a copper solution with sulphuretted hydrogen $\cdot D_4^{25}$ 4·68. On the large scale it is obtained as a paste by precipitating a solution of the sulphate with sodium sulphide. This paste is used in calico printing for the development of aniline black.

The preparation and use of copper sulphide for thermo-couples has been described (Eng. Pat. 11300, 1905).

Rieder has used (Zeitsch. Elektrochem. 1902, 370) an electrolytic method for the preparation of this compound.

A brownish-red *persulphide of copper* has been obtained by Bodroux by adding a solution of calcium pentasulphide to a solution of copper acetate at 0° (Compt. rend. 130, 1397).

Copper acetate v. *Metallic acetates*, art. ACETIC ACID.

Copper arsenite v. *Scheele's green*, art. ARSENIC.

Cupric phosphate is of no technical interest. A brilliant green colour containing a basic phosphate, prepared by heating a mixture of copper acetate, sodium phosphate, and ammonia, has, however, been used in calico printing (Bourcart, Mon. Sci. [3] 4).

Phosphorus combines in several proportions with copper, and produces true alloys, which in many cases are of great value.

Heyn and Bauer state that the phosphorus exists in the alloy as Cu_3P and Cu_5P_2 (J. Soc. Chem. Ind. 1906, 1047) The latter compound has been obtained by Rubénovitch by the action of phosphine on copper sulphate (Compt. rend. 127, 270).

Copper silicide (*Cuprosilicon*) Cu_4Si is obtained when copper and silicon are heated together in the electric furnace (Vigouroux, Compt. rend 1896, 122, 318; Lebeau, *ibid.* 1906, 142, 154) It is now manufactured in Germany and America by this process (Stemhart, Eng. and Min. J. 1899, 67, 710), and is used for purifying and hardening copper, and for adding to tin-, zinc-, and aluminium-bronzes to increase their tensile strength and hardness

Cuprosilicon can be prepared pure by heating together 17 parts silicon and 9 parts copper, in hydrogen, and removing the excess of silicon by solution of sodium carbonate. It is silver-white, with a metallic lustre, and is hard and brittle The sp.gr is 7 58, and it is attacked by chlorine and *aqua regia* (Vigouroux, Compt. rend. 1906, 142, 87; *see also* Philips, Métallurgie, 1907, 4, 587; and Lebeau, *ibid.* 141, 828).

Copper carbonates. The normal salt has not been prepared, but several basic carbonates are known, and used as blue and green pigments. Basic copper carbonate occurs native as *malachite* $Cu(HO)_2 \cdot CuCO_3$, and as *azurite* or *chessylite* $Cu(HO)_2 \cdot 2CuCO_3$. When ground, these minerals form a fine but expensive pigment.

An anhydrous basic carbonate is precipitated on addition of a solution of sodium carbonate to a hot solution of copper sulphate or nitrate. (For a complete description of all the known basic carbonates of copper, *see* Pickering, Chem. Soc. Proc. 1909, 188. *Cf.* Dunnichff and Lal, Chem. Soc. Trans. 1918, 113, 718.) Commercial basic carbonates of copper differ considerably in composition: the amount of carbon dioxide present is below that required for malachite or azurite. A definite basic salt is known of the composition $2CuCO_3 \cdot 5Cu(OH)_2$.

Under the names *Verditer green*, *Verditer blue*, *Bremen green*, and *Bremen blue*, this salt is largely prepared for paper staining, &c. According to Habich (Technologiste, 17, 413), the following processes are in use. A hundred parts of old copper sheathing from which impurities, oxide, &c., have been removed by digestion in dilute sulphuric acid, is cut into pieces and mixed with a paste formed by moistening a mixture of 99 parts potassium sulphate and 100 parts common salt, and the mixture is stirred occasionally for some months to ensure thorough exposure to the atmosphere. The action appears to consist in the production of cupric chloride,

which, in presence of the metal, becomes converted into a basic chloride, and finally, by the action of the oxygen, into an oxychloride. If the oxidation be incomplete, the subchloride is not completely oxidised, and, as it, when subsequently decomposed by alkali, gives an orange-red precipitate of suboxide, the pigment would be lowered in value. The oxychloride may also be similarly prepared from a mixture of 100 parts copper, 60 parts common salt, and 30 parts strong sulphuric acid diluted with three times its volume of water ; or by treatment, with free atmospheric exposure, of copper with a solution of cupric chloride in hydrochloric acid.

To 100 kilos. of this thick magma of oxychloride, which has been washed by decantation, a concentrated solution containing 7 kilos. copper sulphate and 40 kilos. concentrated soda solution (32°–36°Bé.) is added. The mixture is vigorously stirred and poured at once into 150 kilos. of soda solution (20°Bé.). The precipitate is washed, passed through a fine hair sieve, and dried spontaneously or at a temperature below 25°. If hot air be used in the drying, it must be quite free from acid or sulphur gases. To produce the finest colour, desiccation must be perfect.

Habich recommends the following process for making a *verditer* which has a very different composition from the above. A solution of copper oxide in nitric acid is treated with potassium carbonate, which is added in portions until most, but not all, the copper has been precipitated. The green precipitate is washed and introduced into a solution of copper nitrate whereby it is converted into a heavy green insoluble basic nitrate. This is digested in a solution of potassium zincate (formed by dissolving zinc in caustic potash solution). A dark-blue pigment, of great ' body ' but little weight, is thus produced. It contains zinc and copper, apparently combined as a double oxide or as ' copper zincate,' and a small quantity of basic copper nitrate.

Verditer may be prepared by agitating a solution of copper nitrate with chalk. The washed pasty precipitate is mixed with 8–10 p.c. of freshly burnt lime with production of a fine velvety blue pigment. The precipitate without addition of lime is green.

According to Gentele, the following process is adopted at Bremen, Cassel, &c. ; 225 lbs. sea salt and 222 lbs. blue vitriol, both free from iron, are mixed dry and ground between millstones with water to a thick paste. This paste is mixed in strata with 225 lbs. of clean copperplate cut into pieces about 1 inch square, in wooden chests made without nails, and the mixture is allowed for about 3 months with the maximum exposure to air, the whole being well mixed and exposed about once a week. When the action is complete, the undissolved metal is removed and the precipitate is washed with a minimum of water, filtered and thrown into a tub. To 180 lbs. of the magma 12 lbs. of hydrochloric acid (13°Bé.) is added, and the mixture is stirred and left for 24 or 36 hours. Six volumes of this solution is mixed with 15 volumes of caustic alkali (19°Bé.) followed after an interval by 6 volumes of water. The mass is well mixed and left for 36–48 hours, and is then well washed by decantation, filtered,

exposed for some time in a moist condition to the air, and finally dried (*v. also Copper monoxide*).

COPPER-GLANCE or **Chalcocite.** Native cuprous sulphide Cu_2S, crystallising in the orthorhombic system. Excellent twinned crystals were formerly found in abundance in the neighbourhood of Redruth in Cornwall (hence the name redruthite) and Bristol in Connecticut ; usually, however, the mineral is found as compact masses. It is iron-black with metallic lustre, but, on exposure to light, it soon becomes dull with a powdery black coating. It is soft (H. 2½) and sectile, and can be readily cut with a knife ; sp.gr. 5·7. It occurs in veins of copper ore, and is often of importance as an ore, especially when it contains small amounts of silver. Isomorphous with copper-glance is the mineral *stromeyerite* $(Ag,Cu)_2S$, which has been found in considerable quantities in the Altai Mountains in Siberia. L. J. S.

COPPER PAINT *v.* COPPER.

COPPER PYRITES or **Chalcopyrite.** A sulphide of copper and iron $CuFeS_2$, containing when pure 34·5 p c. of copper, and the most important of the ores of copper. It has a characteristic brassy-yellow colour with metallic lustre, and on the surfaces often displays a brilliant iridescent tarnish (peacock-copper-ore). It often occurs together with, and intimately intermixed with, iron pyrites, from which it can be distinguished by its deeper colour and lower degree of hardness ; copper pyrites (H. 3½–4) is readily scratched with a knife, giving a greenish-black powder, whilst iron pyrites (H. 6–6½) is scratched only with difficulty or not at all. It occurs in mineral-veins and in bedded deposits, and by its alteration gives rise to many secondary copper minerals. Crystals are tetragonal with inclined hemihedrism, but only rarely are they distinctly developed ; sp gr. 4·2. L. J. S.

COPRA and **COPRA OIL** *v.* COCO-NUT OIL.

COPROLITES. Concretionary mixtures of calcium phosphate and calcium carbonate, derived from the excrements of certain extinct fishes and reptiles. Formerly much used in the manufacture of superphosphate of lime (*v.* FERTILIZERS).

COPROSMA. The bark, and more especially the roots, of the *C. grandiflora, C. linariifolia,* and *C. areolata,* which belong to the natural family of the *Rubiaceæ,* and are widely distributed in New Zealand, possess tinctorial property (Aston, New Zealand, J. Sci. Tech. 1918, 1, 3), and being related to madder probably contain either alizarin itself or an allied colouring matter. Thus an alcoholic extract of the *C. grandiflora* is coloured purple by alkali, and becomes yellow on addition of acid. From the acid solution, by means of ether, an orange-yellow crystalline substance can be isolated in small amount. A. G. P.

COPYING or **INDELIBLE INK PENCILS.** Unlike iron-gall copying-inks, which will only yield good copies for a relatively short time after writing, solutions of aniline dyestuffs produce writing from which copies may be taken at any subsequent period. In copying-ink pencils the aniline dyestuff, usually methyl violet, is incorporated with graphite, kaolin clay or other basic material. The preparation

of pigments for this purpose was claimed by Petit (Eng. Pat. 4090 of 1874), and their composition was first described by Viedt (Dingl. poly. J. 1875, 216, 96). At the present time these pencils are seldom employed for copying purposes, and their chief use is as a substitute for ink, since they produce a writing which cannot be erased so readily as the marks of a lead pencil. Hence they are frequently described as indelible pencils, although the description is only relatively correct Lehner (Ink Manufacture, 1902, p. 125) gives the composition of four kinds of these pencils made by Faber in Bavaria. The aniline dyestuff ranged from 25·5 to 50 p.c , graphite from 24·5 to 37·5 p.c., and kaolin clay from 12·5 to 50 p.c

Specimens of these pencils examined by Mitchell (Analyst, 1917, 42, 1) had the following composition :—

Origin	Mois-ture	Residue Insol. in water or alcohol	Dyestuff	Loss on ignition (graphite, &c)	Ash (kaolin, &c.)
	p.c	p.c	p c	p c	p.c
American	2·35	76·45	21·20	27·09	47 36
,,	7·48	51·53	40 99	25 48	31·92
,,	2·30	60 89	36·81	56·84	4·05
,,	3 75	63 95	32 30	13·90	50 05
Austrian	3 56	47·14	49·94	44·14	3·00
British	2·72	65·48	31 80	62·08	3 40
,,	4 53	73·05	22 42	69 17	3 88
German	3 72	64·48	31·80	11·86	52·86
,,	6·33	59·83	33 84	7·61	52 22
,,	3 83	57·59	38 58	40·01	17·58

Pigments used in copying-ink pencils may be classified into four main groups –viz. (1) those composed of graphite and dyestuff only ; (2) those in which the dyestuff has been incorporated with approximately equal proportions of kaolin and graphite , (3) those in which the kaolin is largely in excess ; and (4) those in which the graphite predominates. The dyestuff is usually methyl violet, but copying-ink pencils in which red or blue aniline dyes are used are also sold.

The copying properties depend not only on the proportion of the dyestuff, but also on the influence of the basic material. Pencils in which a large proportion of alumina is present yield only faint copies, even when the pigment contains a large amount of the dyestuff. Although methyl violet is usually regarded as a very fugitive dyestuff, experiments have shown that under certain conditions the writing done with these pencils is more permanent than writing done with ordinary ink.

C. A. M.

CORAL is the calcareous substance secreted by many varieties of five kinds of organisms, viz. (1) *Actinozoa*, the principal constituents of coral reefs ; (2) *Hydrozoa*, the large common corals known as millepores ; (3) *Bryozoa*, delicate corals in various forms, resembling mosses, branches, thin filamentary deposits, or more solid masses (in the Palæozoic limestone formations this species of coral abounds) ; (4) *Foraminifera*, chambered shells belonging to

lowly organisms, mostly of very minute size ; (5) *Nullipores*, which, although closely resembling millepores, are veritable algæ or sea-weeds ; they may be readily distinguished from the millepores by the absence of perforations.

Coral is simply a secretion corresponding to the bone of vertebrates or the shell of mollusca, and is composed almost entirely of calcium carbonate derived from sea-water and from the food of the coral-making polyps.

Ordinary coral is somewhat harder than limestone or marble, and, when tapped with the hammer, gives out a ringing sound clearer than is elicited from ordinary calcium carbonate. The sp gr. of 15 specimens examined by Silliman, averaged 2·523

Small and variable quantities of magnesium carbonate, calcium sulphate, calcium fluoride, alkaline chloride, silica, and oxide of iron are found in corals.

The red coral, *Corallium rubrum*, varies in colour from crimson to rose, the latter being the rarest and, therefore, the most prized. It is gathered from the rocky bottom and shores of the Mediterranean ; and it occurs most abundantly at a depth of 25–50 feet ; although, according to Dana, it may be found as deep as 1000 feet. Forchhammer found 2·1 p.c. magnesia in *Corallium rubrum*, and 6·36 in *Isis hippuris*. According to Trommsdorff, the red pigment of coral is a resin soluble in oil of turpentine, and, after removal from the coral by this solvent, is easily soluble in alcohol and ether, but insoluble in caustic potash. In a red madrepore, Vauquelin found a red colouring matter, which was turned violet by alkalis. Moseley has described in some corals and allied organisms a red colouring matter (*Polyporphyrin*) which is insoluble in water, glycerol, alcohol, ether, and in strong solutions of ammonia and potash. It is soluble in moderately strong sulphuric, nitric, or hydrochloric acids. For the formation and distribution of coral and coral-reefs, &c. v. Corals and Coral Islands, J. D. Dana; Coral-Reefs, Darwin ; Murray, in Proc. Roy. Soc. Edinb. 1880, 505. *See also* Forchhammer, J. Pharm. Chim. 49, 52 ; J. 1847, 1291 ; 1849,

813; 1851, 865; 1852, 958-961; Sharples, l.c.; Moseley, Quart. Journ. Microscop. Sci. xvii. 1877; also Max Bauer, Edelsteinkunde, 2nd ed. 1909, Eng. trans. Precious Stones, I. J. Spencer, 1904.

It is now known that the materials constituting coral-reefs sometimes undergo remarkable chemical changes, and that the calcium carbonate is largely replaced by magnesium carbonate or calcium phosphate. In 1846 J. D. Dana and B. Silliman showed that the rock of an upraised coral-reef in the Pacific contained as much as 38 p.c. of magnesium carbonate. The deep boring made in the Atoll of Funafuti in 1897-8, yielded a series of cores, of which a chemical examination was made by E. W. Skeats and Hart Smith in the laboratories of the Royal College of Science. It was found that down to the depth of 637 feet dolomitization had only gone on to a small extent, the proportion of magnesium carbonate never exceeding 16 p.c.; but the lower portions of the core were very rich in the magnesium salt, containing from 30 to 43 p.c., the rock thus becoming almost a true dolomite. A large collection of coral limestones obtained by Alex. Agassiz, from reefs in the Pacific, was subsequently examined by Skeats, who showed that they contained varying amounts of magnesium carbonate up to nearly 42 p.c. Specimens from Christmas Island in the Indian Ocean gave similar varying results, percentages of magnesium carbonate up to over 43 p.c. being found. A coral limestone obtained by boring at Key West, Florida, yielded to G. Stieger, in the laboratories of the U.S. Geological Survey, over 14 p.c. of magnesium carbonate.

Coral reefs that have been covered by deposits of guano are found to have their carbonates largely replaced by phosphates. Thus the rocks of the coral reef known as Christmas Island in the Indian Ocean have been largely worked for the deposits of calcium phosphate, and Teall has shown that Clipperton Atoll in the North Pacific contains rocks with as much as 38½ p.c. of phosphoric acid.

(For changes in the chemical composition of coral rock, see Dana and Silliman, Amer. J. Sci. 2, i. 1846, 189; Judd, Chemical Examination of Materials from Funafuti in 'the Atoll of Funafuti,' Phil. Trans 1904, 362-389; Skeats, The Chemical Composition of Limestones from Upraised Coral Islands, Bull. Mus. Comp. Zool. Harvard, xlii. 1903, 53-126; Teall, Quart. Journ. Geol. Soc. liv. 1898, 230-232.)

CORALLIN, CORALLINPHTHALIN. PHENOLCORALLIN v. AURIN.

CORDIALS and **LIQUEURS** are spirituous compounds flavoured with essences obtained from fruits, herbs, spices, or other substances, usually sweetened with sugar or glycerol, and often strongly coloured. They are manufactured and used to a much greater extent in France and other European countries than in the United Kingdom, and although there is no essential difference between them, the term ' cordials ' is by many restricted to British, and ' liqueurs ' to the foreign preparations.

The spirit in the best qualities of liqueur is derived from the grape, but grain and other spirit is frequently employed, especially in cordials; but, whatever the origin of the spirit,

it should be highly rectified and neutral in character, so as not to impair the flavour of the finished product. The alcoholic strength of cordials and liqueurs varies greatly, but, on the average, they contain from 30 to 40 p.c. of alcohol, or 50 to 70 p.c. of proof spirit. The sugar must be pure, and is added in the form of a clear syrup.

The principal flavouring ingredients employed are (a) those used solely on account of their essential oils, as aniseed, bitter almonds, caraway, juniper berries, mint, lemon-peel, orange blossom, &c; (b) those valued for their bitter principles as well as their essential oils, as cinnamon, cloves, curaçoa apples (a kind of orange), gentian, ginger, orange-peel, sweet calamus, wormwood, vanilla, &c.; and (c) fruits, chiefly cherries, pineapples, raspberries, and strawberries. The flavourings are obtained either by digesting the flavouring ingredients (bruised or cut up) with alcohol and distilling the mixture to obtain an essence; or by filtering the alcoholic extract to form a tincture, or by simply expressing and clearing the juice of fruits or digesting the latter for a more or less prolonged period in spirit.

Artificial essences simulating the above flavourings are frequently employed, but their use in beverages is questionable, since it seems probable that their physiological action differs from that of the natural flavouring substances which they are intended to imitate.

The colouring matters most commonly used are as follows: Red, aniline red, brazilwood, cochineal, cudbear, and sandalwood; yellow, saffron and turmeric; blue, indigo; green, chlorophyll (from nettles, parsley, spinach, &c.) and mixtures of blue and yellow colourings; violet, aniline violet; and brown, a solution of burnt sugar or caramel (v. LIQUEURS).

CORDIERITE v. IOLITE.

CORDITE v. EXPLOSIVES.

CORDYLITE (or **Barium-parisite**). Carbonate and fluoride of cerium-metals and barium (CeF)₂Ba(CO₃)₂, containing Ce₂O₃, 23·72, and (La,Di)₂O₃, 25·67 p.c. It occurs as small, pale wax-yellow, club-shaped hexagonal crystals in syenite-pegmatite at Narsarsuk near Julianehaab in south Greenland; sp.gr. 4·31. It is isomorphous with, and closely related to, parisite.

L. J. S.

COREINE v. OXAZINE COLOURING MATTERS.

CORIANDER FRUIT, Coriandri fructus, B.P. The dried ripe fruit of Coriandrum sativum (Linn.).

CORIANDER, OIL OF, v. OILS, ESSENTIAL.

CORIARIA MYRTIFOLIA v. SUMACH.

CORINDITE. A refractory and abrasive substance obtained by heating a mixture of bauxite and anthracite in a cupola furnace. Aluminium carbide is first formed and is ultimately transformed into a vesicular fused mass of crystalline alumina of high melting-point, low thermal expansibility, and great hardness, suitable for the manufacture of fire bricks for rotary cement kilns, gas and heavy oil ovens, coke ovens, &c.

CORIOFLAVINE v. ACRIDINE DYESTUFFS.

CORIOPHOSPHINES v. ACRIDINE DYESTUFFS.

CORK. Cork is derived from the bark of two evergreen species of oak tree, the cork oak,

Quercus suber (Linn.) and *Q. occidentalis* (Gay). The former yields the best cork, and grows mostly in those countries bordering on the Mediterranean up to the 45° lat. The latter occurs on the Atlantic seaboard of Portugal, Spain, and France up to 48° lat.

The cork tree is from 30 to 60 feet high, and 3-4 feet thick. It grows slowly and reaches the age of 150-200 years. The tree has the peculiarity of throwing off its outer bark when it reaches a certain age, and then reproducing it. It is this that makes the cork industry possible. The chief countries in which cork is produced are:

1. *Spain.* Particularly the province of Catalonia. Here the best cork is grown. Seville is the chief market.

2. *Portugal* Centres : Lisbon and Oporto.

3. *Algeria.* Here the cork trees form great forests ; those belonging to the State were some years ago fully 600,000 acres in extent

4 *Southern France* and the *Pyrenean district.* Large forests of *Q. suber* exist in the more mountainous parts, but in the low-lying 'Landes' the tree is *Q. occidentalis*, which grows as far north as Belle Isle.

5. *The Adriatic coast.* Some is produced in the Austrian provinces, but it is of inferior quality.

6. *Sicily, Sardinia,* and *Corsica* also yield cork of good quality.

For an account of the cork industry in Sardinia, *see* J Chem Soc Ind. 1919, 38, 352 R. From U.S. Com. Rep July 25, 1919.

Speaking generally, the cork tree seems to thrive best on dry granitic and sandy soils, and not to do well in damp or limestone soils

The complete bark of the cork tree consists of two layers :

(1) The dry dead bark, comprising the epidermis and the cork proper, with the mesodermis.

(2) The green living skin which clothes the wood immediately under the dry bark. This may be looked upon as the active cork-producing layer, and contains bast fibres and the endodermis.

The epidermis on one-year-old twigs is green and smooth, but in the second year between it and the green under-skin irregular white waxy masses are formed ; these represent the beginning of the cork formation and increase from year to year, changing gradually into cork proper. At the end of the third year the epidermis dries up and cracks.

Barking the trees. This is the most important operation in the management of a cork forest, because on the care with which it is carried out depends the life of the trees and the regularity of the slabs produced.

. In barking, the workman takes a special tool and makes a cut round the stem above and below the portion of bark to be removed. A vertical cut or cuts are made so that the bark may be stripped off the tree, in which operation the shaft of the tool is used as a lever. Care must be taken not to bruise the green underskin, the real producer of the cork.

The first barking produces so-called ' virgin cork,' which is of little value, as it has not elasticity enough for use as bottle corks. It was formerly used for the production of Spanish

black, but of late years it has been employed in the manufacture of ground cork.

During the first year of growth the tree produces from 3 to 5 mm. of cork, but afterwards less, the mean for the first 9 years being about 2·1-3 mm., giving a total thickness of 20¾ mm. After 9 or 10 years, when barking usually occurs, the growth is slower, but where thicker cork is required, the period is of course longer. The first stripping usually takes place on the 15 20 year-old tree. The best cork is yielded by trees of from 50 to 100 years old. Those growing in the mountainous districts yield a smaller quantity but better quality of cork.

After the cork bark has been removed from the tree, it is stacked and weighted with heavy stones to flatten it, and when dry it is scraped with an iron tool to remove the epidermis The cork is then immersed for 5 or 6 minutes in a tank of boiling water, when it swells, and, according to the quality, retains this swelling more or less permanently. The water also removes tannin, vegetable acids, and their salts. In Spain the cork is occasionally passed through a fire, whereby it is superficially blackened, acquiring, it is supposed, by this treatment especially good qualities or ' nerve.'

After steeping, the plates are placed in heaps, weighted, and by hydraulic presses compressed into bales and bound with hoop iron.

Chemistry of cork. Cork extracted with hot water under pressure, yields gallic acid, colouring matters, iron and magnesium salts By extraction with alcohol it yields ' cerin,' or cork wax $C_{32}H_{26}O$. Siewert examined the alcoholic extract and isolated from it ' decaeryhe acid ' $C_{10}H_{18}O_2$.

The composition of cork has been further studied by Kugler (Arch. Pharm. 1884, 217) ; Gilson (*ibid.* 1890, 690) ; and Hy. Ingle (J. Soc. Chem. Ind. 1904, 1197).

Suberine, according to Kugler, is a real fat, which cannot be entirely extracted by solvents, because they do not penetrate the material sufficiently.

Gilson saponified cork from *Q suber* with 3 p.c. alcoholic potash, and isolated from the filtrate 44 p.c. of fatty acids, consisting of : *Phellonic acid* $C_{22}H_{32}O_2$, m.p. 95°-96°, a monobasic acid giving a violet colour with zinc chloride-iodine solution ; yield 8 p.c. *Suberinic acid* $C_{17}H_{30}O_3$, a semi-fluid sticky substance ; 36 p.c. *Phloionic acid* $C_{22}H_{40}O_7$: fine white needles, m.p. 120°-121° ; in small amount.

Gilson considers suberine not to be a true fat, but rather a mixture of complex esters and possibly condensation products of different acids.

Treated with iodine solutions cork does not give the cellulose reaction, and there is some dispute as to whether cellulose or a pentosan is the carbohydrate present in cork. Gilson, from microscopic examination, considers that cellulose is present.

. Cork also contains certain aromatic compounds, tannin and the aromatic aldehyde of wood, hadromal, besides coniferin and vanillin.

Treated with strong nitric acid, cork produces suberic acid $(CH_2)_6(COOH)_2$, oxalic acid, and other products. Strong sulphuric acid chars it, but it is little affected by hydrochloric acid. Chlorine, bromine, and iodine cause cork to shrink, the two former first bleaching it. Ignited

it burns, swells up, and forms a charcoal called Spanish black.

Physical properties.—The sp.gr. of cork is variously given from 0·12 (Rollmann) to 0·24 (Muschenbroek); on the average 0·16.

The uses of cork depend on its compressibility, elasticity, imperviousness to liquids, its lightness, its stability to weathering, &c. It is used in making stoppers, mats, soles, linings, springs for heavy waggons, as anti-vibratory and sound-deadening materials.

Waste cork is granulated by suitable machinery, sifted, and then ground to powder. The finest dust is mainly used in the manufacture of linoleum. Slightly coarser cork is used for the manufacture of cork carpet, but in both cases the binding material is prepared linseed oil.

Still coarser cork, of the size of peas, mixed with a proportion of lime, is employed in the manufacture of mats, insulating materials for water and steam pipes and cold storage chambers, packing, artificial corks for bottles, &c

In order to bind the particles of cork together are employed (1) collodion; used for bath mats and stoppers. The granulated cork of various grades in suitable proportions is mixed with the solution and the pasty mass pressed into perforated moulds; these are then heated in a suitable chamber provided with a condensing appliance to recover the solvents, ether and alcohol. 'Suberite' belongs to this class. The mat is removed from the mould and 'buffed' (sand-papered) on a buffing machine similar to that used by cabinet makers. Cork stoppers are made in a similar manner, and also insulating slabs and tubes for covering steam and water pipes.

(2) Gluten casein, and glue mixed with oily materials and resins and dissolved in suitable solvents, after mixing with the cork (rendered more or less insoluble by means of formalin, tannin, dichromates, lime, &c.), have also been used and patented for the production of cork slabs, &c., from granulated cork The cork of various degrees of fineness is mixed with the cement, subjected to powerful hydraulic pressure in moulds, and in some cases heated up to 200° to harden the albuminous matters of the cement.

(3) Mixtures of cork with silicate of soda and barytes or other pigment have been used for steam-pipe coverings

Slabs of cork have also been made by soaking cork in soap solutions, then drying, treating with milk of lime, again drying and pressing the resultant mass into heated moulds.

Another use for cork waste, more or less finely ground, is in the production of floors In this operation ground cork is mixed with a cement, such as Portland cement, or more often a mixture of cork and calcined magnesia is mixed with a solution of magnesium chloride and the pasty mass spread on the floor and allowed to harden; other salts, such as lead acetate, are sometimes added.

Cork dust is also used as a packing for the hollow spaces between the walls of cold-storage chambers, round the pipes of ice plants, &c., no binding materials being employed. Mixed with pitch, granulated cork is used as the filling between the outer and inner soles of boots,

especially American. It forms a warm, water-proof and resilient layer.

Granulated cork of various degrees of fineness is also mixed with the paint used to coat iron surfaces where there is danger of the condensation of moisture, such as in the cabins of steamers, in breweries, factories, laundries, and the like.

CORNUTINE *v* ERGOT

CORONITE. An explosive consisting of nitroglycerine, 38–40 parts; nitro-cotton, 1-1½ parts; ammonium nitrate, 26–28 parts; potassium nitrate, 3-5 parts; aluminium stearate, 11–14 parts, rye flour, 8–11 parts; wood meal, 2-4 parts; liquid paraffin, 2-4 parts (*v.* EXPLOSIVES)

COROZO. Vegetable ivory. The seeds of *Phytelephas macrocarpa*

CORROSION OF METALS. By the term 'corrosion' is generally understood the disintegration of a metal through oxidation Usually a skin of oxide is formed which more or less protects the underlying metal from attack. Copper, zinc, lead and aluminium are cases in point. Iron,[1] on the other hand, is exceptional, in that, when oxidised by exposure to ordinary atmospheric influences, a pulverulent, hygroscopic mass of oxide, known familiarly as rust, is produced, which not only fails to protect the underlying metal, but actually accelerates further corrosion. For this reason, and also because iron is of such enormous commercial importance, the various problems associated with the corrosion of iron have received wide consideration and been made the subject of numerous researches; only in very recent years have systematic attempts been made to investigate the corrosivity of the other commercial metals.

Corrosion of iron. It is impossible here to review or discuss the voluminous literature which has appeared on the subject during recent years, and for particulars, including bibliography, the reader is referred to Friend's Corrosion of Iron and Steel (Longmans and Co , 1911), and to The Corrosion and Preservation of Iron and Steel, by Cushman and Gardner (McGraw-Hill Book Co., New York, 1910). It will suffice here to give a short account of the questions at issue.

Conditions essential to the corrosion of iron.—Before passing on to consider the various theories that have been offered to account for the mechanism of corrosion, it is important to have a clear conception of a few of the fundamental facts. These may be briefly summarised as follows :—

1. Liquid water, alone, both at ordinary temperatures and at the boiling-point, is without any appreciable action upon iron. In the course of time the metal frequently becomes very slightly tarnished, but no trace of rust-formation can be detected.

2. Water vapour is without visible action upon iron at ordinary temperatures upwards to about 300°C. At 350°C., and somewhat above, tarnishing occurs owing to a superficial layer of ferrous oxide being produced. At still higher

[1] The word 'Iron' is, both here and in the sequel, used in its broadest sense to cover wrought iron, steel, and cast iron.

temperatures a protective layer of ferroso-ferric oxide is produced, which, however, is not rust.

3. Dry air or oxygen has no visible action upon iron at ordinary temperatures. It is not until the metal is raised to about 220°C. that a pale yellow tint is acquired, which, as the temperature rises, becomes successively straw-coloured, purple, and finally blue. These 'tempering' colours, as they are termed, are due to the formation of thin layers of oxide, and are consequently not produced *in vacuō* (Roberts, Trans. Inst. Mech. Eng. 1881, p. 710), but are produced in perfectly dry air, such as that obtained by prolonged desiccation over phosphorus pentoxide (Friend, J. Iron Steel Inst. 1909, ii. 172).

4. A mixture of water vapour and air is without action on iron at ordinary temperatures. This was demonstrated by Dunstan and his co-workers (Trans. Chem. Soc. 1905, 87, 1548), who further showed that if, under the above conditions, liquid water is allowed to condense on the surface of the metal corrosion proceeds rapidly

From the foregoing it is evident that the rusting of iron is not an example of direct aerial oxidation, but that the presence of both liquid water and air or oxygen is essential.

. *Theories of rusting.*—Now although all ordinary irons readily corrode when exposed to the combined action of distilled or natural waters and air, it is of considerable academic importance to inquire whether or not a pure specimen of iron will corrode when exposed to perfectly pure air and water. In 1888 Crum Brown (J. Iron Steel Inst. 1888, ii. 129) summarised briefly the most important facts then recorded on the corrosion of iron and supported, though he did not originate, the then current idea that the action is primarily the result of acid attack—the acid, in most cases of aerial oxidation, being carbonic. According to this theory the metal is first attacked by dissolved carbon dioxide (carbonic acid) giving ferrous carbonate, or bicarbonate, and hydrogen. The ferrous salt is then oxidised by atmospheric oxygen, and the basic ferric carbonate potentially formed is, in presence of water, converted into hydrated ferric oxide (rust). As the carbon dioxide is thus wholly eliminated at the end of the cycle, it may be supposed to renew its attack on the iron.

This theory received vigorous support from Moody, who proved by a very ingenious experiment (Proc. Chem. Soc. 1907, 23, 84) that rust is formed by the action of oxygen upon iron in solution and not by its action upon the metal itself. In other words, the rusting of iron is preceded by its solution. Moody further satisfied himself, as the result of a careful series of experiments (Trans. Chem. Soc. 1906, 89, 720), that water and oxygen alone are quite insufficient to induce rusting. In experiments where iron had remained bright for many weeks in contact with pure air and water, the introduction of a minute quantity of carbon dioxide at once determined rusting. The experiments of Friend (J. Iron and Steel Inst. 1908, ii. 16 ; Proc. Chem. Soc. 1910, 26, 179) led to the same conclusion.

On the other hand, Whitney, in 1903 (J. Amer. Chem. Soc. 25, 394), applying modern electrochemical theory to the process, expounded the diametrically opposite view that water and air alone suffice to establish rusting. According to modern views, the action of an acid on a metal is ascribed to an exchange of electric charges between the hydrogen ions of the acid and the electrically neutral atoms of the metal, the hydrogen being deposited on the metal in the molecular state, and the metal atoms passing into the solution as metal ions. Inasmuch as pure water is regarded as being to some small extent ionised into hydrogen ions and hydroxyl ions, it is to that extent, electrochemically speaking, an acid, and when iron is immersed in it, there should be a deposition of hydrogen on the iron and an equivalent formation of iron ions. The water round the iron now contains ferrous ions and hydroxyl ions, or in other words, is a dilute solution of ferrous hydroxide. If oxygen has access to the ferrous hydroxide solution, hydrated ferric oxide will be formed and deposited as rust.

Such in outline is Whitney's theory, apart from the detailed application of Nernst's theory of electrolytic solution pressure, which he also introduces. The explanation just given for the action of pure water on pure and physically homogeneous iron, involves the deposition of hydrogen as a film of gas on the immersed portion of the metal. As this film would prevent further contact between the metal and the water, it is supposed that it slowly dissolves in the water and escapes by diffusion, or is oxidised by the dissolved oxygen, so enabling the action to continue. This theory received considerable support from W. H. Walker and his co-workers (J. Amer. Chem. Soc. 1907, 29, 1251), who concluded that they had 'substantiated the work of Whitney, and shown that iron does dissolve in pure water in the absence of carbon dioxide and oxygen.'

Dunstan, Jowett, and Goulding (Trans. Chem. Soc. 1905, 87, 1548).

It may be added, in passing, that the names of Cushman (The Corrosion of Iron, Bulletin No. 30, U.S. Dept of Agric. 1907), Tilden (Trans. Chem. Soc. 1908, 93, 1358), and of Heyn and Bauer (Mitt. Königl. Material-prüfungsamt, 1908, 26), must be added to those who believe that iron will corrode in the presence of pure water and oxygen.

Nearly all the experiments just referred to were carried out with iron of ordinary commercial purity. This circumstance made it possible for supporters of the 'acid theory' to ascribe the rusting in absence of carbonic acid, to the presence of acidic substances generated from impurities in the iron itself. Lambert and Thomson (Trans. Chem. Soc. 1910, 97, 2426) found that carefully purified iron remained unchanged when exposed for several months to purified air and water. Any specimen of commercial iron, or of iron prepared with fewer precautions than the immune sample, rusted quite readily in the same circumstances. From their experiments, the authors concluded that whilst pure iron will not rust in pure air and pure water, iron will do so if it contains only a small amount of impurity, even if the impurity is neither acid in itself nor likely to give rise to acid.

From the foregoing it is evident that opinions widely differ as to the chemistry of corrosion. Academically, therefore, the problem still awaits solution. In actual commercial practice, however,

since neither water, air nor iron itself, is ever quite pure, it may be safely postulated that corrosion will result whenever these three are brought into contact.

The Mechanism of Corrosion.—Aitchison (J. Iron and Steel Inst., 1916, I., 77) has outlined an attractive theory according to which, in the case of a perfectly annealed specimen of pure iron, a difference of potential exists between the crystals of ferrite and the amorphous, inter-crystalline material, thereby leading to corrosion. Any potential difference between the crystal grains themselves, due to strain, in a less perfectly annealed specimen will add to this effect, the total corrosion being the sum of the two actions. In the case of iron containing carbide the main differences of potential will be between the carbide and ferrite, the latter functioning anodically and ₐoxidising away. The case of steels containing alloying metals is interesting. Potential difference exists between the carbide and solid solution, the latter acting as anode. If the alloying element is associated entirely with the carbides, as in the case of small quantities of W, V, and Mo, they do not decrease corrosion. Ni, on the other hand, enters the solid solution, reducing its solution pressure and hence the potential difference between it and the carbide, thus hindering corrosion.

The ferroxyl indicator The study of the susceptibility of iron to rust, and especially of the localisation of susceptibility, has been aided considerably by a device due to Cushman (l c, and J. Iron and Steel Inst. 1909, I. 33) and Walker (J. Amer. Chem. Soc. 1907, 29, 1257) The iron to be studied is fixed in a jelly made of agar-agar, in which small quantities of phenol-phthalein and potassium ferricyanide have been incorporated. Wherever the iron is being attacked, blue ferrous ferricyanide (Turnbull's blue) appears, whilst the second electrode in the circuit declares itself by the pink colour developed from the phenol-phthalein. The pink colour indicates the presence of hydroxyl ions.

The chemical nature of rust.—Rust is a pulverulent, hygroscopic mass, ranging in colour from brown to red, and consisting of iron oxidised more or less completely to hydrated ferric oxide. As a rule, the browner the rust the greater is the extent of hydration. Some ferrous oxide is generally present also, particularly if the original metal has not been completely oxidised away. This ferrous oxide has a blackish appearance and may be found in the innermost layers close to the metal (*see* analyses by Moody, Trans. Chem. Soc. 1906, 89, 726 ; Tilden, *ibid.* 1908, 93, 1358 ; Gaines, Chem. News, 1910, 101, 205 ; Steel, J. Soc. Chem. Ind. 1910, 29, 1141, &c.). Rust also contains free water in addition to that chemically combined with it, and it readily absorbs carbon dioxide from the air. These two properties serve to render it an active stimulator of corrosion, for the carbon dioxide dissolves in the moisture yielding carbonic acid. This attacks a portion of the iron converting it into ferrous carbonate, which in turn is oxidised by the air to rust. The liberated carbon dioxide is now free to attack further portions of iron in a similar manner.

Graphitisation is a form of corrosion to which cast iron is particularly liable, the mass becoming so soft as to be readily cut with a knife. The metallic iron is more or less completely oxidised, mainly to ferrous oxide. Frequently portions of this latter have been washed or dissolved away, the remainder collecting within the pores of the now isolated mass of graphite. Examples are afforded by Berzelius (Traité de Chimie, 1831, vol. iii.), Rennie (Min. Proc. Inst. Civil Eng. 1845, 4, 323), Draper (Chem. News, 1887, 56, 251), Le Naour (J. Iron Steel Inst. 1898, I. 526), Holgate (Gas World, 1913, 58, 479), and others. Of these Berzelius drew attention to the cast-iron cannon balls raised at Karlskrona from a ship that had been sunk fifty years previously. They had been converted into a soft, porous mass which spontaneously heated upon exposure to air. Rennie mentions the case of cast-iron guns reclaimed from the sea in 1822, off Holyhead, after an immersion of about 100 years. When brought out of the water they were quite soft, but upon exposure to the air, they hardened to such an extent that they were used to fire salutes when King George IV. passed through Holyhead on his way to Dublin. It was observed that these old guns gave louder reports than any others. As a rule, this kind of corrosion does not take place with the purer forms of commercial iron, although a few cases of similar softening are on record where wrought iron has been subjected to prolonged immersion in sea water (Lidy, Engineering News, 1897, 39, 85). The percentage of carbon in such cases is, of course, much less than with cast iron, but is frequently much higher than the normal in consequence of the solution and removal of some of the iron.

Influence of dissolved substances on rusting. The effect of dissolved salts in the water has received great attention in both the laboratory and industrial study of rusting.

As a general rule, a dissolved salt might be expected to stimulate corrosion by increasing the conductivity of the water. If the substance gives an acid solution this action will be all the more marked. On the other hand, concentrated salt solutions do not dissolve oxygen to the same extent as pure water, so that if the metal is completely immersed, retardation of rusting might be expected on this account. The above conclusions are borne out by the experimental work which has been done Acids and ammonium salts stimulate corrosion very considerably ; sodium chloride stimulates in dilute solutions and retards in concentrated solutions. Generally speaking, as the concentration is increased the corrosivity increases to a maximum (critical concentration), and then, unless interrupted by saturation of the solution, falls practically to zero (limiting concentration). The limiting concentration in certain cases is found to have an extremely low value, *e.g.* in alkaline solutions and in chromates and dichromates. Chromates and dichromates, and other oxidising agents are known to render iron passive, and Dunstan and Hill (*l.c.*) have shown that alkalis also produce passivity, so that the effects may all be due to this cause. In any case there is no doubt that above a small concentration, many substances, such as potassium and sodium carbonates, permanganates, iodates, chromates, and dichromates, borax, &c., will prevent rusting entirely. This property of

the chromates is beginning to find industrial application in the painting of iron work, and the protection of boilers. When more than one electrolyte is present in the water the effects are more complicated and it is found that the concentration of the inhibitor must usually be considerably greater than when it is present alone, if corrosion is to be prevented. An interesting special case is the behaviour of potassium dichromate in the presence of other salts. In such cases the dichromate being an acid salt reacts with the other salt to produce free acid, which destroys the passivity and allows rusting unless the dichromate is in large excess. For practical application as a rust preventive in such cases, potassium chromate which produces no acid is equally effective (Friend and Brown, J. Iron and Steel Inst. 1911, I. 125).

The temperature of a solution exerts an important influence upon its relative corrosivity. A 3 p.c. solution of sodium chloride at 10°C. is considerably more corrosive than tap water at the same temperature, but as the temperature rises the relative corrosivity falls, until at 21°C the solution is appreciably less corrosive than tap water. The behaviour of sea water, which contains approximately 3 p.c. of sodium chloride, is of practical interest to the engineer. At 11°C. it is considerably more corrosive than fresh water; at 13°C. the two waters act similarly; whilst at all higher temperatures sea water is less corrosive than tap water (Friend and Brown, Trans. Chem. Soc. 1911, 99, 1302). In the western part of the tropical Pacific Ocean a temperature of 32°C. is frequently attained; whilst in the Red Sea and Persian Gulf temperatures of 34·4°C. and 35·5°C. respectively have been recorded. Such waters, therefore, are much less corrosive than river waters at the same temperature. In the Arctic Ocean, on the other hand, the temperature often lies below 0°C., and such waters are much more corrosive than fresh waters. Between these two extremes all grades of temperature occur with corresponding fluctuations in the relative corrosivities.

It is a matter of common knowledge that alkalis, if present in sufficient quantity in solution, will completely inhibit corrosion. The merest traces of sodium or potassium hydroxide will suffice to do this provided the solution is protected from neutralisation by the carbon dioxide of the air. Upon exposure to the ordinary atmosphere, however, carbonates are produced, and these tend to stimulate corrosion at ordinary temperature unless the concentration of the alkali hydroxide is sufficiently great to yield at least the limiting concentration of alkali carbonate, namely, a 0·25 p.c. solution. An interesting case arises when iron is immersed in alkaline solutions containing dissolved inorganic salts. For example, iron will remain untarnished for an indefinite period in a 1 p.c. solution of potassium hydroxide. Upon addition of potassium chloride however, corrosion is readily induced. It is possible, however, to increase the concentration of the alkali to such an extent that corrosion is entirely inhibited, no matter what concentration of chloride be added. The minimum amount of alkali required to inhibit corrosion varies with the nature of the added salt, and rises with the concentration of the same

until saturation of the last-named is reached. It is important to note that when iron corrodes in alkaline solution, the rust invariably takes the form of pitting, being localised at various points on the surface of the metal. When scraped away its interior is found to be dark, consisting largely of ferrous oxide, and the metal is observed to be eaten out or corroded into a small pit. The original cause of this pitting is probably the presence of traces of superficial impurity; nevertheless, even the purest forms of commercial iron, such as Kahlbaum's electrolytic metal, readily pit in this manner. This is a point of considerable importance to boiler engineers, inasmuch as alkaline feed waters are liable to produce serious trouble. It is not difficult to imagine that a large iron boiler or tank might very well lose several pounds in weight through a uniform superficial corrosion, and not be seriously injured thereby. Yet the loss of only half an ounce, if localised in the form of a deep pit passing entirely through the metal, might be disastrous. The remedy in such cases appears to be in raising the concentration of the alkali until the inhibiting point is reached.

Various factors influencing corrosion.—It has already been indicated that the concentration of dissolved oxygen at the surface of the metal has a very important influence on the progress of rusting. Practical experience confirms this in many ways. Pipe lines conveying water have been known to fail mainly on account of the extreme aeration of the water. Bridge structures always rust most readily near the water level, particularly if the water is in slight motion (*see* Cobb, J. Iron Steel Inst. 1911, I. 170). Iron work which is deeply immersed in water or deeply buried, rusts much more slowly than that which is nearer to the atmosphere. The oxygen used up at the metal-water surface, is gradually replaced by diffusion from the air-water surface, and anything which prevents or decreases the rate of diffusion, such as reduction in the size of air-water surface, or covering it with a layer of material impermeable to oxygen, will delay rusting. The rate of flow of the water past the metal might be expected to have, an influence in this respect, and Heyn and Bauer (Mitt. Königl. Material-prufungsämt, 1910, 28, 93) have actually found that slight motion increases the rate of corrosion for both cast iron and steel, especially the former. With an increased rate of flow, however, the corrosion decreased again. At high temperatures, it is naturally found that the tendency to rust is greatly increased although, under many conditions, this may be compensated for by the diminution in the supply of oxygen caused by the lower solubility.

Influence of physical condition.—It is an experimental fact that two samples of iron may possess precisely the same chemical composition and yet exhibit a marked difference in their powers of resisting corrosive influences. This is attributable to variation in the physical properties of the metals. A series of interesting experiments was carried out by Andrews (Min. Proc. Inst. Civil Eng. 1894, 118, 356) on this point, with the object of determining the influence of tensile, torsional and flexional stresses, respectively, upon corrosion. In so far as the first of these, namely, the tensile stress, was

concerned, it was found that the strained portion was cathodic to the unstrained when both were connected in a cell containing sodium chloride solution; in other words, the strained portion resisted corrosion more successfully than the unstrained. On the other hand, Hambuechen (Bull. Univ. Wisconsin, Eng. Ser. 8, 1900), after a similar series of experiments, was led to an opposite conclusion. This apparent discrepancy is explained by the work of Richards and Behr (Pub. Carnegie Inst., Washington, 1906), which makes it clear that any difference of potential existing between strained and unstrained portions of metal is very small and is greatly influenced in direction by local circumstances. Burgess (Trans. Amer. Electrochem. Soc. 1908, 13, 17) found that iron deformed by stretching beyond the elastic limit corrodes more rapidly than unstrained portions, and this is supported by the work of Heyn and Bauer (J. Iron Steel Inst. 1909, 1. 109). As regards the influence of torsional and flexional stress, Andrews found the unstrained portions to be more susceptible to corrosion than the strained. Here again the extent of the strain and the local conditions will each exert due influence upon the result

In 1911 Hanemann drew attention to some interesting effects produced by heat treatment upon the resistance of steel to acid attack (Stahl und Eisen, 1911, 31, 1365). He showed that each steel, according to its carbon content, appears to have an optimum quenching temperature, at which a maximum tensile strength is obtained. His results further indicated the existence of a close connection between the tensile strength and solubility of the steel, the steel with the highest tensile strength exhibiting the greatest solubility in acid. From the foregoing it is evident that the physical condition of the metal exerts an important influence upon its corrodibility.

Influence of chemical composition.—The chemical composition of iron or steel has an important bearing upon its resistance to corrosion. This is most marked in the case of cast iron and steel, since these have a wider range of composition than wrought iron. The most usual effects of alloying elements may be summarised as follows (Friend, Paper read before Staffs. Iron and Steel Inst. Feb. 21, 1914).

1. Some elements, such as sulphur, exist in steels in the form of relatively oxidisable compounds. In manganiferous and cupriferous steels the sulphur is present mainly as the sulphides of copper and manganese. These readily undergo oxidation to sulphureous acids which stimulate corrosion.

2. Not a few elements combine with iron forming alloys or compounds highly resistant to corrosion. Such appears to be the case with phosphorus, nickel, chromium, and silicon.

3. The presence of one element may tend to alter the chemical or physical condition of a second element present in the iron or steel. For example, silicon tends to throw the carbon out of combination with the iron, and effect its separation in the form of graphite. This is a well-known reaction in blast furnace practice, and the consequence is that the corrodibility of the metal is not only influenced by the presence of the silicon *per se*, but also by the altered condition of the carbon.

4. Alloying elements tend to produce segregation or unequal distribution of the components of the metal during solidification. Serious differences of potential are thereby initiated and the liability to corrode is proportionately enhanced.

In addition to lack of homogeneity in the metal itself it must be remembered that contact with a less electro-positive metal, the presence of small quantities of mill scale (Fe_3O_4), or even of rust itself, will cause the iron to become the soluble electrode in a galvanic circuit and thereby hasten its corrosion. It is therefore always advisable to avoid making contacts with other metals, or even with other kinds of iron, at points where electrolytic action might take place. The fact that iron in constant use does not corrode so fast as when at rest has been ascribed to the fact that any oxides formed are quickly removed and do not remain to exercise a galvanic influence.

Influence of carbon and manganese.—Two of the most important alloying elements in steel are carbon and manganese, and the influence of these upon the corrodibility of the metal has been made the subject of considerable study. Hadfield and Friend (J Iron Steel Inst. 1916, l. 48) summarised their results as follows :

1. The addition of carbon from 0 03 to 1·63 p.c. to pure iron containing less than 0·2 p.c. of manganese, results in a steadily increasing rate of corrosion both in tap water and in sea water : an initial fall in corrosion with a rapid rise to a maximum with 1 05 p.c. carbon in alternate wet and dry ; and a rapid rise in corrosion to a maximum with 0 8 p c carbon when exposed to the action of dilute sulphuric acid.

2 The addition of 0·7 p.c. of manganese to the above steels results in a slightly increased corrosion in tap water, sea water, and in alternate wet and dry tests, with a carbon content of up to about 0·4 to 0·6 p c. With higher carbon contents the manganese generally affords a slight protection, which is very decided in the wet and dry tests. On the other hand, the presence of the manganese enormously increases the solubility of the steels of all carbon contents in dilute sulphuric acid. This is a point of great commercial importance since in ordinary steels the manganese content is very liable to fluctuate between 0·2 and 0·7 p.c. and it is very evident that the latter are unsuited for acid atmospheres or liquors. For example, in large towns considerable quantities of sulphur acids are found in the atmosphere, owing to the combustion of bituminous coal, which, containing a small percentage of iron pyrites, leads to the formation of sulphur dioxide, and this dissolving in rain rapidly oxidises to sulphuric acid, giving the rain water an acid reaction. It has been shown that in the industrial quarters of a large manufacturing town this acidity will sometimes represent as much as 90 lbs. of sulphuric acid per acre per annum, whilst in the residential quarters it will probably not be more than about 25 lbs. The sulphuric acid, however dilute, coming in contact with iron-work, accelerates the rusting, and by its corrosive action renders more difficult the protection of the metal.

For such districts steels of very low manganese content would appear to be most suitable.

3 By increasing the manganese content to

2 p.c. upwards the corrodibility of the steels is greatly decreased in neutral media, although in dilute sulphuric acid the solubility is greatly enhanced.

Numerous other researches on the influence of carbon, nickel, chromium, copper, &c., have been carried out by Breuil, Chappell, Aitchison, Buch Diegel, and others, but for accounts of these the reader is referred to the J. Iron Steel Inst.

Relative corrodibilities of wrought iron and steel.—The question as to which of the two metals, wrought iron or steel, is the more resistant to corrosion is one which has attracted much attention. The subject has been discussed by several investigators (see Trans. Faraday Soc. 1916, 11, part 2), who point out that the mean result of examining a large number of samples of wrought iron and of steel after exposure to corroding influences indicates that the two metals are practically equally resistant. Nevertheless wide divergences exist between the different irons and steels in individual cases. This is not necessarily due to any irregularities in the metals themselves, but rather is it attributable to the fact that no one metal can be expected to offer an equal resistance to all kinds of corrosive influences The problem thus becomes one of determining which variety of iron or of steel is the most suitable for any particular purpose. It is conceivable that certain makes of wrought iron will prove most useful in certain circumstances, whilst under other conditions it will prove better to employ steel. Field tests, which are urgently needed to throw light upon these obscure problems, are in progress.

Corrosion of cast iron —Comparatively little research work has been published on the corrosion of cast iron. In 1883 Gruner found that cleaned cast iron was less attacked by air and moisture than wrought iron or steel (Compt rend. 1883, 96, 195), but was more readily attacked by dilute acids. This latter observation was confirmed in 1915 by Friend and Marshall (J. Iron Steel Inst. 1915, I. 353), working with a mild steel and grey cast iron In neutral corroding media there was little to choose between the two metals. The same investigators found (*ibid.* 1913, I. 382) also that a variation in the percentage of silicon between the limits of 1 2 and 2·3 p.c. exerts no influence *per se* upon the corrodibility of the metal. The fact that in many cases cast iron objects appear to have a longer life than corresponding ones in wrought iron or steel is attributable to the protection afforded by the outer skin formed on the cast iron during casting This may also account for the greater resistance offered by cast-iron pipes to the destructive action of stray electric currents (Brown, Electrical Engineer, New York, 1898, 26, 441).

Acceleration tests.—In order to determine what particular variety of iron or steel will resist corrosion most effectively many attempts have been made to employ rapid chemical tests in the laboratory. One of the most usual of these consists in immersing different samples of the metal in dilute sulphuric acid for definite intervals of time and noting the losses in weight. Those specimens that dissolve most readily are regarded as most readily corrodible. It cannot be too strongly emphasised, however, that such tests are of no general value whatever. The only reliable method consists in experimenting with the samples of metal under precisely similar conditions to those to which the metal will be exposed in practice. This, it is true, is a slow process, but the results are sure.

Prevention of rust.—Where the use to which iron is to be put does not admit of any protective coating, it is obviously necessary to consider all the above questions, with a view to providing conditions which shall keep corrosion as slow as possible. The steel plates of a steam boiler, for instance, are subjected to very stringent conditions which often cause extensive pitting, so that special attention has to be given both to the metal of which the boiler is contained and to the feed water. An example is described by Huntley (J. Soc. Chem. Ind. 1909, 28, 339) of remarkable corrosion in a stand-by boiler which could not be prevented by adding alkalis to the water. Blisters were found near the water level of the boiler, filled with a liquid which contained ferrous sulphate and sulphuric acid. The production of the sulphuric acid was found to be due to the presence of manganese sulphide in the steel. The blister of rust had retained the sulphuric acid, and oxygen passed in to oxidise the sulphide more rapidly than sodium hydroxide to neutralise the resulting acid. In this case, a remedy was effected by the addition of sodium arsenite, which presumably acted as a reducing agent combining with the dissolved oxygen. There are various other devices for the removal of oxygen, such as passing the feed water over scrap iron in a closed box, or the addition of an alkaline solution of tannin, which in the boiler forms strongly reducing pyrogallate. The use of dichromates or chromates has already been referred to, although the practice has not yet been widely tested on the large scale. Other attempts to protect iron have been made by placing pieces of zinc in contact with the metal so that the iron would be protected at the expense of the zinc. This practice is not very economical, and usually the effect of the zinc is confined to its immediate locality. In certain circumstances, however, the method is of value. A method of preventing or retarding the corrosion of boilers consists in applying an external current so that the boiler shell is the cathode, an immersed piece of wrought iron the anode, and the boiler-water the electrolyte. A current of 1 to 2 amperes at 4 to 8 volts' pressure is said to show a satisfactory reduction in the extent of the attack on the plates (Harker and Macnamara, J. Soc. Chem. Ind. 1910, 22, 1286).

Where conditions permit it, and especially in the case of structural iron work, it is of course a matter of economy to give to exposed iron work a protective coating. The first essential is to provide a coating which shall be as impervious as possible to air and water. Further considerations arise, particularly with regard to the course of events at points where the coating has given way. For small articles a film of vaseline, black lead, or similar material which can be readily renewed is of great practical value. A coating of hot tar or pitch (Angus Smith) has also found wide application. Wire and articles of sheet metal may be protected by means of a coating of a less corrodible metal,

usually zinc or tin. Tin plate finds its widest application in the manufacture of vessels to contain foodstuffs, and other articles for which a long life is not desired. It is less suitable for severe conditions, since at any point where the iron has become exposed a couple is produced in which the more electro-positive iron acts as the soluble electrode and suffers rapid corrosion. It is therefore of importance that the tin should be as free from pinholes as possible, and the ferroxyl indicator applied in a thin layer to the surface of the metal is a very valuable indication of the extent to which they exist. Every pinhole is indicated by the development of a blue spot which shows that iron is passing into solution. In galvanised or zinc-coated iron the state of affairs is reversed. The zinc protects the iron first by its own resistance to corrosion, and then when the coating is broken, by the fact that the iron is protected at the expense of the more electro-positive zinc. There are several methods now in use for providing the zinc coating in the most suitable form. In the hot dip method the iron, after passing through a 'fluxing solution,' is dipped into molten zinc. The fluxing solution which has for its object the cleaning of the iron surface usually contains hydrochloric acid, and the traces of this which are carried over often have an undesirable effect in producing corrosion of the finished product. In addition to the care necessary to avoid this effect, it is very important to control the bath so that a sufficiently uniform and thick layer of zinc shall be produced on the iron. Other methods of depositing the zinc are by electrolysis and by exposure to the vapour of zinc (Sherardising), and it is claimed that both these methods produce a more resistant coating than the hot dip process. The uniformity of a zinc coating can be tested by dipping the metal in a hot concentrated solution of caustic soda (Walker, Proc. Amer. Soc., Testing Materials, 1909, 8, 430). Pure zinc, under such conditions, is practically unaffected, but in contact with iron, as it would be where there were cracks or pinholes in the coating, a current of hydrogen is produced from the iron. Tested in this way, hot galvanised iron was found by Walker to be relatively free from imperfections, but wet or electrolytically galvanised was frequently porous, indicating the necessity for careful supervision of the rate of deposition of the zinc so as to obtain the most adherent coating. A number of other protective devices, mostly patented, depend upon the production from the iron itself of a resistant surface layer. The best known of these is the Barff-Bower method of producing a fine closely adhering layer of magnetic oxide, by the action of steam on the heated metal. In this way a very uniform and durable coating can be obtained on articles which are not too large. When the metal does become exposed, however, the oxide forms with the metal a couple which results in stimulated corrosion of the iron. In the Tatlock process, the magnetic oxide is obtained by heating in a bath of fused sodium or potassium nitrate. The Coslett process, which is largely used in bicycle manufacture, depends on the production of an insoluble layer of phosphate by the regulated action of phosphoric acid. These and similar methods of protection are all fairly efficient for

the protection of smaller articles or sheets of iron under not too stringent conditions. But where, as is often the case with structural and massive ironwork, the water may contain much soluble foreign matter (often of an acid nature), the progress of corrosion must be carefully watched and checked. This involves the use of a protective coat which shall be renewable *in situ* and easily applied. For this reason, a considerable amount of attention is now being paid to the protection of iron work by paint.

Paints usually consist of an intimate mixture of pigment and liquid vehicle. As regards the latter it is essential that it should excel in chemical permanence, imperviousness towards air and moisture, electric insulation, chemical inertness towards iron, resistance towards physical damage, elasticity, and finally in its drying, hardening or setting power. The vehicle most commonly in use is linseed oil, which, upon exposure to air, absorbs oxygen, being transformed into a tough, elastic solid called linoxyn. This oxidation proceeds only slowly in the case of the raw oil as obtained by pressure from linseed, and in order to facilitate the setting, a substance termed a drier is usually added, which, by some means not thoroughly understood, assists the oil to combine with the atmospheric oxygen. To the same end linseed oil is frequently heated, either in the absence of air or whilst a current of air is blown through; a drier may or may not be added in this case, according to circumstances.

The absorption of oxygen by the oil is at first accompanied by a slight expansion, amounting in the case of pure raw Calcutta oil to about 3 p.c. at 15°C. (Friend, Trans. Chem. Soc. 1917, 111, 162). Hence when thick layers of paint are exposed to the air the outer layer becomes oxidised most rapidly and by expanding causes the familiar crinkled appearance. For this reason the painter prefers to apply his paint in thin layers, so that, upon drying, a smooth and uniform coat results.

If the oxidation of the oil stopped at the formation of the solid linoxyn the paint film would be very permanent. Unfortunately such is not the case. Further oxidation takes place, although very slowly, water, carbon dioxide, and other products being evolved, and accompanied by a simultaneous contraction and embrittling of the film. In course of time the contraction becomes so great that the film cracks and peels away. Such old films are a source of danger to ironwork, inasmuch as they not only fail to protect the metal, but actually stimulate corrosion (Walker and Lewis, J. Ind. Eng. Chem. 1909, I. 754). Hence when cracking of the paint film has once begun it is desirable to scrape off the old paint and apply an entirely fresh coating. All the drying oils are open to this objection, and attempts have been made to utilise other liquid vehicles, such as nitrated cellulose in amyl acetate, &c.

The heating of linseed oil, referred to above, induces a certain amount of polymerisation, reducing its permeability to moisture and generally increasing its protective power when used in paint for iron work. Light greatly accelerates the setting of the oil, but unfortunately it also accelerates its subsequent decomposition; for this reason, other things being equal, the

most permanent paints are those containing black or red pigments, since these absorb the shorter rays of light and prevent them from hastening the destructive oxidation of the linoxyn. As regards the pigments, they should be in a fine state of division in order to admit of thorough incorporation with the oil. They should also be insoluble in water, and chemically both permanent and inert. The last-named property is largely dependent upon the solubility and in the case of certain pigments, such as the chromes, a very slight solubility in moisture is not altogether a disadvantage, since the dissolved chromate tends to inhibit corrosion, as already mentioned. This was found experimentally to be the case in the Atlantic City tests carried out under the ægis of Committee U of the American Society for Testing Materials. These tests were begun in 1908 and for details the reader is referred to Cushman and Gardner, Corrosion and Preservation of Iron and Steel (New York, 1910), and Gardner, Paint Technology and Paints (New York, 1911); suffice it to say, however, that paint mixtures containing chromates yielded promising results.

It is dangerous, however, to use pigments that are markedly soluble in water, since when these have dissolved out of the paint film by repeated rainfalls, pores are left through which moisture and air readily pass to the metallic surface beneath, leading to serious corrosion.

The chief functions of a pigment consist in (1) offering a support to the linoxyn, thereby affording a harder and tougher film, proportionately more resistant to mechanical injury; (2) reducing the permeability of the paint film to air and moisture, since the pigmentary particles are themselves impervious to these (There are other functions, but for further details reference may be made to Friend, Iron and Steel Institute Carnegie Memoir, 1918.) In the case of aerial iron work, a thick coat of paint protects the underlying metal from attack more efficiently than a thin coat, provided the thick coat is not so heavily laid on as to cause crinkling or running. The best results are obtained by multiple coats, two thin coats being more efficient than one thick one of equal weight. The iron structures should be painted whilst the scale is still on after loosely adherent flakes and rust have been scraped off. In this case the paint will last rather longer than if applied to the pickled or sandblasted surface and the labour of removing the scale is saved. Rust need not be so carefully removed prior to painting as was formerly believed to be necessary.

A useful paint for structural iron work not exposed to sea-water consists of oil with red lead, Indian red and lamp black, the three pigments being in approximately equal proportions by weight.

Almost equally good as the red or white lead paints for protection is a bituminous paint made from pitch, the distillation of which has not been carried too far. This must be absolutely free from free carbon and tar acids or ammonium salts, and if applied hot to the structure to be protected, gives very good results, the colour being the main drawback.

There are many circumstances in which such a bituminous paint is preferable to an oil paint, as, for instance, in gas works, urinals, or slaughter houses, where there is much ammonia in the air, which has an extraordinarily destructive effect upon oil paints.

Corrosion of iron in concrete.—In view of the widespread use of concrete reinforced with iron or steel the question of the corrosion of the metal in these circumstances is fraught with unusual importance. Owing to the fact that iron, upon rusting, undergoes considerable expansion (Bauermann, J. Iron Steel Inst. 1888, II 135), it follows that should corrosion of the metal occur when it is embedded in concrete, a cracking of the latter becomes inevitable, more air and water enter, so that corrosion proceeds with an increased rapidity and the structure becomes proportionately weakened. If the concrete is well made and the whole is undisturbed by stray electric currents it would appear that ferro-concrete structures may last almost indefinitely. The ingredients of the concrete should not be too coarse, otherwise thorough mixing and good contact will hardly be possible. The mixture must be well punned into position in order to eliminate voids in so far as is possible. A sufficient thickness of concrete should be applied, since, if it is too thin, it may crack mechanically and thus admit air and water to the metal. Substances likely to contain acids or acid producing constituents should be avoided, such as, for example, coke breeze and slags, which frequently contain dangerous sulphur compounds (*see* Report of Science Standing Committee of Concrete Inst. Mar 9. 1911 Friend, Trans Concrete Inst. 1917 18, vol IX.).

Concrete may be advantageously coated with some waterproofing material to render it still more impervious, provided such proofing is entirely free from acid or acid producing substances. This course is specially to be recommended in the case of reinforced concrete structures exposed to the action of sea-water, since the salt exerts a deteriorating effect upon the concrete. For this reason Creighton points out that if beach gravel is used in making the concrete it should first be very thoroughly washed to remove the salt, and furthermore salt should not be added to the concrete during building in cold weather to prevent its freezing (J. Franklin Inst., Nov. 1917.)

Corrosion of Non-Ferrous Metals.—The corrosion of non-ferrous metals has not been made the subject of so much study as that of iron and steel, nevertheless a considerable amount of useful information has been accumulated. The rare or precious metals, such as platinum, iridium, and gold, are so resistant to oxidation or corrosion at ordinary temperatures that they may be said, for all practical purposes, not to corrode at all. Nickel and cobalt are also very resistant to corrosion, although less so than the foregoing metals. Silver tarnishes, particularly in contact with sulphur or sulphureous substances, and is readily pitted or corroded by chlorides such as common salt. Mercury or quicksilver likewise tarnishes upon exposure to air, but the layer of oxide tends to protect the underlying metal from attack, if the liquid is kept stationary. Pitting is, of course, an impossible phenomenon in the case of a liquid. This leaves us with the following commercial metals to consider, namely

aluminium, copper, lead, tin, and zinc, together with their alloys. Such metals as rhodium, ruthenium, &c., hardly concern us here, being rather of the nature of chemical curiosities than otherwise.

Aluminium.—The study of the corrosion of aluminium has acquired a considerably enhanced importance of late years owing to the ever-increasing use of this metal for air-craft, fittings of sea-going vessels, and for domestic culinary operations.

Aluminium tarnishes upon exposure to air, and the layer of oxide, adhering closely to the metal, affords good protection in temperate climes against further corrosion. In hot, tropical countries, where moisture is plentiful, the aluminium corrodes more rapidly, and the coating of oxide, although apparently continuous, may be minutely porous. Aluminium drinking vessels acquire a foul taste in such climates, probably owing to the absorptive properties of this porous oxide layer (Desch, Trans. Faraday Soc. 1916, 11, Part 2).

Aluminium is oxidised by prolonged contact with hot distilled water in the presence of air, the insoluble hydroxide being formed. Scala (Atti R. Accad. Lincei, 1913, 22, (1), 43, 95) concludes that this is mainly due to the presence of iron, which passes into pseudo solution in colloidal form as ferrous hydroxide and catalytically accelerates the oxidation of the aluminium.

The greater the purity of the metal, and the less its variation in homogeneity, the greater is the resistance of the metal towards corroding influences. Consequently annealed samples are more resistant than those which have not been so treated (Bailey, J. Inst. Metals, 1913, 9, 79). Organic acids, particularly when hot and in the presence of dissolved chlorides, act upon aluminium (Watson Smith, J. Soc. Chem. Ind 1904, 23, 475), whilst boiling with dilute sodium carbonate solution causes the formation of soluble sodium aluminate, from which the hydrated oxide of aluminium is precipitated on passage of carbon dioxide. Both pure and crude alcohol attack aluminium fairly readily, and are rendered turbid thereby (Karpinski, Z. Spiritus-industrie, 1912, 35, 660). Hydrogen peroxide in dilute solution readily effects the oxidation of the metal (Droste, Chem. Zeit. 1913, 37, 1317), as do also dilute solutions of ammonia, sodium hydroxide, and sodium carbonate respectively, in the cold (Hale and Foster, J. Soc. Chem. Ind. 1915, 34, 464).

Copper and its alloys.—Copper tarnishes upon exposure to moist air at ordinary temperatures, and the skin of oxide thus formed tends to protect the underlying metal from attack. Water alone does not appreciably affect copper, and the employment of this metal for kettles for boiling water for culinary purposes is quite safe. Copper differs from iron in that it does not decompose steam, even at red heat. Indeed, cupric oxide heated in steam is reduced to cuprous oxide. Nitric acid readily attacks copper, and the metal oxidises in contact with alkaline solutions. Dilute hydrochloric acid attacks copper in the cold more seriously than nitric or sulphuric acid under similar conditions (Hale and Foster). When embedded in damp concrete copper remains in excellent condition

(Gaines, J. Ind. Eng. Chem. 1913, 5, 766). Sulphur tarnishes copper, and organic acids gradually convert it into basic salts (*see* VERDIGRIS, &c.). Solutions of electrolytes such as sea-water, &c., also attack the metal. [See report of Corrosion Committee J. Inst. Metals, 1919, 21, 87.]

The corrosion of an alloy is usually a more complicated process than that of a single homogeneous element, since the different constituents in an alloy do not behave alike towards corroding media. Owing to the corrodibility of iron and steel various alloys of copper are used commercially on a large scale for special purposes, as, for example, in the manufacture of condenser tubes, millions of which are in use at any moment by the Admiralty. Consequently a study of the conditions under which corrosion takes place assumes a position of corresponding importance. During the last few years increased attention has been given to this subject, notably by the Institute of Metals, and for full details of the work carried out under their auspices, the reader is referred to Bengough's Reports to the Corrosion Committee, as published in the Journal of the Institute.

Much so-called corrosion of metal-work really consists of mechanical abrasion. For example, furnace gases carrying with them fine particles of solid material on passing through metal tubes tends to wear them away. This action is accentuated by the presence of chlorides or sulphur compounds, since these yield with the metal compounds less hard in character, and which are in consequence more easily abraded, or they may even give rise to volatile salts which readily disappear as vapour. This is a common source of trouble with copper and its alloys.

Brass is an alloy of copper and zinc, and the resistance offered by it to solutions of electrolytes has been studied by many investigators. The action of chlorides in particular has received attention, notably by Desch and White (J. Inst. Metals, 1913, 10, 305; 1914, 11, 235; J Soc. Chem. Ind. 1915, 34, 258), whose results may be briefly summarised as follows :¦ Corrosion of brass takes place mainly by dezincification, for although both copper and zinc are removed in solution, the proportion of the latter metal in solution and in the flocculent precipitate is much higher than in the alloy. Consequently a layer of metal is left, in which the percentage of zinc is much less than in the original alloy, and which has an open, spongy texture that readily yields to oxidation under the influence of air or dissolved oxygen. This explains the presence of the layer of cuprous oxide frequently observed on the corroded surface of brass tubes, and which is thus probably not of direct, but of secondary origin. The removal of zinc grains proceeds at first along the boundaries of crystal grains, and in such brasses as exhibit twinning (α-brasses) along the dividing planes between twin crystals.

The presence of iron in solid solution in brass accelerates the corrosion, but small quantities of lead up to 1 p.c. apparently do no serious harm (Brühl, J. Inst. Metals, 1911, 6, 302). With 2 p.c. lead a protective layer of basic salts is formed, which tends to retard further action (Desch).

2 o

An interesting example of corrosion is afforded by a condenser tube taken from a vessel on the Manchester Ship Canal, and described by Desch. The composition of the original metal was Cu, 72·72 ; Zn, 27·04 ; Fe, 0·15 ; and Pb, 0·09. Along the bottom of the tube the metal had been almost completely dezincified, and a transverse section showed that practically only spongy copper remained. At a somewhat higher level the spongy copper extended only partly through the metal, but the boundary between the copper and unaltered brass was perfectly clear.

Tin, as is well known, greatly enhances the resistance of brass to attack by sea-water, and for this reason bronzes are in considerable demand for marine work. The standard Admiralty alloy for condenser tubes contains Cu, 70 ; Zn, 29 ; Sn, 1 0. The protective influence of the tin appears to be largely mechanical, in that it forms in neutral or faintly alkaline solutions of electrolytes a tough adherent layer of basic salt, which can only be detached with difficulty.

The behaviour of bronzes towards acid solutions has been studied by Giohtti and Ceccarelli (Gazz. chim. ital. 1909, 39, ii. 557), who find that their susceptibility to acid attack is intimately associated with microscopical appearance.

When embedded in damp concrete (Games, J. Ind. Eng. Chem. 1913, 5, 766) both monel metal and manganese bronze appear to resist corrosion exceedingly well. Addition of phosphorus to bronzes increases their resistance to corrosion, and phosphor bronzes, which contain up to 1·75 p.c. of phosphorus, have proved very valuable in marine work

Alloys of copper and aluminium, such as those containing up to 10 p.c. of the latter metal, have also proved very resistant to sea-water and dilute alkalies, a property that is further enhanced by the addition of nickel (Read and Greave, J. Inst. Metals, 1914, 11, 169), although, curiously enough, the nickel, if it has any action at all, tends to increase the corrodibility of the alloys in tap water, dilute mineral acids, and vinegar.

Lead.—(1) Pure Lead. The corrosion of lead of exceptional purity has been investigated by Lambert and Cullis (Trans. Chem. Soc. 1915, 107, 210). The metal, having been prepared in a high state of purity by the method of Stas (Bull. Acad. roy. Belg. 1860, 10, 295), was finally distilled *in vacuô* in quartz tubes at a temperature approximating to 1200° C. Its behaviour towards air, water, and a mixture of oxygen and water was then investigated. It was observed that, if the metal was exposed to air only a short time after distillation, its surface was quickly tarnished in the cold, indicative of slight superficial oxidation. If the metal, however, was kept *in vacuô* for several months, subsequent exposure to air did not cause any appreciable decrease of lustre for several days.

Other samples of freshly distilled lead underwent rapid corrosion upon exposure to pure water and oxygen. In the case of totally submerged specimens, white crystals of lead hydroxide were formed, together with a brown deposit, probably consisting of hydrated plumbous oxide $Pb_4O,2H_2O$. When the metal was only partially immersed in the water a bright yellow oxide was formed within half an hour of the admission of oxygen. The colour gradually turned to a dull red, the change requiring many months for completion, being accelerated by exposure to sunlight.

A sample of lead kept in contact with water for 12 months *in vacuô* presented an undiminished lustre, and no evidence was obtained in other experiments indicative of the slightest solubility of the metal under such conditions. Admission of pure oxygen led to no visible corrosion or tarnishing for more than a week, and even after six months oxidation had proceeded to such a slight extent that the layer of oxide was sufficiently attenuated to display interference colours.

From the foregoing it is evident that pure, distilled lead behaves somewhat differently towards air or aerated water, according to its 'age,' the specimens that have been most recently distilled proving more susceptible to corrosion than those that have had time to age, although the actual mechanism of the corrosion appears to be the same in either case. Most probably this is due to a difference in the physical character of the metal, and it is in accordance with the behaviour of other substances to suppose that the most unstable form or forms will predominate in the freshly distilled metal, thus giving it a heterogeneous character which gradually settles down to a homogeneous condition of maximum stability.

(2) Commercial Lead. Although commercial lead is a remarkably pure metal for technical and trade purposes, it cannot be compared with the distilled product of Lambert and Cullis It is important, therefore, to study its behaviour towards such corroding agents as are commonly met with in practice. This is particularly necessary, since the subject is intimately associated with the national health owing to the extensive employment of leaden pipes for the conveyance of potable waters to private dwellings.

The results obtained by early investigators are somewhat conflicting in many of their details (*see* Summary by Heap, J. Soc. Chem. Ind. 1913, 32, 771, 811, 847), but the following facts may be regarded as well established. Although Lambert found that pure water exerts no appreciable solvent action upon pure distilled lead in finite time, it is generally agreed that distilled water, freed from air by boiling, readily dissolves commercial lead, and even refined lead. Clowes (Proc. Chem. Soc. 1902, 18, 46) found that a sample of very pure lead dissolved to the extent of 0·3 gram per million parts of water, and according to Traube-Mengarini and Scala (Mem. R. Accad. Lincei, 1911, 8, 576), the dissolved metal is suspended in the water in colloidal form. Admission of oxygen converts the colloidal metal into colloidal hydrated oxide, the particles of which slowly aggregate to give a crystalline deposit, the liquid becoming turbid. Oxygenated waters are thus very corrosive towards lead.

The question now arises as to the influence exerted by atmospheric carbon dioxide upon the foregoing reactions. Water containing dissolved carbon dioxide has but little action upon lead in the absence of oxygen, and the presence of carbon dioxide in oxygenated waters reduces

their corrosive action by effecting the precipita-
tion of an insoluble carbonate of lead which
protects the metal from further attack. Thus,
for example, Graham (J. Soc. Chem. Ind. 1851,
4, 400) found that pyrophoric lead, which is
simply the metal in a state of exceedingly fine
subdivision, rapidly renders aerated waters
poisonous if carbon dioxide is not present, in
consequence of the formation and solution of
lead hydroxide, which is soluble to the extent
of 1 part of PbO in 10,000 parts of water
(Pleissner, Chem. Zentr. 1907. 11, 1055). The
presence of 3 p.c. of carbon dioxide, however,
prevents the water from becoming poisonous
owing to the formation of relatively insoluble
lead carbonate, 1 part of which requires 4 million
parts of water to effect its complete solution.
Lead is readily attacked by dilute nitric acid
in the cold, much less rapidly by hydrochloric
acid, and still less by sulphuric acid under like
conditions (Hale and Foster, J. Soc. Chem.
Ind 1915, 34, 464).

Yorke, in 1834, had already observed that
dissolved salts exert an important influence
upon the solubility of lead in waters. Of these
the most powerful inhibitors are phosphates,
such as those of the alkali metals, small quan-
tities of which almost entirely prevent the solu-
tion of lead. This is due to the formation of a
protective layer of lead phosphate which dis-
solves in water to the extent of only 1 part in
7 million parts of water. Carbonates and bi-
carbonates are also very effective, and it has
proved a useful procedure to pass certain
moorland waters through beds of chalk or
limestone to reduce their corrosivity. This
does not, in all cases, entirely prevent the solu-
tion of lead, since a mere trace of carbonate is
not sufficient for the purpose, 4 parts of CaCO₃
or MgCO₃ per 100,000 of water being required
as a minimum. Nevertheless, the procedure is
highly beneficial (Thresh, The Examination of
Waters and Water Supplies, Churchill, 1913 ;
Liverseege and Knapp, British Association,
Birmingham, Section B, 1913). Birmingham
water, which comes chiefly from Wales, is
treated at its source with powdered chalk for
the same purpose.

The foregoing offers an explanation of the
fact that waters which are temporarily hard
do not attack lead ; in other words, the lead
does not pass into solution continuously, since
a coat of insoluble carbonate is formed on its
surface. Permanently hard waters, on the
other hand, frequently attack lead rather
vigorously. Sodium silicate diminishes the
corrosivity of water. Dissolved nitrates, par-
ticularly ammonium nitrate, attack lead vigor-
ously ; but sulphates, chlorides, and acetates, as
a rule, much less so. Calcium oxide and
alkalis generally have a marked action ; and
damp concrete may produce serious corrosion
(Gaines, J. Ind. Eng. Chem. 1913, 5, 766). Pure
rain water and melted snow resemble distilled
water in their activity, but rain waters collected
in localities where macadam roads are in common
use are laden with calcareous dust, which reduces
their activity (Heap). Hence the first rain
water from such a district, after a spell of fine
weather, may have a comparatively slight action
on lead, whilst that which falls after the air has
been washed may be expected to act more

vigorously. On the other hand, rain water
collected in the neighbourhood of manufacturing
cities, is charged with nitrates, haloid salts, and
sulphur compounds resulting from the com-
bustion of coal, and may or may not be very
corrosive according to circumstances

The influence of organic matter upon the
solubility of lead in water is obscure. It is
generally believed that waters derived from
moorland and peaty sources are particularly
corrosive, and this is usually attributed to the
presence of peat acids or of carbon dioxide
(Thresh). Experiments carried out by Heap,
on the other hand, suggest that such waters,
though variable in activity, are considerably
less active than pure rain or distilled water.
Indeed, both distilled and rain water exhibited
in his tests less action on lead after contact
with peat, even although their acidity was in
some cases increased thereby. Water contain-
ing certain forms of organic matter yield,
after prolonged contact with lead, a floccuent
precipitate containing the metal and organic
material. This tends to deposit on the lead
surface and to form a loosely attached protective
layer (Heap).

Rise in temperature in general increases the
solubility of lead in water.

When sheet lead is immersed in a slightly
acid solution of lead nitrate or acetate it gradually
disintegrates, becoming loose in structure, and
ultimately is converted into a spongy crystalline
mass, owing to the metal having dissolved and
separated out again (see Heller, Zeitsch. physikal.
Chem. 1915, 89, 761 ; Cohen and Heldermann,
ibid. 733 ; Creighton, J Amer. Chem. Soc.
1915, 37, 2064). This phenomenon is character-
istic both of the purest assay foil and of commer-
cial lead (Desch), and possibly indicates the
existence of stable and metastable allotropes
(Cohen), the latter of which dissolves and
recrystallises as the former. Such a hypothesis
is, at any rate, in harmony with the observa-
tions of Lambert, to which reference has already
been made.

Lead antiques in museums frequently undergo
a gradual disintegration, being converted into a
white powder consisting essentially of lead
carbonate. In such cases chlorides are always
present in the powder (Matignon, Compt. rend.
1912, 154, 1619). Lead that has been immersed
in sea-water and dried so that crystals of salt
remain attached to the metal undergoes pro-
gressive destruction, for which the following
cycle of reactions is suggested :

$$2NaCl + Pb + O + CO_2 \rightarrow Na_2CO_3 + PbCl_2$$
$$\rightarrow PbCO_3 + 2NaCl$$
The sodium chloride thus acts as a catalyser,
and is able to effect, in the presence of air and
carbon dioxide, the disintegration of indefinite
quantities of lead.

Tin.—Metallic tin remains bright and
untarnished for long periods, both in dry and
in moist air, at ordinary temperatures. In a
piece of tin from an aboriginal cemetery in
Florida, Keller (J. Amer. Chem. Soc. 1917, 39,
2354) noticed a number of cavities lined with
small shining crystals, both in the form of thin
plates and acicular in shape. These consisted
of basic chloride SnCl₂.SnO. Water is practi-
cally without action upon tin both in the absence

of, and in the presence of, air. Tin is also very resistant to the action of dilute sulphuric and vegetable acids, and is thus exceedingly useful for protecting iron or steel from corrosion in the manufacture of articles required for culinary purposes. Caustic soda attacks it, but sodium carbonate, and particularly ammonia, are much less corrosive (Hale and Foster). When alloyed with copper or its alloys it greatly enhances their resistance to corrosion (*see* Bronze, above), and it exerts a powerful protective influence in other alloys, such as type metal (Meyer and Schuster, Zeitsch. angew. Chem 1914, 27, 12).

Zinc.—Ordinary commercial zinc readily oxidises in air, and is rapidly attacked by acids. Minute quantities of arsenic, antimony, copper, and tin, particularly the first two elements, accelerate the corrosion of the metal.

Zinc is largely used in the manufacture of galvanised iron, and waters passing through galvanised iron pipes or stored in galvanised iron tanks usually give a reaction for zinc. As a rule, however, this is not in sufficient quantities to be toxic.

Boiling water attacks zinc (Watson Smith, J. Soc. Chem. Ind. 1904, 23, 475), the hydrated oxide of the metal separating out. It is attacked by boiling solutions of sodium chloride, as also by hot dilute solutions of alkalis, such as sodium carbonate, zinc hydroxide being produced. The hydroxide does not form a protective layer in these cases, but, being readily detached from the metal, exposes fresh surfaces to attack. Dilute solutions of sodium hydroxide or ammonia corrode zinc in the cold, but sodium carbonate acts less vigorously (Hale and Foster. See also Report of Corrosion Committee J. Inst. Metals. 1919, 21, 59)   J. N F.

CORROSION, PROTECTION OF METALS FROM. Of the metals in common use iron (including steel) is not only the most corrodible, but because of its extensive and varied applications under widely diverse conditions, its protection from corrosion constitutes by far the most important case for consideration With the other common structural metals and their alloys corrosion has in some special cases to be provided against, as in the corrosion of condenser tubes, but, in general, copper, tin, lead, and zinc seldom need this attention.

In order to protect the surfaces of iron and steel structures methods based on several distinct principles are employed.

1. Exclusion of the agents causing corrosion : air, moisture, or water in the case of submerged structures.

This may be accomplished by :—

(*a*) Coating with an impervious oil film, or asphalt, pitch, &c.

(*b*) The use of paints, varnishes, &c.

(*c*) Coating with another metal not easily attacked by the corrosive agents.

2. By forming a non-corrodible skin consisting of some compound of the metal on its surface, such as the magnetic oxide (Bower-Barff process), phosphide, or nitride.

3. By the use of a substance which greatly reduces ('inhibits') corrosion.

4. Placing the iron in an electro-negative condition to another metal, so that the former is protected at the expense of the latter, or making the surface to be protected the cathode

(negative) and furnishing a continuous current from an external source.

It will be seen that there is a wide choice of methods, but practical considerations limit their application. In the case of large structures, ships, bridges, tanks, &c., the large surface, the fixed character of such structures, and the necessity for renewal of the protecting coat, determine the use of some form of paint or varnish paint. Deposition of another metal is applicable to a variety of conditions of use, ranging from the ordinary galvanising for tanks, roofing, &c., to electro-deposition of nickel, as in the case of bicycle parts. For small articles generally, processes of inhibiting, oiling, and formation of a surface compound are alternatives.

Before any system of protection can be properly applied it is essential that the metal surface shall be properly cleaned from dirt, mineral oil, rust (the ordinary ferric oxide Fe_2O_3), and mill scale (the black magnetic oxide Fe_3O_4) Plates from the rolling mills generally show patches of this oxide. Although it is an excellent protection against rusting when thinly and evenly covering the metal, patches of mill scale may set up active corrosion locally by galvanic action. Further, patches of scale are generally covered with fine cracks through which corrosive agents may pass, and the patch may scale off, carrying any protective composition with it, so that it is essential that all scale shall be removed before coating.

Rust and scale may be removed by mechanical means, scraping, wire brushing, and sand blasting, the latter being very efficient. Commonly they are removed by pickling the plates in sulphuric acid, 25 p c. In this acid red rust dissolves, and mill scale is thrown off by penetration of the acid, hydrogen being generated and forcing the scale from the plate. Arsenic in the acid is regarded by many as injurious. The plates should then be washed with water jets under fair pressure (if the plates are immersed in still water a 'gummy' film forms), and then steeped in hot milk of lime to neutralise any acid remaining.

Temporary protection from rusting is commonly done by smearing small articles with vaseline or heavy oil. Several processes of similar nature, have been patented, the principle of which is immersion of the metal at temperatures up to a red heat in various oils, and withdrawing while still hot, also spraying of metal hot from the rolls with oil. A layer of slaked lime pasted on is said to be more efficient than smearing with oil, and one patent has been granted for a paste of slaked lime made with a volatile solvent, like naphtha.

Asphaltic and coal-tar pitch compositions have great value as preservatives of iron and steel. For many purposes the black colour is prohibitive, but for buried pipes, &c., no better preservative can be employed. In 1848 Dr. Angus Smith took out his well-known patent covering the use of pitch. The pipes were preferably first heated, dipped in linseed oil, then heated to 300° F., and dipped in hot pitch at the same temperature. He also mentions the use of linseed oil as an addition to the pitch to keep it of the right consistency, and give a tough elastic coating.

Undoubtedly the finest material for this method of protection is natural asphaltum or bitumen, to which enough heavy mineral oil has been added to give a tough and elastic film. Pitch from petroleum ('maltha') has much the same characters. The Sabin process consists in dipping in a hot coating mixture like the above, draining, and then heating for two hours in a vertical oven at 400° F. Steel water mains up to 5 feet diameter, and in sections weighing 5 tons, have been treated by this process in America, and the United States Navy adopted the process for copper fire mains and flush mains, which are rapidly acted upon by salt water. It has also been employed for the small steel tubing for electric conduits which require an elastic and tough coating.

Heavy coal tar is commonly employed for hot dipping of cast-iron pipes. In practice the process amounts to distillation of the more volatile portions of the tar from the hot pipe, leaving a pitch coating, so that success is largely dependent on the correct dipping temperature. The soft pitch obtainable from tar produced in the low temperature distillation of coal will undoubtedly prove one of the best commercial products in this country. Tar acids and ammonia compounds are both undesirable constituents of tar for this purpose, as both tend to increase corrosion.

The anti-corrosive or protective paints are widely applicable. They may be classified as :—

1. Linseed oil paints, containing some drier, and usually also a proportion of varnish.

2. True varnish paints (enamels) consisting mainly of resins and oil.

3. Varnishes made from a natural resin with a volatile solvent. Each of the above will carry pigment, of which a large proportion is usually iron oxide (Fe_3O_4).

4. Asphalts, or coal-tar pitch, with a certain amount of boiled linseed oil, dissolved in a volatile solvent, such as coal-tar naphtha or petroleum naphtha.

In general, whilst the linseed oil paints are cheaper and easy to apply, they are not so satisfactory as the varnish paints, in which the natural gum or resin reduces the porosity of the film. This has been particularly noticed in the case of coatings for plates submerged in water. Also the more elastic the kind of varnish the better the result. Class 3 constitutes an important class of protective compositions specially suited to ship use, where the slow drying ordinary type of varnish can seldom be employed owing to lack of time for drying. The volatile spirit rapidly evaporates, leaving the resin and oil binding the pigment.

Cushman and others, from the results on steel plates in water carrying various pigments in suspension, obtained a classification of these ingredients of paints into 'inhibitors,' 'indeterminates,' and 'stimulators.' (Proc. Amer. Soc. for Testing Materials, Vols. III. to VIII., 1903-1908.) The result is, in part, dependent on the purity of the pigment, but, broadly, zinc pigments, chrome green, Dutch process white lead, and some Prussian blues fall in the 'inhibitor' class; lamp black, other carbon blacks, precipitated barium sulphate (blanc fixe), ochre and bright red oxide, and some Prussian blues are 'stimulators.' Such a classification would appear to have little value if the pigment particles are thoroughly 'sealed' in the paint medium, but if through porosity, or absorption of water, electrical contact between the pigment particles and the iron is established, the activity of the pigments is probably of the order given; the results certainly suggest an advantage of a first coating with one of the inhibitor class.

The most perfect protection with paints is afforded by enamels (varnish paints or 'japans') which have been stoved on to the metal; a good example is seen in cycle frames, &c. The stoving treatment causes the resin and oil to flow into a perfect film, free from porosity, and to set with a fine hard surface. The one objection is the liability to chip with a blow. For under-water work stoved metal is said to show little advantage, and Sabin states that unbaked varnish paints are better.

Coating with another metal less liable to corrosion includes zinc galvanising and tin plating, both of which are carried out by hot dipping the thoroughly cleaned plate in the molten metal. For more special work electro-deposition of copper or nickel (usually on a first coating of copper), and of other metals is occasionally employed. Electro-deposition of zinc is also largely employed for certain classes of work, such as frames, &c., for ships.

These deposits afford a fair protection, but even with the best class of nickel plating, as applied to cycle parts, rusting under wet conditions is found to occur. Should the metal protecting film become broken, so exposing the iron beneath, in most cases this exposure leads to more rapid rusting, as the iron is electro-positive to the protecting metal, and galvanic action at its expense is set up. Zinc coatings are, however, free from this defect, and as long as a good surface of zinc is still in contact with the iron, it will be the former metal which is mainly attacked. Tin plate offers a complete contrast in this respect.

A special process for applying zinc is the sherardising process of Cowper Coles. The cleaned articles are packed in metal vessels with zinc dust, a mixture of finely divided zinc and zinc oxide, and heated for several hours at a temperature below the melting-point of zinc. This metal slowly penetrates the iron, and to a far greater depth than with hot galvanising ; a hard alloy is formed which is practically non-corrodible, and is capable of being polished.

Processes dependent upon the formation of a protective skin date from the old Bower-Barff process, where the heated iron was treated with steam, so that a film of the black oxide (Fe_3O_4) was formed. The good surface of 'Russian iron' is due to a similar film, and as long as the film remains intact, protection is excellent, but rusting is accelerated once the film is broken. A more recent process is that of Coslett, in which the iron is immersed in a dilute solution of phosphoric acid. Later the inclusion of a subsequent dipping in chromic acid was patented by Coslett. Richard and Adams have patented a process in which the article is immersed for from 2 to 20 minutes in a solution made by dissolving 1¼ lbs. of manganous carbonate in boiling phosphoric acid (60 fluid ounces of B.P. phosphoric acid to 87 fluid ounces of water).

Another process aims at the production of a

film of nitride of iron, the article being heated in a suitable gaseous mixture, such as ammonia, or treating the highly heated metal in a bath of salts which will yield gases capable of forming the nitride.

Protection by 'inhibiting' the corrosive action almost invariably involves dipping in dilute chromic acid.

One of the most successful methods of preventing corrosion, especially in the case of boilers and condensers, is that of Elliott Cumberland. The galvanic action leading to corrosion is overcome by inserting insulated iron anodes, these being connected to the positive pole of a small dynamo ; current always passes from the anode to the part to be protected, which forms the cathode. A difference of potential of 6–10 volts is usually employed. In the case of brass tube condensers 1 ampere per 500 square feet of surface is found to ensure complete protection. In the case of boilers it is found that the hydrogen set free at the cathode plates or tubes is very effective in preventing the formation of a hard scale.

Corrosion of Boilers.—A serious form of corrosion is to be found in the rusting and pitting of the plates and tubes of high-pressure boilers. Before the adoption of mineral lubricants, it was supposed that the decomposition of the lubricating oils by the superheated steam in the cylinders caused the corrosion owing to the fatty acids liberated, but the same effect has been found with hydrocarbon oils, so that the pitting is evidently not due to this cause.

There are several causes which lead to the corrosion found in boilers, amongst which are ordinary corrosion, set up by the carbon dioxide and oxygen which occur naturally in all water, and which act on the metal when the boiler is out of use. This form of corrosion can be prevented by filling the boiler quite full with boiled water rendered slightly alkaline with a little lime and closing air-tight whilst at rest. The most frequent cause of corrosion in land boilers is dissolved salts, or free acids and alkalis in the feed water, which become concentrated solutions by evaporation. Acid waters, notably those collected in peaty districts, are particularly injurious Nitrates and nitrites, chloride and nitrate of magnesia are salts most liable to cause corrosion. Complete analyses of the saline constituents of the water can alone determine the requisite treatment required to prevent corrosive action. Secondly, galvanic action, induced by the difference in potential between the rust formed by ordinary corrosion and the iron, and also by metallic impurities in the iron and specks of foreign metals deposited upon it. This action can be prevented to a great extent by the use of zinc blocks inside the boiler and in metallic connection with the iron of the plates, or by the Cumberland system already described. A third cause of corrosion is to be found in the solvent action of distilled water upon the metal of the boiler, the action getting less with increase in the quantity of salts in solution in the water. The fourth cause arises from high local temperatures, often not far below a dull red heat, and then iron decomposes water, forming black magnetic oxide of iron and liberating hydrogen :

$$4H_2O + 3Fe = Fe_3O_4 + 4H_2$$
Overheating is most likely to be due to deposits or incrustations, and in such cases is checked, or stopped, by the sole use of condensed water, or a properly softened natural water, for the feed.   J. S. S. B.

CORROSION AND FOULING OF STEEL AND IRON SHIPS. AND ITS PREVENTION. In the days of wooden ships the hull troubles that had to be guarded against were the attacks of wood-boring animals and the loss of speed due to the growth of weed and shell at and below the water line ; but with the launch of the first sea-going vessel built of iron, in 1822, comparatively simple problems became of great complexity, and at the present time the protection of our Navy and mercantile marine from corrosion and fouling is a question of the greatest importance, affecting, as it does, both the life and speed of the vessels.

Corrosion.—The troubles due to corrosion are by no means limited to the exterior plates of the ship, but also affect the interior of the structure, boilers, and condensers.

The corrosion of iron and steel is brought about by the actions which ultimately result in the conversion of the metal into oxides, and these being accelerated by galvanic actions, which it is almost impossible to eliminate in a huge metallic structure like the hull of a modern ship in the presence of sea water, makes prevention far more difficult than in the case of an iron building or bridge.

In sea water the process of corrosion is accelerated by the salts contained therein, as these aid the galvanic action set up in the metal by various means, such as impurities in the iron, the presence of mill scale on the plates, high temperature, or even the different stresses imparted to portions of the same plate, whilst in certain waters, such as the mouths of rivers on the west coast of Africa, or in harbours where the water contains much sewage, the sulphates are decomposed by various vegetable and animal organisms with evolution of sulphuretted hydrogen, which greatly increases the corrosion of the metal.

The examination of the condition of the bottom plates of vessels that have been at sea for long periods, shows. when the protective paints and compositions have been removed, that three distinct forms of rusting may be distinguished.

1. Rust patches, generally near the edges of the plates, consisting of small areas of fine rust, probably caused by moisture on the plate when the protective paint was on. These patches are never thick, and cause but little damage to the plates if all rust be removed before a new coating of paint is put on.

2. Rust nodules are a more localised form of corrosion which has attacked the metal where particles of mill scale have been left on the surface of the new plate, or where small particles of slag or foreign matter have been rolled into the plate during manufacture. These give slight pitting of the plate, but seldom to a serious extent.

3. Rust cones are an accentuated form of rust nodules, and are due to the most local form of galvanic action, caused by the presence of a speck of deposited copper, lead, or other foreign metal, or even a small particle of rust

or mill scale left on the surface of the iron, and covered by the compositions used as protectives and antifoulers. As soon as the sea water penetrates these, galvanic action is set up, water is decomposed, rust formed, and the escaping hydrogen pushes up the composition, forming a blister; the hydrogen escapes and water leaks in, the action becoming more and more rapid, and the blister gradually filling with the product of the action—rust. The blister bursts, but the cone of rust has by this time set fairly hard, and continues to grow from the base, the layers of rust being easily distinguished in a well-formed cone, and when the rust cone is detached, the pitting of the metal at the base of the cone is, as a rule, found to be of considerable depth.

Certain portions of a ship's hull are exposed to special risk of corrosion from galvanic action, owing to the bearings of the screw shaft and valves for the escape of waste water, bilge, &c , being made of alloys containing copper. In order to prevent this, zinc protectors, consisting of heavy masses of the metal, are placed round all openings where copper or copper alloys are present, and the zinc, being more electro-positive than the iron, places the iron in the electro-negative condition, so that whilst the iron escapes injury the zinc rapidly dissolves. The Cumberland process (*vide supra*) has been successfully employed in such cases, insulated iron anodes being fixed to the hull close to the part to which it is necessary to afford protection.

The general procedure for protecting the exterior of the bottoms of iron and steel ships from corrosion is to coat them with so-called anti-corrosive or protective paints and varnishes. In order that this should be successful, much depends upon the state of the hull at the time at which the protective is put on.

The bottom plates of the newly built vessel are thickly coated, as a rule, with mill scale or magnetic oxide of iron Fe_3O_4, which is formed on the surface of the plate during rolling, and which, if it remains perfectly intact, would be an excellent protective, as it forms, indeed, the basis of the Bower-Barff process for the protection of iron; but during the shearing and riveting of the plates this scale gets broken off and exists only in patches, which, if left upon the plate, would excite rapid local galvanic action, owing to the fact that this scale is strongly electro-negative to the iron, so that it would need only the exciting influence of the sea water to start the action.

In naval vessels, the plates are pickled in dilute sulphuric acid, as already described, until all the scale is removed. In the mercantile marine it is an ordinary practice to launch a vessel without any paint on the hull, leaving the active, but fairly even, rusting which ensues to remove the scale, the ship being scrubbed down and then protective compositions painted on when it is docked.

This method has the advantage of cheapness, and also of giving a very slightly roughened surface, to which the protective composition adheres firmly, and answers well with tramp steamers and other craft where speed is not an object of paramount importance; but with service vessels and liners, slight as the roughening is, it undoubtedly has an influence on the speed.

The hull of the vessel, being perfectly free from mill scale, and as free as it can possibly be got from the ordinary oxide, is then painted with the protective, but for this to prove effective, the hull must be absolutely dry, a condition which it is exceedingly difficult to obtain, as the big mass of iron is generally a few degrees in temperature below that of the moisture-laden air, and under these conditions a trace of moisture condenses on the surface, which is spoken of as 'sweating' of the metal, and this prevents the proper adhesion of the paint to the metallic surface, and also starts rusting under the paint.

Oil paints are the oldest form of protectives in use, and, when the plates are painted when hot and dry, amongst the best and most lasting ; but the drying of such paints, being dependent upon the slow oxidation of the boiled oil by air into a resin, requires that a considerable time must elapse between the painting of the ship and the coating becoming hard enough to allow of the anti-fouling composition being painted on over it, and as a rule so short a time is allowed for docking that this is a great drawback.

The old paints for this class of work used to consist of red or white lead mixed with boiled linseed oil, but it was shown by M. Jouvin that with the perishing of the vehicle the lead compounds were converted into chlorides and oxychlorides by the sea water, and these were then reduced by the action of the iron of the hull with formation of crystals of lead, which set up galvanic action and led to rapid corrosion.

Spirit varnish protectives came into use when it became necessary to cut down the time expended in docking, and they owe their rapid drying powers to the fact that, instead of waiting for oxidation to form a resinous mass, as in the drying of boiled oil, a resin is dissolved in a highly volatile solvent, being mixed with boiled linseed oil to give the necessary elasticity, and when this is painted on the hull of the vessel, the rapid evaporation of the solvent leaves the resin and oxidised oil binding the body colour together.

Shellac, rosin, kauri, and many other gums and resins are used, whilst the solvents may consist of light hydrocarbons, such as the various grades of solvent naphtha, alcohol, and even fusel oil, but in the Navy very low flash-point solvents have now been discarded owing to the danger in storage.

The drawbacks to the last two classes of protectives are that the solvents employed for dissolving resins and gums are mostly affected by water, with the result that if the plates are not dry, the resins are apt to be deposited in a pulverulent condition, whilst the cold produced by the rapid evaporation of the solvent tends to increase the amount of moisture deposited, which assists in the deterioration of the coating. Alcohol varnishes have, however, the great advantage that they are not so affected by moisture on the metal, or deposited moisture, since the spirit will absorb a moderate amount of water.

These varnishes also, even when dry, are not impervious to gases and liquids. Under a microscope the coating is seen to be full of minute pores, through which the sea water finds its

way to the iron beneath, and, when once corrosion has been started, the protective coating is gradually forced away from the surface of the iron, exposing more metal to be acted upon. The best results are secured by employing several coats of the varnish, and applying it only in weather favourable to the operation, plenty of time being given for the thorough hardening of the material before water comes in contact with it.

In most of the various paints red oxide of iron is used to give body and colour to the mixture, and, as it is the same colour as the rust that may form under it, it is very popular with the composition manufacturer, and, providing it be free from acid and soluble sulphates, is unobjectionable ; but perhaps a better material would be the mixture of finely divided zinc and zinc oxide, such as is obtained in the Belgian process of distilling zinc, as, even after the varnish had perished, the zinc would afford a further term of protection. After extensive trials the U.S Naval Authorities adopted an anti-corrosive paint of the following composition : gum shellac, 7·9 lbs ; turpentine, 0 6 gallon ; pine oil, 0 6 gallon ; alcohol, 7¼ gallons ; dry metallic zinc, 9½ lbs. , white zinc oxide, 28½ lbs. ; the above making 10 gallons.

The protection of the interior surface of the hold of a ship presents some special complexities, as it is exposed to the wear and tear of taking in and discharging cargo and one has to take into consideration such sources of trouble as the action of bilge water, the high temperature, and the presence of foreign bodies such as coal-dust and leakages from cargo There are three classes of protectives used for the interior portion of a ship :

Cements ;

Bituminous coatings ;

Paints.

Although cement is very largely used, yet there are certain drawbacks attached to it which render it by no means the ideal material It has a certain amount of porosity, so that any corrosive liquid penetrates it and acts on the iron beneath ; its rigidity causes it to come away from the metal on any strain being thrown on the latter, variations in temperature having the same effect, and where the coating has parted from the iron, corrosion will start and remain unseen until perhaps too late.

Bituminous coatings applied hot are far preferable to cement, but are rather more troublesome to put on.

Fouling of ships and its prevention. The question of the fouling of ships' bottoms is one that has existed from the earliest days, and was of even more importance formerly than it is at the present time, owing to the increase in dock accommodation allowing the more frequent cleaning and painting of the ships ; but even now in the case of war the loss in speed during blockading operations, owing to the fouling of the vessels, might prove an important factor in a struggle for supremacy.

Fouling consists of various marine growths, both animal and vegetable, which attach themselves to the bottom of the vessel, and by increasing the skin friction whilst the vessel is in motion, seriously reduce its speed.

The nature of these growths needs to be studied in properly equipped marine biological laboratories, as but little is at present known of the life-history of many of the organisms which are found on a ship's bottom. The main factors, however, are that it is only during the germ or spore period of their existence that they can attach themselves to the bottom of the vessel, and that although the full-grown results are found when the vessel is docked, these growths have taken place *in situ*.

The open ocean and the northern seas are comparatively free from these organisms, but directly inland seas or tropical waters are reached they increase to an enormous extent in variety and numbers, and some harbours, such as the port of Sourabaya, are noted for the fouling influence of their waters. Moreover, it is found that the period of the year exercises a very important influence upon the fouling nature of the water, the spring and early summer being the chief time for these growths to find a lodgment on the bottom of a vessel.

The more common growths are serpulæ, generally called coralline, barnacles, mussels, membranæ, and oysters, usually classified together under the name of ' shell,' whilst at or near the water line are found luxuriant growths of sea grass (*Enteromorpha compressa* and *Zostera marina*), and towards the bottom ribbon and other weeds, like the tufted weed or bugula, flourish

Fouling commences with the deposition of a slight slime on the side of the vessel, which is apparently of an albuminous nature, and contains the germs and spores of various marine growths, and is so slight as to escape notice.

The first visible sign of fouling on a ship is the appearance of green grass at the water line, and this, in bad waters, will begin to show after a few weeks, whilst the growth will spread downwards from the surface for 5 or 6 feet, but rarely extends below 10 feet, as the growth needs plenty of light and warmth.

It is the most widely distributed form of fouling, and appears in nearly all waters, and, once formed, the grass protects the germs of other growths, and so helps on the general fouling.

In northern waters fouling seldom goes beyond the ' grass,' but in warm climates, especially if long in port, ' shell ' soon begins to appear, unless a really good anti-fouling composition is employed for coating the vessel's bottom.

Ships trading to or stationed near the mouths of rivers often show curious results in the kind and extent of the fouling, the marine growths being often killed by the fresh water, but such vessels foul again very rapidly when once more going to sea, owing to slight deposits of mud and calcium carbonate from the river water.

With wooden ships the necessity of protection against the wood-boring teredo worm as well as fouling led to the adoption of copper sheathing, and when the metal used was of a fairly pure character, it was found to be thoroughly satisfactory, and not only to give complete protection to the vessel, but also to enable it to remain at sea for a very considerable period. The cost, however, was high, and attempts were made to prevent the excessive waste of the copper by using zinc protectors, as advocated by Sir Humphry Davy, but it was soon found

that with the prolongation of the life of the copper plates, fouling again became serious, whilst when later rolled sheets of alloys containing zinc, such as Muntz metal, were tried, the same trouble again appeared, and it has been clearly proved that the power a copper plate exercises in preventing fouling is inversely proportional to its power of resisting the action of the sea water.

The action of the copper in anti-fouling is that, in the first place, the salts in solution in the sea water act upon the copper with the formation of chlorides and oxychlorides, the former poisonous to all forms of marine life in the germ state, whilst the latter formed a coherent pellicle to which the growths attached themselves and which was torn off during the passage of the vessel through the water by the skin friction, thus enabling it to shed any form of growth that might have attached itself to the plate by a process of scaling.

It was found, however, that if the copper were not of the purest, coralline growths very soon attached themselves so firmly through the surface of the skin of copper compounds that it was difficult to remove, and gave points of adherence for fresh vegetable growths.

With the introduction of steel and iron ships, as was natural, attempts were made to utilise the same form of protection from fouling which had proved so satisfactory with wooden ships, and from time to time during the past efforts have been directed to sheathing iron ships with copper in the same way. It was soon found, however, that this sheathing set up such severe galvanic action with the hull of the vessel as to be impracticable, and although these attempts were abandoned at a very early period in the mercantile marine, the naval services of several countries have tried its use for service vessels, the generally adopted method being to sheathe the iron hull with wood and to attach to this the copper in such a way as to be insulated from the electro-positive iron, but if water penetrated the insulation was broken down. The alternative of saturating dry wood with paraffin wax has been suggested.

With increase in dock accommodation, the tendency has been more and more towards the use of anti-fouling paints or compositions, which could be painted on over the protective coating of the vessel, and a number of compositions have been placed on the market with varying success for this purpose.

When anti-fouling paints were first manufactured, the only fact at the service of the maker was the experience which had been gleaned from copper sheathing, and on the assumption that the action had been due to the poisonous character of the chloride and oxychloride of copper produced on the plates by the salts in the sea water, compositions were made containing large quantities of corrosive metallic poisons, which, held in a varnish of a more or less lasting character, gave the protection from fouling for a few months

As has already been pointed out, the action of the copper sheathing was due to two causes : first, the poisonous action of the copper salts on the germ life ; and, secondly, the stripping of the pellicle by skin friction when any quantity of growth had formed on its surface, an action

termed 'exfoliation.' How important this latter action was may be judged from the fact that when the vessel remained at anchor in a harbour, the sheathing would last from 10 to 12 years, whilst when on active service the same sheathing would last for only 4 or 5.

Finding that poisons alone gave very unsatisfactory results, the manufacturers of anti-fouling compositions began to make perishable varnishes and grease paints, which should, by the deterioration and wasting of their surface, imitate as nearly as possible the exfoliation of the copper sheathing, and such anti-foulers gave under certain circumstances much more successful results. The idea was that the ship, having been coated with a protective paint or composition to preserve the iron, a second or more coatings was put on over the protective, consisting of varnish paints which should slowly yield soluble poisons to the sea water, and in doing so would lead to the disintegration of the varnish surface, which, being washed off, exposed fresh quantities of the poisons to the water.

Such compositions proved very satisfactory in the mercantile marine, and all the time that a vessel was actively engaged in going from port to port gave excellent results, but directly these same compositions, which had gained a reputation in the merchant service, were tried on Service vessels, they were found to be as unsatisfactory as those which before had been in use. The reason for this failure is evident. Take the case of a liner trading between New York and England : she is run at a high speed between these two ports for the main portion of her life, remaining in the basin for as short a period as possible in order to utilise to the full her money-earning capacity ; for such work it is easy to arrange an anti-fouling composition, which, with the aid of the skin friction of the vessel, would cause just sufficient wasting of the coating to give the best results. When, however, this is applied to a Service vessel, she probably goes out from dock into the basin and remains there stationary for perhaps months, and then goes to sea, where she is kept manœuvring at various rates of speed for a considerable period. During the period she is in the basin, the composition undergoes practically no wasting, and a thin film of carbonate of lime and mud deposits on the surface, which forms an excellent foothold for any germs and spores that may be in the water, and which, on going to sea, have often advanced too far for the growth to be readily got rid of.

The bad results so obtained led to a composition being put on which wasted with sufficient rapidity to prevent any such deposition in harbour, with the result that when the vessel went to sea, the deterioration being accelerated to an enormous extent by skin friction, the composition was practically all exhausted in a very short time.

The most efficient anti-fouling compositions all contain copper or mercury as the poison. In some cases soluble salts of these metals are employed with a fairly strong and lasting varnish ; in others oxides or insoluble salts are used with varnishes which perish more rapidly on their surfaces and allow the action of the

sea water to convert the compounds into soluble salts.

It is evident that with compositions containing such metallic compounds every attention must be paid to the protection of the hull, as otherwise the formation of soluble salts of copper and mercury might result in the deposition on the iron of these metals by reduction, in which case rapid galvanic action would be set up, and would lead to serious pitting of the plates of the vessel.

The compositions of the present day may be divided into two classes :

1. Grease paints containing a metallic poison ;
2. Quick-drying varnish paints, also charged with the same poisonous constituents.

The former class has met with a considerable degree of success, but they have also several very serious drawbacks As regards the prevention of fouling, they give results not very far-removed from the best varnish paints, and in certain waters, such as the Mediterranean, have proved themselves to be excellent antifoulers, but they undoubtedly increase the skin friction of the vessel, and so tend to diminish speed ; whilst a second trouble is that, although a varnish paint may often be scrubbed and touched up where fouling has been but slight, with a grease paint the whole has to be removed before recoating, and they are much more costly than the varnish paints, with the result that in the merchant service they are used only to a very limited extent. Another drawback to their use is that it is impossible to properly scrape and recoat the vessel during the short period of docking which would suffice for a varnish paint.

In the manufacture of varnish paints it is necessary to mix with the solution of gum or resin in a volatile solvent a sufficient proportion of linseed oil to give elasticity to the vehicle, and these paints have been in use in England since about 1870, the greatest advance in them being due to the introduction of the hot process in their manufacture, which enables a more intimate mixture to be made with greater adhesive power and a smoother surface.

The rate at which disintegration of these paints takes place is governed largely by the kind of gum used in the varnish, and by the amount of mineral matter introduced as colouring and poisonous material, the solubility of these having a considerable influence on the rate of disintegration.

With a tough and tenacious vehicle, which by itself would undergo but little disintegration under the action of sea water, it is quite possible to use soluble mercury or copper salts, which are liberated only very slowly during the gradual destruction of the varnish. On the other hand, if a rosin varnish be employed, insoluble bodies, like the oxides of copper and mercury, the subchloride of mercury, or Scheele's green (copper arsenite), may be used, the oxides and other salts, when exposed to the sea water, being very slowly converted into soluble chlorides.

Many compositions contain arsenic and arsenic compounds, such as sodium arsenite, as these had been found effective as weed killers under ordinary conditions, and it was expected that in a composition they would prevent the growth of grass at the water line, which, as it caught the eye, gave the impression of the ship being very foul. Experience showed, however, that the arsenic had but little effect, and mercury and copper still remain pre-eminently the metallic poisons of the greatest value in anti-foulers. H. Williams, Naval Constructor, U.S. Navy, has given the following composition for a paint adopted with great success for naval vessels : grain alcohol, 6 gallons ; gum shellac, 13¼ lbs. ; turpentine, 1 gallon ; pine-tar oil, 1 gallon ; white zinc oxide, 13¾ lbs. ; Indian red, 13¼ lbs. ; red oxide of mercury, 4¼ lbs. It was found that the cost of this paint was only one-third of the price charged for the proprietary paints.

In some anti-fouling varnish paints the poisonous metals themselves have been carried in a very fine state of division, some paints containing very finely divided copper, precipitated from the solution of a copper salt by iron or zinc , whilst others contain metallic mercury in a comminuted condition, obtained by adding stannous chloride to the solution of a mercurous salt ; these paints, however, show but little advantage over those containing salts of the metals.

One of the most difficult portions of the ship to deal with is what is known as the ' boot top,' that is, the portion between the heavy and light load line, as when a ship is discharging cargo the anti-fouling composition over this portion is exposed to the sun and rapidly perishes and peels off, whilst when the ship is again loaded, it is once more immersed, and the alternate action of sunshine and air and sea water perishes the paint at the very spot where it is most likely to be abraded by contact with lighters and barges, the result being that it is often necessary to touch up this portion of the vessel with paint during the voyage, and as good anti-fouling paints are rarely carried for this purpose, this portion of the ship is often painted with ordinary paint, and hence is liable to more damage than other parts of the vessel.

V. B. L.

CORROSIVE SUBLIMATE (*Mercuric chloride*) *v.* MERCURY.

CORUBIN *v.* ABRASIVES.

CORUNDUM. (*Corundon*, Fr. ; *Korund*, Ger. ; from the Sanskrit name *korund*.) Crystallised alumina (Al_2O_3). The crystals belong to the rhombohedral system, and are isomorphous with hæmatite (Fe_2O_3). They vary considerably in habit, having the form of hexagonal prisms, pyramids, or tables. In some crystals the combination of six faces of the primary rhombohedron with two faces of the basal plane produces a form strikingly similar to the regular octahedron. There is no true cleavage, but often the crystals and crystalline masses show a pseudo-cleavage or parting parallel to the basal plane or to one or more faces of the primary rhombohedron, due to lamellar twinning on these planes. On these surfaces the lustre is sometimes pearly, but otherwise it is usually vitreous, or inclining to adamantine in character. The fracture is uneven to conchoidal ; and the sharp jagged edges of the irregular grains give effect to the cutting power of the material when used as an abrading agent. Analyses show the presence of 95-99 p.c. of alumina, with small

amounts of ferric oxide, magnesia, silica, water, &c., and sometimes traces of chromium. Sp.gr. 3·9–4·1. The crystals are optically uniaxial and negative; refractive indices for sodium light $\omega=1·7690$, $\epsilon=1·7598$. The dichroism is marked. Next to diamond, it is the hardest of minerals, being placed as No. 9 in the scale of hardness; on this account it was formerly known as adamantine spar.

A distinction is made between the transparent 'precious corundum' and the dull, opaque 'common corundum,' while a third still less pure variety is known as emery (q.v.). This division also corresponds with the economic uses of the mineral, 'precious corundum' being used for gem-stones, and 'common corundum' and emery for abrasive purposes. The pure, well-crystallised material is perfectly colourless and transparent with a high degree of brilliancy. Traces of inorganic impurities, however, produce a wide range of colours, which are more vivid in the stones of gem-quality, namely red (ruby), orange and yellow ('oriental topaz'), green ('oriental emerald'), blue and indigo (sapphire), and violet ('oriental amethyst'). Parti-coloured stones are not uncommon. The colour of common corundum is usually grey or brown.

Corundum is not a widely distributed mineral, but it is found in abundance at certain localities. It occurs in igneous and metamorphic rocks, such as granite, syenite, gneiss, peridotite, and serpentine, and in crystalline limestones. Material of gem-quality is usually collected as water-worn pebbles in gravels derived from these rocks. Material for gem-stones and for abrasive purposes is not, as a rule, mined in the same localities. Taking first the localities for the gem-varieties, the following may be noted as a few of the most important. The best rubies are obtained from the famous mines near Mogok in Upper Burma, where they occur in a white crystalline marble near its contact with gneiss; they are mined in this rock and also in its products of decomposition. Dark-coloured rubies are obtained with sapphire from alluvial deposits in the provinces of Chantabun and Krat in Siam. Stones of good quality have also been mined together with common corundum in Macon Co., North Carolina. The best sapphires come from the gem-gravels of Ceylon; other localities of importance are Siam and Kashmir. Dark-blue and greenish-blue sapphires occur abundantly in gravels near Anakie in Queensland; while paler stones of various shades ('fancy stones') are plentiful in the neighbourhood of Helena in Montana.

Common corundum as used for abrasive purposes (apart from emery, q.v.) was formerly mainly mined in the United States; later the Canadian deposits came into prominence; while now the latter are being ousted by the artificial products carborundum and alundum. India has also since remote times produced a certain amount which has been largely used by the native lapidaries. In the United States the corundum deposits extend along the Appalachian Range from Alabama to Massachusetts, reaching their greatest development in North Carolina and Georgia. Here they occur in peridotites near their contact with gneiss. In Canada a belt of corundum-bearing syenites

(nepheline and related alkaline syenites), associated with the Laurentian gneisses, extends for 100 miles across Renfrew, Hastings, and Haliburton counties in Ontario, the principal mining district being near Craigmont in Renfrew Co. Large rough crystals of corundum are abundant in gneiss in Madagascar and at Steinkopf in Namaqualand, South Africa. More recently, important deposits have been discovered and worked in the Zoutpansberg and Pietersburg districts in northern Transvaal.

The corundum-bearing rock as mined is crushed between hardened steel rolls and the heavier corundum separated in water by means of jigs and concentrating tables. It is sifted into different grades of fineness and used (1) as loose grains; (2) mixed with glue or other soft cement as a coating on paper or cloth; and (3) as corundum-wheels for grinding. The last named are of three classes: (a) The 'vitrified wheel,' in which the corundum is mixed with clay and baked at a high temperature, with the result that the grains of corundum are set in a matrix of porcelain. (b) The 'chemical wheel,' in which sodium silicate is the binding material. (c) The 'cement wheel' with shellac, rubber, linseed-oil, &c., or magnesium oxychloride. Another use for corundum, depending on its hardness, is for the pivot supports for watches (watch-jewels) and other delicate instruments, the poorer qualities of gem-material being used for this purpose. Although corundum is the richest ore of aluminium, there are difficulties in its use for the extraction of the metal. It has, however, been used directly in the preparation of aluminium-copper and aluminium-iron alloys.

The artificial preparation of crystallised corundum was first effected by M. A. Gaudin, in 1837, by decomposing potash-alum with charcoal. It has since then been produced by a variety of methods, and is now manufactured on a large scale both for use as gem-stones and for abrasive purposes. Beautiful crystals of ruby were prepared by E. Frémy and Feil, in 1877, by heating a mixture of alumina and red-lead with potassium dichromate in a porous fireclay crucible; a fusible aluminate of lead was thereby formed, which was decomposed by the silica of the crucible with the separation of crystallised alumina. The crystals so obtained, though of some size, good colour, and perfectly transparent, were unfortunately too thin for cutting as gems. A far greater measure of success was achieved by A. Verneuil in 1902, who has produced fine gems of all colours (v. GEMS, ARTIFICIAL). Interesting experiments from a petrological point of view were conducted by J. Morozewicz in 1898, in which he obtained crystallised corundum in silicate magmas supersaturated with alumina. Artificial corundum, used as an abrasive under the trade name of alundum (aloxite, adamite), is now manufactured on a large scale at Niagara Falls by fusing bauxite in an electric furnace. 'Corubin' is also an artificial corundum, formed as a by-product in the Goldschmidt thermite process.

CORYBULINE, CORYCAVINE v. CORYDA-LINE.

CORYDALINE AND THE CORYDALIS ALKALOIDS. These alkaloids occur in the roots of the *Corydalis tuberosa* (DC) (syn *C cava, C. bulbosa, Bulbocapnos cavus*), belonging to the Fumariaceæ, and also in some other species of this genus (*C. ambigua, C. vernyi, C nobilis*). Corydaline was discovered by Wacken-roder, in the year 1826 ; and forty years later Wicke (Annalen, 1866, 137, 274) described the alkaloid more fully, assigning to it the formula $C_{18}H_{19}O_4N$. An investigation by Adermann (Inaug. Dissert., Dorpat, 1890) indicated that *C. cava* contained three or four different alka-loids, and the formula $C_{20}H_{23}O_4N$ was attributed to the one which is now regarded as corydaline

This base was more completely examined by Dobbie and Lauder (Chem. Soc. Trans. 1892, 61, 244, 605), and Josephi (Annalen, 1893, 277, 1), who respectively ascribed to it the formula $C_{22}H_{24}O_4N$ and $C_{22}H_{27}O_4N$, the latter being probably the more correct formula. About the same time Freund and Josephi isolated three other alkaloids from *C. cava* roots, namely *bulbocapnine, corycavine*, and *corybulbine* ; whilst Dobbie and Lauder described a fifth, *corytuberine* (l c 1893, 63, 485).

Several other corydalis alkaloids have since been isolated, the chief of which are *dehydro-corydaline, isocorybulbine, corycavamine, cory-cavidine,* and *corydine*. Gadamer, Ziegenbein, and Wagner have classified the principal alka-loids into the following three groups :—

	Corydaline	$C_{22}H_{27}O_4N$
(1)	Dehydrocorydaline	$C_{22}H_{23}O_4N$
	Corybulbine	$C_{21}H_{25}O_4N$
	*iso*Corybulbine	$C_{21}H_{25}O_4N$
	Corycavine	$C_{23}H_{25}O_6N$
(2)	Corycavamine	$C_{21}H_{21}O_5N$
	Corycavidine	$C_{22}H_{25}O_5N$
	Bulbocapnine	$C_{19}H_{19}O_4N$
(3)	Corytuberine	$C_{19}H_{21}O_4N$
	Corydine	$C_{20}H_{23}O_4N$
	*iso*Corydine	$C_{20}H_{23}O_4N$

The alkaloids in the first group are of weakly basic character, those in the third are strong bases, and the members of the second group are intermediate in this respect. All are oxidised by iodine, the first group yielding berberine-like compounds, except in the case of dehydro-corydaline, which is, itself, already such a com-pound. The third group will contain phenolic hydroxyl, and are therefore dissolved by alkalis.

Protopine and two other alkaloids, one of which has the formula $C_{20}H_{17}O_4N$, and is isomeric with berberine, have been found in

Chinese corydalis tubers (*C. ambigua*), as well as the first three members of Group 1 (Makoshi, Arch. Pharm. 1908, 246, 381). Five more alkaloids, including *glaucine*, have been obtained from parts of *C. tuberosa* by Haars and by Gadamer (Arch. Pharm. 1905, 243, 154 ; and 1911, 249, 224).

To separate the chief corydalis alkaloids Gadamer, Ziegenbein, and Wagner extract the ground root with alcohol, distil off the solvent, dilute and acidify the residue with acetic acid. After filtering, the acid filtrate is purified by extraction with ether, then made ammoniacal, and the alkaloids extracted by means of ether. From the ethereal solution, after most of the solvent has been distilled off, a mixture of corydaline, bulbocapnine, corycavine, and cory-bulbine is deposited ; these are separated, in the order given, by successive extractions with boiling alcohol. More corydaline is obtained from the mother liquor on further concentration. The residue evaporated to dryness is converted into hydrobromides and fractionally precipi-tated with ammonia, this treatment giving more corydaline, and also corybulbine, *iso*corybulbine, corycavamine, corycavine, corydine, and bulbo-capnine, in the order named. Corytuberine remains in the ammoniacal solution, and is obtained by extraction with chloroform after evaporating the solution to a syrupy consistency. To purify the crude corydaline it is converted into the hydrochloride and precipitated, together with some corycavine, from an aqueous solution by addition of alkali ; any bulbocapnine present remains in solution, and can be recovered by passing carbon dioxide into the alkaline liquid. The corydaline and corycavine may then be separated by repeated crystallisation from absolute alcohol ; corydaline, being the more soluble of the two, accumulates in the later fractions.

Corydalis roots have been used in pharmacy, and are credited with antiperiodic properties. The alkaloids have a narcotic effect, but are not employed in medicine. The members of the three groups above-mentioned are closely related in physiological action as well as chemical constitution. According to Peters (Arch. expt. Path. Pharm. 1904, 51, 130) and Gadamer (Arch. Pharm. 1905, 243, 147), the alkaloids of the corydaline group produce paralysis of the spinal cord, and those of the corycavine group stimulate the motor centres ; whilst the members of the bulbocapnine group give rise to increased reflex action. All except corytuberine induce in frogs narcosis like that due to morphine, and have a prejudicial effect upon the action of the heart. It has been suggested that bulbocapnine may be useful as a narcotic in veterinary prac-tice, in the case of animals on which morphine has a stimulating effect.

Group 1. *Corydaline* $C_{22}H_{27}O_4N$ crystallises from alcohol in hexagonal prisms, m.p. 134·5°, $[\alpha]_D^{20} +317°$ in chloroform or $+310°$ in alcohol. It dissolves easily in ether, chloroform, carbon disulphide, benzene, or warm alcohol, but is sparingly soluble in cold alcohol, and insoluble in water or alkalis. Corydaline and its solutions are quickly coloured yellow by the action of light or heat. It gives well-crystallised salts. The *aurichloride* ($B·HCl)_2AuCl_3$ crystallises from

dilute alcoholic hydrochloric acid as orange-coloured needles, m.p. 207° ; the *platinichloride* (B·HCl)$_2$PtCl$_4$ forms brown crystals, m.p. 227° ; the *hydrochloride* B·HCl,2H$_2$O, columnar crystals, m.p. 206°–207° ; and the *ethyl sulphate* B·C$_2$H$_5$HSO$_4$H$_2$O, large colourless prisms, m.p. 152·5°.

On oxidation with iodine in alcohol corydaline yields *dehydrocorydaline*, which occurs with it in *Corydalis tuberosa* (Schmidt, Arch. Pharm. 1908, 246, 575). Four methoxyl groups are present in corydaline, and the base contains a tertiary nitrogen atom, since it reacts with methyl iodide to form corydaline methiodide B·CH$_3$I. Oxidised with permanganate, it gives eventually hemipinic and *meta*-hemipinic acids, showing the presence of two benzene nuclei in the molecule At the same time, another oxidation product, *corydaldine* C$_{11}$H$_{13}$O$_3$N, is formed ; and from the constitution of this the presence of an *iso*quinoline nucleus in the original alkaloid is inferred.

On oxidation of corydaline with dilute nitric acid instead of permanganate, dehydrocorydaline is first produced. One of the benzene nuclei is next destroyed, and a yellow dibasic acid, *corydic acid* C$_{16}$H$_{17}$O$_6$N + $\frac{1}{2}$H$_2$O, is formed When corydic acid is in turn oxidised with permanganate, it yields first an insoluble, colourless, tribasic acid C$_{17}$H$_{15}$O$_8$N, *corydilic acid*, and eventually *meta*hemipinic acid, and a methyl pyridine tricarboxylic acid, which latter on further oxidation is converted into pyridine-2 : 3 : 4 : 6-tetracarboxylic acid C$_9$H$_5$O$_8$N. The position of the methyl group in the tricarboxylic acid is thus indicated ; and from this and the foregoing results the following constitutional formulæ for corydaline and dehydrocorydaline are deduced (Dobbie and Lauder, Chem. Soc. Trans 1892, 61, 605 ; 1894, 65, 57 ; 1897, 71, 657 ; 1899, 75, 670 ; and 1902, 81, 145) :—

Corydaline.   Dehydrocorydaline.
This formulation indicates the close relationship shown by these alkaloids with tetrahydroberberine and berberine respectively. The former differs from corydaline only in having a dioxymethylene group substituted for the two methoxyl groups in ring 4, and a hydrogen atom for the methyl group in ring 2. Between the absorption spectra of corydaline and tetrahydroberberine there is also a very close relation ; in fact, the only difference is that the general absorption shown by tetrahydroberberine is slightly greater than that of corydaline (Chem. Soc. Trans. 1903, 83, 598).

By reduction of dehydrocorydaline two optically inactive corydalines are produced, *r*-corydaline, m.p. 135°, and *r*-mesocorydaline, m.p. 158°–159°, the two compounds being stereoisomeric. The former is obtained when an aqueous solution of dehydrocorydaline hydro-chloride is treated with platinised zinc and dilute sulphuric acid at the temperature of the water-bath. Its sulphonic acid can readily be resolved by means of brucine into the corresponding *l*- and *d*-salts. *r*-Mesocorydaline is obtained together with its isomeride under milder conditions of reduction, by keeping an alcoholic solution of dehydrocorydaline hydrochloride with zinc-dust and sulphuric acid at the ordinary temperature until it is decolourised. The separation of the two bases is easily effected by crystallisation from ether, the *r*-mesocorydaline alone separating (Gadamer and Klee, Arch. Pharm. 1916, 254, 295). By means of the camphorsulphonate it can be resolved into active components, but neither the *l*-form nor the *d*-form is identical with natural corydaline.

Dehydrocorydaline C$_{22}$H$_{23}$O$_4$N occurs in the roots of *C. tuberosa*, *C. ambigua*, *C. solida*, and *C. vernyi*. From corydaline it is produced by the action of mild oxidising agents, such as dilute nitric acid. It is a yellow crystalline powder, m.p. 112°–113° (deomp.), and gives crystalline salts ; the aurichloride B·HAuCl$_4$ forms red-brown needles, m.p. 219°. It gives a crystalline oxime, m p. 165° : and, like berberine, unites with one molecule of chloroform, yielding a colourless crystalline compound, m.p. 154°. Haars ascribes the formula C$_{22}$H$_{25}$O$_5$N to dehydrocorydaline, and regards the alkaloid as having a keto-structure when in the free state, but as being a quaternary base when in solution (Arch Pharm. 1905, 243, 165).

Corybulbine was first separated by Freund and Josephi (*l c.*) from commercial corydaline, and more fully investigated by Dobbie and Lauder, who assigned to it the formula C$_{21}$H$_{25}$O$_4$N (Chem. Soc. Trans. 1894, 65, 25). It is soluble in boiling alcohol, from which it separates, on cooling, as a fine crystalline powder, m.p. 238°–240°. It is practically insoluble in water, sparingly soluble in ether and in methyl alcohol, readily in carbon disulphide, chloroform, and hot benzene. The solution in chloroform is dextrorotatory, $[a]_D^{20} + 303\cdot3°$. Corybulbine gives well-crystallised salts ; the *hydrochloride* B·HCl forms yellowish prisms, m.p. 245°–250°. On oxidation with iodine in alcohol corybulbine gives *dehydrocorybulbine* C$_{21}$H$_{21}$O$_4$N, m.p. 210°–211°, and on treatment with hydriodic acid furnishes 3 molecules of methyl iodide. On methylation with methyl iodide in the presence of potassium hydroxide, it yields corydaline, so that it differs from the latter only in containing an —OH group in place of an —OMe group, probably in the *iso*quinoline nucleus (Dobbie, Lauder, and Paliatseas, Chem. Soc. Trans. 1901, 79, 87).

iso-*Corybulbine* C$_{21}$H$_{25}$O$_4$N, first obtained by Gadamer, Ziegenbein, and Wagner, and subsequently examined by Bruns (Arch. Pharm. 1902, 240, 19), crystallises from alcohol in voluminous leaflets, m.p. 179°–180°, $[a]_D + 299\cdot8°$ in chloroform, and, on oxidation with iodine in alcohol yields *dehydroisocorybulbine*

$$C_{21}H_{21}O_4N$$

The latter resembles dehydrocorydaline and dehydrocorybulbine, and its hydriodide reduced with zinc and sulphuric acid gives *i*-iso*corybulbine*, m.p. 165°–167°. Three methoxyl groups

are present in *isocorybulbine* (*cf.* Bruns, *idem.* 1903, 241, 634).

Group 2. *Corycavine* $C_{23}H_{23}O_4N$ was first obtained by Freund and Josephi (Annalen, 1893, 277, 15). It is insoluble in water and in alkalis, sparingly soluble in cold, but more readily in hot absolute alcohol, from which it crystallises in rhombic tablets, m.p. 218°-219°; the alkaloid is optically inactive. The *hydrochloride* $B·HCl,H_2O$ forms broad needles, m p 219°; the *hydriodide* $B·HI,H_2O$ has m.p 236°; and the *aurichloride* $B·HAuCl_4$ has m p. 178°-179° (decomp). With methyl iodide it reacts as a tertiary base, the methiodide produced forming rhombic tablets, m p. 218°. Corycavine contains a dioxymethylene group, but no —OH or —OMe group (Ziegenbein, Arch. Pharm. 1896, 234, 523; and Gaebel, *idem.* 1910, 248, 207).

Corycavamine $C_{21}H_{21}O_4N$, like corycavine, contains no methoxyl group, but probably a dioxymethylene group. It is a crystalline base, forming rhombic columns, m.p. 149°, and has $[a]_D^{20}+166·6°$ in chloroform; but on heating at 180°, or by warming with acetic anhydride, it may be converted into an optically inactive modification, m p. 213°-214°, resembling cryptopine (Gadamer, Ziegenbein, and Wagner, Arch. Pharm. 1902, 240, 81)

Corycavidine $C_{22}H_{25}O_5N$ has been described by Gadamer (*idem* 1911, 249, 30). The mixed amorphous alkaloids of *C. cava* on conversion into thiocyanates can be separated into two groups, one giving crystalline thiocyanates, soluble with difficulty in alcohol, the other readily soluble, and amorphous From the second group corycavidine was isolated It is crystalline, and has m.p. 212°-213°, $[a]_D^{20}+203·1°$ in chloroform. It appears to be corycavamine, in which a dioxymethylene group is replaced by two methyoxyl groups. Like corycavamine, it is converted on heating into the optically inactive form, m.p 193°-195° after recrystallisation ; the change occurs at 209°. Corycavidine crystallises from hot chloroform with 1CHCl₃ on addition of alcohol. It forms a crystalline hydrochloride and nitrate. The aurichloride $BHAuCl_4$ is a red powder, which sinters at 85° and melts at 170° (decomp.).

Group 3. *Bulbocapmine* $C_{19}H_{19}O_4N$ was obtained by Freund and Josephi from the roots of *Corydalis cava* (Annalen, 1893, 277, 10). It separates from hot absolute alcohol in rhombic needles, m.p. 199°, $[a]_D+237·1°$ in chloroform, and yields crystalline salts. The *hydrochloride* $B·HCl$ forms needles, m.p. about 270°; the *hydrobromide* $B·HBr$ has m.p. 250°-270°; the *hydriodide* $B·HI$, m.p. 230°-270°; and the *platinichloride*, m p. 200°-230° (decomp.). The *methiodide* $B·CH_3I$ forms shining needles, m.p. 257°.

Bulbocapnine is insoluble in water, but dissolves in alkalis, and is precipitated from its solutions in these by addition of carbon dioxide or ammonium chloride. Its four oxygen atoms are accounted for by the presence of a methoxyl, a hydroxyl, and a dioxymethylene group (Gadamer and Kuntze, Arch. Pharm. 1911, 249, 503, 598). Further, ' exhaustive methylation ' gives rise to 3 : 4-dimethoxy-5 : 6-dioxy-methylene-8-vinyl-phenanthrene, which brings

bulbocapnine into close relationship with apo-morphine. The same authors have investigated the other members of this group, and assign the following formulæ to the four alkaloids concerned (*ibid.* 641) :—

Bulbocapnine.

Corytuberine.

Corydine.
iso-Corydine.

Corytuberine $C_{19}H_{21}O_4N,5H_2O$ was obtained by Dobbie and Lauder from commercial cory-daline by extraction with hot water (Chem. Soc. Trans. 1893, 63, 485) It crystallises from alcohol in fine, silky needles, m.p. 240°, $[a]_D^{20}+282·6°$ in alcohol. The alkaloid is nearly insoluble in cold water, ether, or chloroform, slightly soluble in benzene, and dissolves readily in hot water or in solutions of alkalis. It forms crystalline salts, including a methiodide. Two methoxyl and two hydroxyl groups are present. On methylation with methyl sulphate or diazo-methane a mixture of two isomeric monomethyl ethers is obtained ; these correspond with corydine and *iso*corydine The dimethyl ether of corytuberine is glaucine. Corytuberine in alkaline solution is readily oxidised by air, giving a dark green liquid Its physiological action is very similar to that of apomorphine ; and as with bulbocapnine and corydine, the characteristic emetic effect disappears when the two hydroxyl groups are methylated (Gadamer, Arch. Pharm. 1902, 240, 81 ;, and 1911, 249, 503, 641).

Corydine $C_{20}H_{23}O_4N$ was first described by Merck, and later by Gadamer and his collaborators (*idem.* 1902, 240, 81 ; 1911, 249, 669). It crystallises from alcohol with ½EtOH, m.p 124°-125°, or 149° dry ; $[a]_D^{20}+204·3°$ in chloroform. Three methoxyl groups and one hydroxyl group are present in the alkaloid. Oxidised with iodine, it yields the hydriodide of dehydro-corydine $C_{20}H_{19}O_4N·HI$, which, on reduction, gives *i*-corydine, m.p. 165°-167°. From this *l* corydine is obtained by recrystallisation of the *d*-tartrate. As shown above, corydine is a monomethyl ether of corytuberine.

iso*Corydine* $C_{20}H_{23}O_4N$ is obtained, as already shown, by methylating corytuberine. It crystallises in tablets, m.p. 185°, and has $[a]_D^{20}+195·3°$ in chloroform. Its *methiodide* has m.p. 213°-214°, and $[a]_D^{20}+143·3°$.

COSMOS REDS *v.* AZO- COLOURING MATTERS.

COTARNINE *v.* OPIUM.

COTO BARK. True coto bark is obtained from Bolivia, the Amazons (Brazil), and Venezuela. It has been considered identical with Winter's bark [from *Drimys Winteri* (Forst.)], but its source is really unknown (Jobst and Hesse, Annalen, 282, 191). It comes into the market in long strips about 8 cm. broad and 12 mm. thick, and is tough and hard. The colour is cinnamon brown, and a cross section shows numerous yellow spots. It has an aromatic odour, and contains *cotoin*, *dicotoin*, *hydrocotoin* and *methyl-hydrocotoin*, resins, tannin, &c. The supply of the true coto bark is limited, so inferior barks, chiefly *para-coto bark*, are sold. These contain little or no cotoin, but instead *protocotoin* and *methyl-protocotoin*.

Cotoïn or *Benzoyl-phloroglucinol-mono-methyl ether* $C_{14}H_{12}O_4$, is found, together with various

OH

OH
related substances, in true coto bark, but not in para coto bark, and has been the subject of much investigation by Ciamician and Silber (Ber. 24, 299 and 2977; 25, 1119, 26, 777; 27, 409 and 841; 28, 1549), Jobst (N Repert Pharm. 1876, xxv. 23; Ber. 11, 1031), Jobst and Hesse (Ber 10, 249; Annalen, 199, 17), and Hesse (Ber. 26, 2790; 27, 1182; Annalen, 282, 191). As a result its constitution has been made clear and a number of its derivatives described.

Cotoïn can be isolated from true coto bark by extracting the powdered bark with cold ether, distilling off the ether from the extract, and mixing the residue, whilst still hot, with light petroleum, whereupon a resinous-oily mass separates, from which the solution of cotoïn can be decanted and the product obtained from it in the form of large yellow crystals. A further quantity can be obtained from the resinous mass mentioned above by boiling it with lime-water, and treating the solution obtained with hydrochloric acid, when the cotoïn is precipitated. Cotoïn may be recrystallised from alcohol, or hot water, when it separates in yellow prisms, melting-point 130°-131°C. It is difficultly soluble in cold water, readily soluble in hot, is fairly soluble in alcohol, ether, and chloroform, but sparingly soluble in light petroleum or benzene. It dissolves in alkalis forming yellow solutions from which it is reprecipitated on acidification. As decomposition products of cotoïn, phloroglucinol as also benzoic acid have been obtained.

Cotoïn has been used pharmaceutically in cases of diarrhœa and of phthisis.

The *diacetyl derivative* $C_{18}H_{16}O_6$, produced by the action of acetic anhydride, or acetic anhydride and sodium acetate, on cotoïn, consists of large prisms, melting-point 94° C. If sodium acetate is used in the acetylation, the diacetyl derivative is accompanied by the

acetyl derivative of *methoxy-hydroxy-phenyl-coumarin acetate*, melting-point 142°C.—
Benzoyl cotoïn, obtained by the action of benzoyl chloride on cotoïn, crystallises in prisms, melting-point 110°-112°C.

Dibenzoyl-cotoïn consists of needles, melting-point 134°-135°C.

Dimethyl-cotoïn, obtained by the action of methyl iodide and alkali on cotoïn, crystallises from alcohol, and has melting-point 138° C. It yields a mono-acetyl derivative, colourless needles, melting-point 150° C., hence the formula

$$HO\cdot C_6H\cdot Me(OMe)_2\cdot CO\cdot C_6H_5$$
has been proposed for it by Ciamician and Silber.

Dibromcotoïn $C_{14}H_{10}O_4Br_2$, which crystallises in large colourless needles, melting-point 116° C., is prepared by the action of bromine on cotoïn in chloroform solution.

Cotoïn oxime $C_{14}H_{13}NO_4$ crystallises in plates, soluble in alcohol, difficultly soluble in water, and has been prepared by the action of hydroxylamine hydrochloride on a cold aqueous solution of cotoïn in sodium carbonate.

Mono-nitroso-cotoïn consists of dark red leaflets, or orange-yellow needles (from acetic acid), melting-point 153°-154° C (both forms). The needle variety possibly contains acetic acid of crystallisation (Pollak, Monatsh. 1901, 22, 996).

A dilute solution of cotoïn in sodium carbonate is capable of coupling with diazonium compounds, and in this way Perkin and Martin (Chem. Soc. Trans. 1897, 1149) have prepared the following derivatives :—

Cotoïn-azo-benzene $C_{14}H_{11}O_4\cdot C_6H_5N_2$ crystallises from acetic acid in orange-yellow needles, melting-point 183°-184° C. ; it yields a *diacetyl* derivative, $C_{14}H_9O_4\cdot(C_2H_3O)_2\cdot C_6H_5N_2$, when treated with acetic anhydride and sodium acetate, scarlet needles, melting-point 155°-156° C. ; on treatment with hot alkalis the acetyl compound is hydrolysed with formation of the free azo compound.

Cotoïn-azo-o-toluene, similarly prepared from diazotised *o*-toluidine and cotoïn, orange-yellow needles, melting-point 203°-204°C.

Cotoïn-azo-p-toluene consists of orange-yellow needles, melting-point 207°-208°C.

Hydro-cotoïn, which occurs together with cotoïn, is a *dimethyl ether of trihydroxy-benzoyl-benzene*, $C_6H_5\cdot CO\cdot C_6H_2(OH)(OMe)_2$.

A number of poly-hydroxy benzophenone derivatives, including products found in coto bark and related to cotoïn, have been prepared by W. H. Perkin and Robinson (Proc. Chem. Soc., 1906, 305).   A. G. P.

COTTON consists of the long hairs which cover the seeds of various species of *Gossypium*, a genus of the nat. ord. *Malvaceæ.* The botanical classification of cotton is in a confused state, and this is doubtless mainly due to the cultivation of the plant for extensive periods, the large

interchange of seed which has taken place between the different countries of production, and the consequent gradual modification of the distinctive characters of the original species.

American cottons.—The ordinary Upland cotton is fairly generally considered to be derived from *Gossypium hirsutum* (Linn.). Some authorities, however, are of opinion that it is derived from *G. herbaceum* (Linn.), whilst others regard these two species as identical. Sea Island cotton has usually been regarded as *G. barbadense*, but is considered by Watt (Wild and Cultivated Cotton Plants of the World) to be a hybrid form.

Egyptian cottons.—The Egyptian cottons probably cannot be referred to any particular species, but are mostly hybrid forms of *G. barbadense* with other species. Most commonly, Egyptian cottons are regarded as *G. barbadense*, but Watt places them under *G. peruvianum* (Cav.), which some authorities consider as identical with the former

Indian cottons —With reference to these varieties, G. A. Gammie, of the College of Science, Poona, writes, in his monograph on The Indian Cottons : ' It is clearly evident that we have at the most only one true species of cotton in India, *Gossypium obtusifolium*, with its two sub-species, *G. arboreum* and *G. herbaceum* All other forms should be treated as derivatives of these.' Other botanists, however, regard the Indian cottons as derived from various distinct species, including *G. herbaceum, G. neglectum, G. Wightianum,* and *G. arboreum.*

Brazilian and Peruvian cottons – Brazilian cotton is generally considered to be the product of *G. brasiliense* (Macf.), and rough Peruvian cotton that of *G. peruvianum* (Cav)

The cotton plant grows as a shrub or small tree. It is of perennial habit, but, in cultivation, is usually treated as an annual. In certain districts of Brazil and Peru, however, arborescent forms are grown, which are allowed to remain in the ground for several years. When the flower-bud first opens, the petals are generally white or pale yellow, but they gradually become darker and redder until the third or fourth day, and then fall to the ground. The young fruit remains attached to the flower-stalk and enveloped in the calyx ; it gradually increases in size, and is known as the ' boll.' When the boll is ripe, it dehisces by from three to five valves, exposing the cotton, which, now that the pressure on it is released, rapidly expands and forms a large fluffy mass. As soon as the boll has opened completely, and is quite dry, the cotton is ready to be gathered. The seeds, with the cotton fibre adhering to them, form the product known as ' seed cotton ' ; this is collected from the ripe bolls, and the cotton (or ' lint '), after being torn from the seeds by the process of ' ginning,' constitutes the raw cotton of commerce. Seed cotton usually consists of about one-third of its weight of cotton fibre and two-thirds of seeds.

The cotton fibre is composed of a single hollow cell, and, while unripe, has the form of a long narrow tube. As the fibre matures, it becomes more or less flattened, and presents the appearance of a narrow, somewhat opaque ribbon or band, with slightly thickened, rounded edges. The ripe fibre possesses a peculiar characteristic twist. This twist appears to be an acquired character ; it is not present in wild cotton, and is increased by care in cultivation. The number of twists in a given length is very variable, and, as a rule, is, roughly speaking, inversely proportional to the diameter of the fibre, the twist being most numerous in the finest variety (Sea Island). Unripe cotton consists of thin, transparent fibres with little or no twist. Such fibres are known technically as ' dead cotton,' and, being very weak and brittle, they break up in the process of manufacture, thus increasing the amount of waste, and also tending to weaken the yarn or fabric into the composition of which they enter ; they also possess the defect of not being able to take dyes satisfactorily.

According to the length of the individual fibres, cottons are classed in commerce as long-, medium-, or short-stapled. The long-stapled cottons are 1¼ inches or more in length, the medium-stapled are about 1 inch long, and the short-stapled are less than 1 inch. The principal long-stapled varieties are Sea Island cotton, Egyptian varieties, and the improved American Upland forms, which have been evolved from the ordinary Upland kinds by continuous selection and careful cultivation. The Brazilian and Peruvian cottons vary from about 1 to 1½ inches, and are, therefore, either medium- or long-stapled. The chief medium-stapled cottons are the ordinary American Upland kinds, and the short-stapled class is represented by the Indian varieties.

Sea Island cotton is grown in South Carolina, Georgia, Florida, and the West Indies. The fibre is very long, fine, silky, and of a lustrous creamy tint, and this cotton is therefore the most valuable variety. It is used in commerce for spinning the finest and best yarns. Considerable care is required in the cultivation of this cotton, and the yield per acre is usually lower than that of other kinds.

American Upland cottons are produced in enormous quantities in the United States, and are the principal kinds used in the Lancashire spinning industry. They are of longer staple and better quality than the Indian varieties, and are employed for the manufacture of yarns of medium quality.

Egyptian cottons exist in several varieties, most of which yield a fibre of a brownish tint. These cottons are long, strong, and fine, and more lustrous than American Upland, but inferior to Sea Island cotton. Egyptian cotton is preferable to American Upland for the manufacture of goods requiring a soft, smooth finish and high lustre.

The Indian cottons are mostly short and coarse, and are consequently less valuable than American Upland kinds. The chief markets for these varieties are Japan and Germany, comparatively little being imported into the United Kingdom.

Brazilian cotton is harsh and wiry, of medium strength and of good length. One of the varieties grown in North Brazil is a tree cotton, which lives for 8 years or more. The ordinary annual cottons are more largely cultivated and are more productive than the arborescent form, but the fibre of the latter has the longer staple.

Peruvian cotton is chiefly of two kinds,

known respectively as 'rough' and 'smooth.' The former is the product of a cotton tree which is allowed to remain in the ground for from 4 to 6 years; the fibre is well known for its peculiarly harsh and crinkly character, which renders it especially useful to spinners for mixing with wool. 'Smooth' Peruvian is very similar to American Upland cotton, and is used for the same purposes.

The following table gives the approximate length and average diameter of the fibres of the principal commercial varieties. The diameters of the fibres of any one variety show great variation among themselves, but the figures given under this head are the average of a large number of determinations by various observers, and can, at least, be regarded as relatively accurate :—

Variety		Usual length	Average diameter
		inches	inch
Sea Island	.	1·6–2·2	0 00064
American Upland	.	0 8–1 1	0·00077
Egyptian .	.	1·3–1·6	0 00068
Indian .	.	0 6–1 0	0·00084
Brazilian .	.	1·1–1·4	0 00080
Peruvian (rough)	.	1·2–1·5	0·00078
„ (smooth)	.	0·9–1·1	0·00077

Cotton consists of about 83 7 p.c. of cellulose (q.v.), together with 7 p.c. of water, 0 6 p.c. of wax and oil, 1·5 p c of protein, and about 1·65 p.c of mineral matter (ash) (Bull. 33, U.S. Dept. Agric). The actual composition of cotton varies with its origin

The wax is present as a thin layer on the surface of the fibre, and renders it incapable of absorbing water readily. This substance, to which Schunck (Manchester, Mem. Lit. Phil. Soc. [iii.] 4, 95) has given the name 'cotton wax,' resembles other vegetable waxes, such as cerosin prepared from the leaves of the sugar-cane, and the waxes from the leaves of the carnauba palm [*Copernicia cerifera* (Mart.)], and the raphia palm [*Raphia pedunculata* (Beauv.). It is insoluble in water, but soluble in alcohol or ether; it melts at 86°, and solidifies again at 80°–82°. Pure cotton wax is insoluble in solutions of caustic alkali; it contains C 80 4, H 14 5, O 5 1. Associated with this wax is a fatty acid, which was regarded by Schunck as margaric acid, but is more probably a mixture of stearic and palmitic acids; it melts at 55·5°, and resolidifies at 50·5°.

The oil in the cotton fibre appears to be identical with that contained in the seed. In the preparation of the so-called absorbent cotton wool, the wax and oil are removed by boiling the fibre with dilute caustic alkali under pressure; the material is subsequently washed, treated with bleaching powder and hydrochloric acid, again washed, and dried.

The nitrogenous constituents of cotton consist of the remains of the cell protoplasm and allied substances.

The mineral substances contained in the fibre are chiefly phosphates, chlorides, and sulphates of potassium, sodium, magnesium, and calcium, together with small quantities of iron

and traces of aluminium. If the amount of ash is much more than 2–3 p.c., the excess is probably due to the presence of sand and other mechanical impurities.

When cotton is immersed in a strong solution of caustic soda, it undergoes certain remarkable changes, the chief of which is the production of a silky lustre. This phenomenon was discovered by John Mercer in 1844, and has led to results of great commercial importance. The process is now carried out on an extensive scale under the name of 'mercerisation' (q.v.), and is sometimes applied to the yarn and sometimes to the woven fabric. The material is either kept in a state of tension during the operation, or is allowed to shrink in the alkaline liquid, and afterwards stretched to its original length before being washed The process not only produces an exceedingly high lustre on the cotton, but also increases its power of absorbing dyes. The structure of the cotton fibre undergoes alteration; the flattened, twisted tube, characteristic of ordinary cotton, swells out, and is thus converted into a hollow, cylindrical form. This change is accompanied by a decrease in length and also by an increase in tensile strength, mercerised cotton being in some cases as much as 50 p.c. stronger than ordinary cotton. Egyptian cotton generally mercerises better than ordinary American cotton.

When cotton is treated with a mixture of nitric and sulphuric acids, it is converted into nitro-cellulose or gun-cotton (v. EXPLOSIVES). On dissolving gun-cotton in ether, or a mixture of ether and alcohol, the product known as collodion is obtained (v. PHOTOGRAPHY). Nitro-cellulose also enters into the composition of celluloid (q.v).

Among the more important works on this subject may be mentioned The Cotton Plant, Bull No 33, Office of Expt. Stat. U.S. Dept. of Agric.; Bowman's Structure of the Cotton Fibre; and Oppel's Die Baumwolle.   E. G.

**COTTON BROWNS, SCARLETS, YELLOWS,** *v.* AZO- COLOURING MATTERS; PRIMULINE.

COTTON FLOWERS. Among the various portions of the cotton plant which have been industrially employed must be included the flowers which constitute one of the numerous Indian dyestuffs. According to Watt (Dictionary of the Economic Products of India) they are thus used in the Manipur district. *Gossypetin* was first isolated in small quantity from the flowers of the ordinary Indian cotton plant, *G. herbaceum* (Perkin, Chem. Soc. Trans. 1899, 75, 826), and has been more completely studied at a later period (*ibid.* 1913, 103, 650). For its preparation a concentrated alcoholic extract of the flowers is treated with hot water and the mixture digested when boiling with addition of hydrochloric acid for three hours. After removal of tar by filtration the hot liquid on cooling deposits a brownish-yellow powder, which contains a mixture of quercetin and gossypetin. These colouring matters are separated by a fractional crystallisation of their mixed acetyl derivatives from acetic anhydride, acetylgossypetin being in these circumstances the least soluble. The acetyl compound is finally hydrolysed by sulphuric acid in the presence of acetic acid in the ordinary manner.

Gossypetin $C_{15}H_{10}O_8$ forms yellow needles,

melting-point 311°–313°, closely resembles quercetin in appearance, and is readily soluble in alcohol, but only very sparingly soluble in water. Concentrated alkaline solutions dissolve it, forming orange-red liquids which on agitation and dilution with water, become green, then blue, and finally assume a dull brown tint. Alcoholic lead acetate gives a deep red precipitate in the cold, passing into dull brown at the boiling-point, and with alcoholic ferric chloride a dull olive-green liquid is obtained.

Gossypetin like quercetin forms compounds with mineral acids which crystallise in orange-red needles, and with alcoholic potassium acetate the *monopotassium* derivative $C_{15}H_9O_8K$ is produced. The *hexa-acetyl* derivative

$$C_{15}H_4O_8(C_2H_3O)_6$$

forms colourless needles, melting at 228°–230°. By fusion with alkali or by dissolving the colouring matter in cold 50 p.c. aqueous potassium hydroxide and allowing the solution to remain exposed to air for twenty-four hours, with shaking, *protocatechuic acid* is obtained. A phenolic substance also produced by these methods of hydrolysis has not yet been identified.

When methylated with excess of methylic iodide and methyl alcoholic potash *gossypetin hexamethyl ether* $C_{15}H_4O_2(OMe)_6$, colourless needles, melting-point 170°–172°, is produced, and this by hydrolysis with alcoholic potash gives *protocatechuic acid dimethyl ether* and *gossypitol tetramethyl ether* $C_{12}H_{16}O_6$, needles, melting-point 115°–116°. By ethylation in a similar manner, *gossypetin hexaethyl ether* $C_{15}H_4O_2(OEt)_6$, melting-point 144°–146°, can be prepared, and with alcoholic potash yields *diethylprotocatechuic acid* and *gossypitol tetraethyl ether* $C_{16}H_{24}O_6$, melting-point 110°–111°. The latter forms an *oxime* $C_{16}H_{25}O_6N$, melting-point 127°–129°, and when oxidised with permanganate gives *gossypetonic acid*, yellow needles, melting-point 154°–155°. The constitutions assigned both to this latter (1) and to gossypitol tetraethyl ether (2) are given below:—

(1) $HO \cdot C_6H(OEt)_3CO \cdot CO_2H$

(2) $HO \cdot C_6H(OEt)_3CO \cdot CH_2 \cdot OEt$

and from these that of gossypetin naturally follows:—

When an alkaline solution of gossypetin is exposed to air the blue liquid on acidification yields a reddish-brown precipitate which on gentle warming becomes crystalline. Again, if benzoquinone is added to a solution of gossypetin in cold absolute alcohol a similar reaction takes place. On keeping for a few minutes crystals commence to separate, and by then heating to 50° a semi-solid mass is obtained.

Gossypitone $C_{15}H_8O_8$, the name assigned to this substance, consists of microscopic needles of a dull red colour, which are difficultly soluble in the usual solvents. It dissolves in dilute alkalis with a pure blue colouration and its solution in concentrated sulphuric acid is dull brown. Sodium hydrogen sulphite solution reconverts it into gossypetin. Gossypitone possesses strong

dyeing properties, and gives the following shades on mordanted woollen cloth:—

Chromium.	Aluminium.	Tin.
Dull brown.	Orange-brown.	Orange-red.
	Iron.	
	Deep olive.	

These, it is interesting to note, are identical with those given in these circumstances by gossypetin itself, and it is accordingly evident that during the dyeing operation oxidation of the latter to gossypitone takes place. Until a definite knowledge of the tetrahydroxybenzene nucleus in gossypetin has been obtained the position of the hydroxyl groups in this portion of the molecule can only be conjectured. Existing as it does side by side with quercetin it seems natural to consider that gossypetin is a hydroxyquercetin. Again, should gossypitone be a *p*-quinone, the constitution of gossypetin will be the same as that which Neirenstein and Wheldale have suggested (Ber. 1911, 48. 3487) for the flavonol (1) which they obtained from quercetone, an oxidation product of quercetin, but the descriptions of the two compounds are not in agreement [1] On the assumption of the necessity for a quinol nucleus in gossypetin a second constitution (2) is however possible.—

Again, a third expression (3), representing gossypetin as an hydroxyquercetin, is available, though in this case gossypitone must be regarded as an ortho- rather than a para-quinone:

The glucosides present in cotton flowers have been examined by Perkin (Chem. Soc. Trans. 1909, 95, 2181), who in the first place employed the Egyptian variety. The Egyptian cottons appear, according to the researches of Messrs. Fletcher and Balls, to be derived from natural crosses of brown Peruvian cottons with the Sea Island variety.

A concentrated alcoholic extract of the flowers deposits on cooling a semi-crystalline powder, and this consists mainly of the potassium salts of two glucosides, quercimeritrin and gossypitrin, whereas a third glucoside iso-quercitrin is present in the filtrate. A rough separation of the latter from this mixture may also be effected by means of aqueous lead acetate, for in these circumstances the precipitation of isoquercetin does

[1] This compound, more recently synthesised by Neirenstein (Chem. Soc. Trans. 1915, 107, 872), is described as melting at 354°–355°, and its hexamethyl ether at 145°–147°.

not occur, at least to any extent. The isolation of quercimeritrin and especially of gossypitrin in a pure condition from these flowers is however of too tedious a character to be described here, and for details of the processes involved the original paper must be consulted.

Quercimeritrin $C_{21}H_{20}O_{12}$, $3H_2O$, melting-point 247°–249°, consists of small, glistening, bright yellow plates, insoluble in cold and fairly readily soluble in boiling water. Its alkaline solutions possess a deep yellow tint; with aqueous lead acetate it gives a bright red precipitate, and with ferric chloride an olive-green colouration. *Octa-acetylquercimeritrin*, needles, $C_{21}H_{12}O_{10}(C_2H_3O)_8$, melting-point 214°–216°, is sparingly soluble in alcohol, whereas *monopotassium quercimeritrin*, a yellow powder, can be obtained by means of alcoholic potassium acetate. By hydrolysis with dilute sulphuric acid quercimeritrin yields quercetin and glucose according to the following equation :—

$$C_{21}H_{20}O_{12}+H_2O=C_{15}H_{10}O_7+C_6H_{12}O_6$$
and is thus analogous to quercitrin which in this manner is converted into quercetin and rhamnose.

On wool mordanted with aluminium, tin, chromium, and iron, quercimeritrin gives the following shades :—

Aluminium.	*Tin*	*Chromium*
Orange-yellow.	Bright orange.	Reddish-brown
		Iron
		Olive-brown.

And these results are interesting, because with the exception of the iron mordanted pattern, which is of a rather browner character, the colours thus produced closely resemble those which are given by quercetin itself when dyed in a similar manner. They are widely different from those given by rutin and quercitrin, and mainly as a result of this property there can be little doubt that quercimeritrin is to be represented by one of the two following formulæ :—

$$C_6H_7(OH)_4 \cdot O \left\langle \begin{array}{c} O \\ \\ OH \end{array} \right. \begin{array}{c} C--- \\ \parallel \\ CO \end{array} C \cdot OH \left\langle \begin{array}{c} OH \\ \\ \end{array} \right\rangle OH$$

$$HO \left\langle \begin{array}{c} O \\ \\ \end{array} \right. \begin{array}{c} C--- \\ \parallel \\ CO \end{array} C \cdot OH \left\langle \begin{array}{c} OH \\ \\ \end{array} \right\rangle OH$$

$$C_6H_7(OH)_4 \cdot O$$
Quercimeritrin is also present in the flowers of the *Prunus emarginata* ? (Finnemore, Pharm J. 1910, (iv.), 31, 604).

Gossypitrin $C_{21}H_{20}O_{13}$, only isolated with considerable difficulty. is more readily prepared from the *G. neglectum* (see below). When crystallised from dilute acetic acid it contains $2H_2O$ of crystallisation, and is readily dissolved by hot water, but on boiling this solution yellow needles of the anhydrous substance, melting-point 240°–242°, separate. When anhydrous it does not absorb water of crystallisation from moist air, but on boiling with acetone the hair-like needles are broken up into much finer needles, which when dried at 100° possess 1 molecule of water of crystallisation. Such a preparation melts at 200°–202°, and when dried

at 160° on standing in air now absorbs water. Preparations possessing this lower melting-point can be obtained in other ways, and it is accordingly evident that gossypitrin exists in two interchangeable modifications.

Gossypitrin dissolves in alkalis with a pale yellow colouration, and gives with lead acetate a deep red precipitate. It is almost insoluble in boiling acetone, a property which readily distinguishes it from quercimeritrin, which is fairly soluble in the latter solvent.

Acetyl gossypitrin $C_{21}H_{11}O_{13}(C_2H_3O)_9$, colourless needles, melting-point 226°–228°, is almost insoluble in alcohol.

When hydrolysed with dilute sulphuric acid gossypitrin yields gossypetin and dextrose according to the equation—

$$C_{21}H_{20}O_{13}+H_2O=C_{15}H_{10}O_8+C_6H_{12}O_6$$
The shades given by this glucoside on mordanted wool are as follows :—

Chromium.	*Aluminium.*	*Tin.*	*Iron.*
Reddish-brown.	Dull yellow.	Bright orange.	Dark olive-brown.

Gossypitrin reacts, like gossypetin itself, with benzoquinone, and yields in this way a quinone to which the name *Gossypitrone* $C_{21}H_{18}O_{13}$, has been assigned. This consists of maroon-coloured needles, which possess no definite melting-point, although fusion of the product occurs about 255°–259°. By the action of warm dilute sulphurous acid solution it is reconverted into gossypitrin, and the same change appears to occur in the dyeing process, for the shades produced are identical with those yielded by this latter glucoside. It is considered probable that the sugar group of gossypitrin is attached to its tetrahydroxybenzene nucleus, though until the exact nature of this has been decided, its position is necessarily uncertain.

Isoquercitrin $C_{21}H_{20}O_{12}$, $2H_2O$, crystallises from dilute alcohol in pale yellow needles, melting at 217°–219°. It is sparingly soluble in water, and dissolves in alkaline solutions with a deep yellow tint, but its most interesting property is the fact that with aqueous lead acetate solution it gives a bright yellow precipitate entirely distinct from the deep red deposit which is produced in this manner from the isomeric quercimeritrin.

Again, though more readily susceptible to hydrolysis than the latter glucoside, it yields identical products :—

$$C_{21}H_{20}O_{12}+H_2O=C_{15}H_{10}O_7+C_6H_{12}O_6$$
Dyeing experiments with isoquercitrin give shades entirely distinct from those given by quercimeritrin, and these, although slightly paler, resemble those yielded by quercitrin.

Chromium.	*Aluminium.*	*Tin.*	*Iron.*
Brownish-yellow.	Golden-yellow.	Lemon-yellow.	Brownish-olive.

The properties of this substance indicate that its sugar group is not attached as in quercimeritrin to the phloroglucinol nucleus of quercetin. Indeed, it is probably constituted similarly to quercitrin, which, however, contains a rhamnose in the place of the glucose residue. Three formulæ are possible for isoquercitrin, which may be briefly expressed by the statement that the position of the sugar

residue in respect to the quercetin group is at one or other of the points in the following which are marked with an asterisk :—
The aqueous extract of the Egyptian cotton flowers employed in this investigation gave by hydrolysis with acid 1·86 p.c of crude colouring matter, and in this approximately 10 p c. of gossypetin was present. Dyeing experiments with the flowers in the usual way gave the following shades :—

Chromium.	Aluminium.	Tin.	Iron.
Reddish-brown.	Green-yellow.	Orange-brown.	Olive-brown.

and these though duller were somewhat similar in character to those given by quercimeritrin In comparison with the shades similarly produced from other natural dyes, they most nearly resemble those of the so-called 'Patent Bark,' a preparation of quercitron bark in which quercetin and no quercitrin is present.

Among the types of cotton flowers there are (a) red, (b) pink, (c) yellow, and (d) white flowered plants In the offspring of a cross between (a) and (c) there occurs in the second and subsequent generations red and yellow plants which breed pure, whereas in the offspring of a cross between (a) and (d) all four forms occur which breed pure. As a supplementary investigation to that of the Egyptian flowers the petals derived from such pure plants occurring among the offspring of one or other of these crosses have been examined (Perkin Chem.. Soc. Trans. 1916, 109, 145) (cp. Leake, Proc. Roy. Soc. 1911, (B), 83, 147)

The types were as follows : red flowered, G. arboreum (Linn.) ; pink, G. sanguineum (Hawsk) ; yellow and white, two varieties of G. neglectum (Tod), usually now treated as one species but originally described as G. neglectum and G. rosarum. As a result it has been found that the red flowers of G. arboreum contain isoquercitrin, quercimeritrin and gossypitrin in this case being absent, whereas in the yellow flowers of G. neglectum, gossypitrin and isoquercitrin were present, and quercimeritrin appeared to be absent. On the other hand, the white flowers of G. neglectum and the pink flowers of G. sanguineum gave but traces of colouring matter too small for complete identification, though the respective products obtained resembled in their properties apigenin and quercetin. An examination of the ordinary Indian cotton flower, G. herbaceum, available only in small amount, gave the same results as the G. neglectum.

Gossypetin is also present in the flowers of the Hibiscus sabdariffa or 'red sorrel' of the West Indies, a small shrub which is widely cultivated throughout the hotter parts of India and Ceylon (Perkin, Chem. Soc. Trans 1909, 95, 1855). The stems yield the 'Rozelle hemp' of commerce, and this is obtained by retting the twigs as soon as the plant is in flower. The yellow flowers are just capable of dyeing yellow, but are not used at all in India for this purpose ; on the other hand, the red calyces are employed

for dyeing in an obscure degree in two remote parts of the country (Burkill, Agricultural Ledger, Calcutta, 1908, No. 2, 13).   A. G. P

COTTON SEED OIL is obtained on a large scale from the seeds of the several species of the cotton tree, Gossypium. In the United States, Gossypium hirsutum (Linn.), 'Upland cotton,' covered with 'linters,' is extensively cultivated, whereas the plant grown in the Sea Islands and in Egypt is G. barbadense (Linn.). The Indian variety of cotton seed is generally assumed to be G. herbaceum and G. arboreum, whilst the South American cotton plants are frequently classified as a separate species, G. acuminatum or peruvianum. Formerly the seed not required for planting was mostly wasted, as the oil contained therein could not be refined. Cotton seed oil was first expressed in this country in the year 1847. Since then the industry has assumed such enormous dimensions that the annual import of cotton seed to this country from Egypt, the East Indies, and South America amounts to more than 600,000 tons ; in addition very considerable quantities of cotton seed oil are imported from the United States, which produce almost 200,000,000 gallons of oil per annum, of which approximately 50,000,000 gallons are exported to Europe

The seed contains, on the average :—

				Per cent.
Oil	.	.	.	. 20 0
Water	.	.	.	8·5
Proteins	.	.	.	. 20·0
Carbohydrates	.	.	.	. 32·0
Crude fibre	.	.	.	. 15·0
Ash	.	.	.	. 4 5

The proportion of oil in the seed varies considerably with the origin of the seed. Thus Egyptian seed contains up to 24 p.c. of oil ; East Indian seed on the average only 18 p.c. ; American 'Uplands' and Jamaica seed 23–24 p c. ; and Brazilian and Peruvian no more than 20–21 p.c. of oil. The seeds consist on an average of 60 p c. of kernel and 40 p.c. of husk.

A distinction must be made between seed which must be decorticated before crushing, owing to the fine 'linter,' which cannot be removed readily, and seed which is crushed in the undecorticated state. Undecorticated seeds are chiefly crushed in England, France, and Germany, from Egyptian, Bombay, and also Smyrna seeds, whereas the vast majority of the American 'Upland seed' must be decorticated before being crushed. In some European establishments Bombay seed is decorticated before crushing.

The kernels ('meats') are permeated with cells containing a deep-brown colouring matter ; hence the crude cotton seed oil running from the hydraulic presses has a ruby-red to almost black colour. The depth of the colour of crude cotton oil depends, in the first instance, on the state of freshness of the seed. The American seed, which is, as a rule, crushed shortly after having been harvested, yields a crude oil of a much paler colour than that of crude oil obtained in England, France, and Germany from Egyptian seed. The palest Egyptian crude oil is obtained from fresh seed arriving in October. When the seed is stored it undergoes deterioration ('heating,' which may also occur during the voyage) ;

hence the crude oil obtained from Egyptian seed in July and August has a very dark colour.

In the American trade three grades of crude cotton seed oil are recognised, viz. 'prime,' 'choice,' and 'off' qualities. The crude oil is refined by treatment with a dilute caustic soda solution, at a temperature not exceeding 120° F., whereby the free fatty acids are neutralised; the soap so formed falls to the bottom and carries with it the brown colouring matter, so that the supernatant oil is of a bright-yellow colour. The oil is then washed free from soap, or, in the case of a technical oil, is treated with bleaching powder, to yield the bright-yellow oil of commerce. The first qualities of cotton seed oil which are not bleached with chemicals are used as edible oils, and are consumed in enormous quantities either as such, as a cooking oil, for tinning sardines, table oil, &c, or in the manufacture of lard substitutes, under such names as salad oil, sweet nut oil, butter oil. The last-named product is chiefly used in the manufactu e of margarine and compound lard

Official methods for analysing cotton seed oil, and tests for determining its behaviour when refined or bleached, have been published by the Interstate Cotton Crushers' Association, U.S.A. (Oil, Paint and Drug Rep, 1913, June 30; 1914, 33).

Cotton seed oil is, at the ordinary temperature, a pale-yellow oil of characteristic, but not unpleasant, taste. At about 12° 'stearine' deposits. This 'stearine' would interfere with the use of cotton seed oil as a table oil or salad oil; therefore the 'stearine' is removed on a large scale by cooling the oil to a low temperature, and filtering off the deposit. The filtered oil is known in commerce as 'winter oil' ('demargarinated cotton seed oil'). According to the requirements of the market, it will not 'cloud' at 40° F. or 32° F, or even at 28° F. The sp.gr. of cotton seed oil is 0·923-0·925 at 60° F The saponification value varies from 190 to 193, and its iodine value from 105 to 115.

The solid fatty acids in cotton seed oil consist chiefly of palmitic acid; small quantities of arachidic acid seem to be present, but stearic acid appears to be absent. The liquid fatty acids would seem to consist of oleic and linolic acids only.

Cotton seed oil eminently typifies a semi-drying oil. In the Livache test (see OILS AND FATS) it absorbs 5·9 p.c. of oxygen in 24 hours. By blowing air through cotton seed oil at a temperature of about 90°-100°, oxygen is absorbed, with the formation of a small amount of oxidised acids, the acetyl value of the oil rising at the same time considerably. This reaction is used on a large scale in the preparation of 'Blown Cotton Seed Oil' (see OILS AND FATS), which is used in considerable quantities as a lubricating oil in admixture with mineral oils, to produce the 'Marine Lubricating Oils' of commerce.

Cotton seed oil hardened by hydrogenation is used as a solid fat in the manufacture of margarine. A typical commercial hardened oil melts at about 38°, and has a saponification value of about 196 and iodine value of about 70.

A reliable test for the identification of cotton seed oil, and for the detection of it in other oils and fats, down to even 1 p.c. (under favour-

able circumstances), is the *Halphen* colour test, which is carried out in the following manner: 1-3 c.c. of the oil is dissolved in an equal volume of amyl alcohol; to this is added 1-3 c.c. of carbon disulphide, holding in solution 1 p.c. of sulphur flowers. The test-tube is immersed in boiling water, or, better, in boiling brine, the carbon disulphide being allowed to evaporate off. In the course of 5-20 minutes, a deep-red colouration appears, the intensity of which stands in direct proportion to the amount of cotton seed oil in the sample. The reagent which produces the colouration appears to be an impurity in the amyl alcohol, and the test may be rendered more delicate by substituting pyridine for amyl alcohol. In this way as little as 0·25 p.c. of cotton seed oil may be detected (Gastaldi, Giorn. Farm. Chim. 1912, 61, 289). Although the test cannot be used as a quantitative one, yet it must be considered, if positive, as one of the best means of recognising the presence of cotton seed oil qualitatively. A negative Halphen test is, however, no conclusive proof of the absence of cottonseed oil in a mixture, as the colouring matter is destroyed by heating cotton seed oil to 250°, or by keeping it at 200° for some prolonged time, or by 'blowing' it. Hence 'blown cotton seed oils' do not show the Halphen colour reaction. J. L.

COTTON SEED, COLOURING MATTER OF.

Cotton seeds contain, in addition to cotton-seed oil, a phenolic substance *gossypol*, which remains dissolved in the oil when this is expressed.

By extracting the oil with caustic soda and neutralising the solution thus obtained a voluminous precipitate separates which consists of the colouring matter admixed with fatty acids, and the products of its own oxidation. For the isolation of gossypol Marchlewski (J. pr. Chem. 1899, 60, 84) employed a partially purified preparation of this character from which the main bulk of the fatty acids had been eliminated. By extraction with ether, repeated crystallisation from glacial acetic acid, and from a mixture of alcohol and 50 p.c. acetic acid, it was isolated in the form of small yellow prisms.

As the result of analyses of this substance dried *in vacuó* over sulphuric acid, Marchlewski suggested two formulæ, $C_{13}H_{14}O_4$ and $C_{32}H_{34}O_{10}$, and of these the first is considered preferable. Preparations dried at higher temperatures appeared to suffer alteration as they thus became darker, and had then a lower melting-point.

Thus the gossypol when quickly heated melted at 188°, but when previously dried at 125°-130°, at 179°-180°. It is easily soluble in the usual organic solvents, and dissolves in sulphuric acid with a cherry-red colouration, a reaction by which its presence in cotton-seed oil can be detected. In alkalis, gossypol dissolves with a yellow colouration which rapidly changes to violet, and then slowly fades. The ready susceptibility of alkaline gossypol solutions to air oxidation accounts largely for the impure nature of the crude colouring matter isolated by such reagents from the oil, and it appears that if care is taken in the process, it is possible to obtain a much cleaner material in the first instance. An alcoholic solution of gossypol gives with ferric chloride a dark-green colouration, and with the neutral and basic acetates of lead a deep-yellow precipitate. The analysis of the

lead salt corresponded to $C_{18}H_{12}O_4Pb$. According to Marchlewski, gossypol yields amorphous acetyl and benzoyl derivatives and appears to possess two hydroxyl groups. It contains no methoxy groups, and is not a glucoside. It dyes iron mordanted material a grey shade, but the product obtained by a careful oxidation of its alkaline solution possesses, it is stated, tinctorial properties of greater importance. Gossypol can be employed on cotton fabrics as a mordant for the basic colouring matters.

F. E. Carruth (Amer. Chem. J. 1918, xi. 4, 647) isolates gossypol from the decorticated cotton-seed kernels which have been crushed by rollers before they are 'cooked' in the oil mill. From these a considerable amount of oil is removed by percolation with ligroin, and the residue is then extracted with ether and the extract evaporated. The product is now treated with one-half to one-third its volume of glacial acetic acid, and on keeping for some days, or more quickly by gentle warming, crystals of *gossypol acetate* separate For purification it is dissolved in ether, glacial acetic acid is added, and the solution evaporated until crystallisation commences.

To obtain gossypol itself an ethereal solution of the acetate is treated with water, and the ether distilled off. The gossypol thus remains suspended in the water as crystalline crusts, and may be recrystallised from alcohol.

A second interesting method consists in adding aniline to an ethereal extract of cotton seed. The solution after warming on the water-bath gradually deposits on standing an orange-yellow microcrystalline precipitate, which apparently consists of an aniline salt of gossypol, $C_{30}H_{28}O_9$, $2C_6H_5NH_2$ or $2C_{30}H_{28}O_9$, $5C_6H_5NH_2$ The yield is practically quantitative, and the process may be used to estimate gossypol in extracts of cotton-seed products.

To regenerate gossypol from the aniline compound, it is dissolved in hot alcoholic potassium hydroxide, and the aniline removed by steam distillation From the alkaline liquid the gossypol is precipitated on acidification, and may be purified by conversion into the acetate according to the method given above.

Gossypol acetate, a molecular compound of gossypol and acetic acid, is evidently the substance described by Marchlewski as the 'free colouring matter. It is a comparatively stable substance, and when heated does not evolve acetic acid readily below 180°. Its formula determined by alkali titration is

$$C_{30}H_{28}O_9, C_2H_4O_2 \text{ or } C_{10}H_{30}O_9, C_2H_4O_2$$
Hence gossypol itself is $C_{30}H_{28}O_9$ or $C_{10}H_{30}O_9$, and this result is in harmony with other analytical figures given in Carruth's paper.

Gossypol acetonate, $C_{30}H_{28}O_9 \cdot CH_3 \cdot CO \cdot CH_3$, is obtained as glistening crystals when gossypol is dissolved in acetone, and the solution concentrated. Like the acetate it is a stable compound, and when heated at 140°–150° it alters but little in weight.

Acetyl and benzoyl derivatives of gossypol could not be obtained in a crystalline condition, but as a result of their examination the evidence was sufficient to indicate that four or five hydroxyl groups are present in gossypol. When gossypol is heated to 186°–190° it fuses with the

evolution of vapour, and then solidifies to a black mass. On treating the residue with ether a sparingly-soluble yellow crystalline compound *B. gossypol* separates, which is much less toxic than gossypol and melts at about 246°–248°. Again, by fusion with alkali, a second new crystalline substance *C. gossypol* can be obtained, and this, which is soluble in alkalis with a blue colour is probably closely related to the purple oxidation product of gossypol referred to above.

Cotton seed meal which has been submitted to the 'cooking process' loses much of its toxic property, and contains then practically no gossypol. By extracting this product with aniline, the aniline compound of *D. gossypol* which crystallises in orange-yellow prisms can be isolated.

Alcoholic potash converts this compound into *D gossypol* itself, yellow crystals, which darken and soften at about 256°.

From the cooked meal 1·2 p c. of the aniline compound can be obtained These products have not as yet been closely examined.

COUMARANE GROUP.   Leuco-benzoyl-coumarane—

$$C_6H_5—CH \cdot OH— \text{}$$
according to v Kostanecki and his co-workers is probably the mother substance of the catechin present in Gambier catechu, though the correctness of this view has not yet been fully established. *Coumarane* or *hydro-coumarone*, the inner anhydride of *o*-hydroxyphenyl ethyl alcohol -
was first prepared by Alexander (Ber. 1892, 25, 2409) by reducing coumarone in alcoholic solution with sodium—

Coumarone.   Coumarane.
It forms a colourless oil, boiling-point 188°–189°, and gives in sulphuric acid solution by addition of ferric chloride a violet colouration. Stoermer and Göhl (Ber. 1903, 36, 2873) have obtained coumarane and its homologues by the action of sodium on *o*-bromo-phenol brom-ethyl esters according to the following equation :—
By the interaction of coumarane and benzoyl chloride in the presence of aluminium chloride

4 benzoyl-coumarane, colourless crystals, melting-point 44°—

$$C_6H_5—CO—\text{(coumarane)}\begin{smallmatrix}CH_2\\CH_2\end{smallmatrix}$$

is produced (v. Kostanecki, Lampe and Marschalk, Ber. 1907, 46, 3660), and when reduced in alcoholic solution, the leuco-benzoyl-coumarane above referred to is obtained   A. G. P.

COUMARANDIONE, COUMARANONE v. KETONES.

COUMARANONE GROUP. Though colouring matters derived from coumaranone (keto-cumaran) have not as yet been isolated from natural sources, there is some probability of

Ketocumaran.   Cumaran.
their presence in certain flowers, and they are not only historically connected with the earlier attempts to synthesise the flavones, but have in certain instances been successfully converted into flavonols.

Coumaranone (1) is obtained (Friedländer and Neudorfer, Ber. 1897, 30, 1077) by boiling acetyl o-hydroxyacetophenone bromide (2) with an aqueous suspension of chalk, or by the action of dehydrating agents on phenoxyacetic acid (3)—
(Friedländer, Ber. 1899, 32, 1867), and consists of colourless needles, melting-point 97°. It condenses with benzaldehyde in the presence of hydrochloric acid with formation of benzylidene-coumaranone—
which was at first considered by Friedländer and Neudörfer (Ber. 1897, 30, 1077) to consist of flavone. On substituting protocatechuic aldehyde for benzaldehyde these authors obtained the dihydroxy compound—
and this is a strong dyestuff which gives on aluminium mordanted fabrics an orange, and with iron and chromium mordants brown-coloured shades.

The first colouring matter of this group was, however, prepared in 1896 by Friedländer and Rüdt (Ber. 29, 878) from chlorogallacetophenone and benzaldehyde—
and from the analogous resacetophenone derivative other hydroxy compounds of this group were obtained later. These are of an orange or orange-red colour, as a rule form oxonium salts, and those possessing tinctorial property dye alum mordant a much more orange shade than the flavone colouring matters. There is indeed a close resemblance in this latter respect between these compounds and the colouring matters derived from chalkone—
(Perkin, Chem. Soc. Trans. 1904, 85, 1465), for butein (a tetrahydroxy chalkone obtained from the *Butea frondosa*) and the 3 : 4 : 3′ : 4′ tetra-hydroxybenzylidene coumaranone of Friedländer and Rudt give almost identical shades. The benzylidene coumaranones dissolve in sulphuric acid with the production of a red or red-violet colouration, and can thus again be distinguished from flavones which in this manner give either colourless or pale yellow solutions.

In 1896 Kesselkaul and v. Kostanecki (Ber. 29, 1886) suggested that judging by its colour reactions the colouring matters of Friedländer and Rudt were not, as these authors suggested, flavone but rather coumaranone derivatives, and the true constitution of these substances became evident on the synthesis of flavone itself by Feuerstein and v. Kostanecki (*l.c.*). That benzylidenecoumaranones can be converted into flavanol derivatives has been shown by Auwers and Müller (Ber. 1908, 41, 4203), and this transformation is discussed under FLAVONOL.

Coumaranone is also interesting as the source of ox-indigo—
the oxygen analogue of indigotin. This crystallises in yellow prisms, but does not possess any tinctorial value.

Analogous colouring matters can be obtained from diketohydrindene (indandione), this also possessing the reactive methylene group, with aldehydes. Thus by heating this compound with protocatechuic aldehyde at 110°–120° v. Kostanecki prepared the dihydroxybenzylidene derivative—

which consists of brownish-yellow needles, melting-point 257°, soluble in alkaline solutions with a red-violet colour and gives yellow shades on aluminium mordanted fabrics.

From indoxyl also in a similar way Perkin and Thomas (Chem. Soc. Trans. 1909, 95, 798) prepared dihydroxybenzaldehydeindogenide—
crystallising in orange-red needles, and producing with aluminium mordanted fabrics dull scarlet shades.

Chalkone or benzylideneacetophenone is readily prepared by the interaction of acetophenone and benzaldehyde (Claisen, Ber. 20, 257)—

$$C_6H_5 \cdot CO \cdot CH_3 + C_6H_5COH$$
$$\rightarrow C_6H_5 \cdot CO \cdot CH_2CHOH \cdot C_6H_5$$
$$\rightarrow C_6H_5 \cdot CO \cdot CH \cdot CH \cdot C_6H_5 + H_2O$$

It consists of yellow rhombic prisms, melting-point 57°–58°.

When submitted to hydrolysis it is reconverted into the aldehyde and ketone, a reaction which is the reversal of that given above—

$$C_6H_5 \cdot CO \cdot CH : CH \cdot C_6H_5$$
$$\rightarrow C_6H_5 \cdot CO \cdot CH_2 \cdot CH \cdot OH \cdot C_6H_5$$
$$\rightarrow C_6H_5 \cdot CO \cdot CH_3 + C_6H_5CH(OH)_2$$
$$\rightarrow C_6H_5 \cdot COH + H_2O$$

By the employment of hydroxyacetophenones and hydroxybenzaldehydes, in general previously methylated, numerous chalkone derivatives have been obtained by v. Kostanecki and his co-workers. Only one natural colouring matter of this group, known as *butein*, has at present been isolated, and the synthetically prepared compounds have been more specially interesting owing to their employment for the synthesis of the flavonol group of colouring matters.

Ryan and O'Neill by the aid of diacetoresorcinol have obtained dichalkone compounds. Thus diacetoresorcinol dimethyl ether and benzaldehyde form dibenzylidenediacetoresorcinol dimethyl ether, and this by the action of aluminium chloride is demethylated with production of the free hydroxy compound—

$$C_6H_5 \cdot CH : CH - CO - \underset{OH}{\overset{OH}{\bigcirc}} - CO - CH \cdot CH \cdot C_6H_5$$
It was obtained as yellow crystals melting at 196°–198°.

Interesting is the fact shown by these authors that by a variation in its method of preparation four distinct varieties of this dichalkone can be produced. Whereas three of these designated as α, β and δ are stereo-isomers, the fourth or γ variety is structurally related to the other three.

When 2-hydroxychalkone is digested at the boiling temperature with alcoholic sulphuric acid, *flavanone* (dihydroflavone) is produced according to the following scheme :—
and this is the method generally adopted for the synthesis of flavanone derivatives. On the other hand, though as a rule a chalkone only is produced by the interaction of aldehyde and
hydroxyketone, when gallacetophenone dimethyl ether (Woker, v. Kostanecki, and Tambor, Ber. 1903, 36, 4235) or quinacetophenone monomethyl ether (v. Kostanecki and Lampe, *ibid.* 1904, 37, 773) are condensed with benzaldehyde in the presence of sodium hydroxide the respective flavanones (1 and 2) are thus directly obtained—
On hydrolysis the flavanones yield chalkones, a reversal of the equation given above. The reaction in these cases is not unidirectional, and the conversion of flavanone into chalkone, or chalkone into flavanone, is never complete.

Chalkones which contain hydroxyls in the ortho position to one another, in the position 3′·4′ are powerful colouring matters, whereas flavanones possessing similar hydroxyls are not dyestuffs, as indeed their constitution indicates. During the dyeing operation, employing mordanted woollen material hydrolysis occurs, with subsequent chalkone production, and the shades produced by them are in reality those derived from the latter. Flavanone crystallises in small colourless needles, melting at 75°–76°.

Bromflavanone (1) by elimination of hydrobromic acid readily yields flavone (2)—

and, again, flavanones may be converted into flavonols.   · A. G. P.

**COUMARIN** $C_9H_6O_2 = C_6H_4 \Big\langle \begin{smallmatrix} CH : CH \\ | \\ O - CO \end{smallmatrix}$ (1, 2)
was obtained by Vogel (Gilb. Ann. 64, 161), in 1820, from the tonka bean (the seed of *Dipteryx (Coumarouna) odorata*, Willd.), or from the melilot (*Melilotus officinalis*, Lam.), and from the woodruff (*Asperula odorata*, Linn.), but was mistaken by him for benzoic acid. Guibort, however, showed that the crystalline odoriferous principle of the tonka bean was distinct from benzoic acid, and named it *coumarin*. It occurs in *Peristrophe angustifolia* (Nees), *Achylis triphylla* (DC.), and in many other plants, and is a normal constituent of lavender oil. It is present in plants as a glucoside, which is decomposed by a ferment present in the plant. This ferment is destroyed by alcohol or boiling water (Molish, J. Pharm. Chim. 1902, 279).

It was first obtained synthetically by Perkin by heating the sodium compound of salicylaldehyde with acetic anhydride (Chem. Soc. Trans.

1863, 53); or more simply by boiling together salicylaldehyde, acetic anhydride, and dry sodium acetate (*ibid.* 1887, 388; see also Tiemann and Herzfeld, Ber. 1877, 284). Acetyl coumaric acid is first formed:

$$C_6H_4{<}{}^{CHO}_{OH} + {}^{CH_3 \cdot CO}_{CH_3 \cdot CO}{>}O$$

$$= C_6H_4{<}^{CH : CH \cdot COOH}_{O \cdot CO \cdot CH_3} + H_2O$$

which then parts with acetic acid, yielding coumarin:

$$C_6H_4{<}^{CH : CH \cdot COOH}_{O \cdot CO \cdot CH_3}$$

$$= C_6H_4{<}^{CH : CH}_{O \longrightarrow CO}{\Big|} + CH_3 \cdot COOH$$

By treating salicylaldehyde (1 molecule) with excess of acetic anhydride (4 molecules) for 6 hours at 180°, coumarin is formed (Reychler, Bull. Soc. chim. 1897, 17, 517)

Coumarin is also formed in small quantity by heating a mixture of phenol and malic acid with sulphuric acid

$$C_6H_5 \cdot OH + {}^{CH_2COOH}_{CH(OH) \cdot COOH}{\Big|}$$

$$= C_6H_4{<}^{CH : CH}_{O \longrightarrow CO}{\Big|} + CO + 3H_2O$$
(Von Pechmann, Ber 1883, 2119; 1884, 929, 1649)

It has also been obtained from *o*-chlorocinnamic acid which is reduced electrolytically to *o*-chloro-hydrocinnamic acid and then heated with aqueous sodium hydroxide to 250°, when melilotic acid is produced. Thionylchloride converts melilotic acid into melilotic anhydride, from which coumarin results by oxidation with bromine vapour at 270°–280° (Meyer, Beer and Lasch, Monatsh. 1913, 34, 1665).

Substituted coumarins may be obtained by condensing phenols with acetoacetic ester or with malic acid in the presence of concentrated sulphuric acid.

The condensation of acetoacetic ester or malic acid with substituted phenols (containing alkyl, hydroxyl or dialkyl-amino groups) gives good yields if the groups are present in the positions as shown—

The condensation is, however, prevented by the presence of nitro, carboxyl or carbethoxy groups (Clayton, Chem. Soc Trans., 1908, 2018). It is also very considerably affected by the concentration of the sulphuric acid used.

Coumarin forms rhombic crystals melting at 70°; boils at 290°–290·5°; has a pleasant, aromatic odour; is scarcely soluble in cold water, readily soluble in boiling water, very soluble in alcohol and ether. Crude coumarin may be purified by repeated boiling with light petroleum (Claassen, Pharm. J. 1897, 161).

It dissolves in caustic alkalis, and is reprecipitated on addition of acids. If, however, it is heated for some time with concentrated

caustic alkali, or better, with sodium ethoxide, a solution is formed from which acids precipitate

$$coumaric\ acid\quad C_6H_4{<}^{CH : CH \cdot COOH}_{OH}\quad (1, 2).$$
This compound can be reconverted into coumarin by heating it with acetic anhydride; but when heated alone it is decomposed, yielding phenol and other substances. Reduction of coumarin with zinc in alkaline solution or sodium amalgam in aqueous solution yields melilotic acid as the chief product; with sodium amalgam and alcohol hydrocoumaric acid is formed (Williamson, J. 1876, 587).

On account of the differences shown between coumarin and thiocoumarin, it has been suggested that the two compounds should be represented by the annexed formulæ:

(Clayton, Chem. Soc. Trans. 1908, 524).

The *thiocoumarin* is produced by heating coumarin with phosphorus pentasulphide, and in contradistinction to coumarin is coloured. It also reacts with phenylhydrazine, yielding coumarin phenylhydrazone (with elimination of hydrogen sulphide), which cannot be obtained directly from coumarin itself. For an account of the synthetic benzotetronic acids (hydroxy-coumarin carboxylic acids), *see* Anschütz, Annalen, 367, 174.

In Germany, woodruff (Ger. *Waldmeister*) is steeped in white wine, to which it imparts the pleasant aroma of coumarin (*Maiwein, Maitrank*). Instead of woodruff, an alcoholic solution of coumarin is employed for the same purpose under the name of *Maiweinessenz*. In larger doses coumarin is stated to have a narcotic action.

Coumarin has the agreeable odour of asperula, and is used in perfumery for the preparation of asperula essence. It is also frequently used to adulterate extract of vanilla (*q.v.*) (*v.* LACTONES).
COUMARONE $C_6H_4{<}^{CH}_{O}{>}CH$. An oil obtained from the coal-tar fraction boiling between 165° and 175°. After the pyridine bases and phenols have been removed by acid and alkali, it is obtained as the dibromide on addition of bromine. The dibromide is reduced to coumarone by alcoholic potash and sodium amalgam (Kraemer and Spilker, Ber. 1890, 78). It can also be obtained from this source by adding picric acid to the mixture of oils, whereby the picrate of coumarone crystallises out. This is separated, decomposed by hot water or dilute alkali, and the coumarone obtained by steam distillation. The picric acid is recovered and used for another operation (Ch. Fab. Act. ges. Hamburg, Eng. Pat. 1422; D. R. P. 53793; Ber. 1891, Ref. 233). Coumarone has been synthesised by heating *o*-hydroxy-ω-chlorcinnamene OH·C$_6$H$_4$·CH : CHCl with potash, hydrogen chloride being eliminated (Komppa, Ber. 1893, 2968). It has also been prepared by heating phenoxyacetaldehyde with zinc chloride in glacial acetic acid (Stoermer, *ibid.* 1897, 1700).

Coumarone boils at 174·0° (corr.) (Perkin, Chem. Soc. Trans. 1896, 1249). It is unacted

upon by potash or by hydrochloric acid. Sulphuric acid reacts with coumarone in benzene solution, producing a soluble resinous material *paracoumarone* $(C_9H_6O)_4$, which is used to preserve wood and paper. Other polymerides are known. Coumarone is of interest as, when passed through a red-hot tube with benzene, phenanthrene is produced, and with naphthalene, chrysene is produced (Kraemer and Spilker, Ber. 1890, 84). The methyl coumarones are present in the coal-tar fraction of b p. 185°–195° (Stoermer and Boes, *ibid.* 1900, 3013).

COUMARONE RESINS. Technical Coumarone resins are prepared by treating solvent naphtha with sulphuric acid. They differ from the pitches by their ready solubility in acetone, and from the condensation products of phenols with formaldehyde by their solubility in petroleum spirit and by not yielding phenol when heated with soda-lime at 260°. They differ from the natural resins in being optically inactive, in having a lower melting-point, saponification value and iodine value. They are classified for commercial purposes according to their colour and hardness; those softening above 50° are termed 'very hard,' between 40° and 50° 'hard,' and between 30° and 40° 'medium hard' For methods of their examination, *see* Marcusson, Chem Zeit 1919, 43, 109–122; Analyst, 1919, 44, 203.

If coumarone resins are distilled under ordinary or under reduced pressure they yield yellow oils between 150° and 240°, consisting mainly of coumarone, or partially depolymerised paracoumarone, together with indene hydrindene and small quantities of phenol By treatment with condensing agents and catalysts these oils again yield resins varying in character with the nature of the catalyst. Coumarone oils are not autoxidisable like drying oils, but when mixed with 4–6 p.c. of driers, such as the resinates of lead or manganese, they yield dry films. The distinctive oxidation process of coumarone oils is to be attributed to indene (E Stern, Zeitsch. angew. Chem. 1919, 32, 246)

COUPIER'S BLUE *v.* INDULINES.

COVELLITE. Native cupric sulphide, CuS, crystallising in the hexagonal system. Crystals are rare and have the form of thin six-sided plates. Fine large crystals have been found at Butte in Montana. The mineral has a characteristic indigo-blue colour, hence the name *indigo-copper* (German, *Kupferindig*). It occurs in most copper-mines as a blue, earthy coating on other sulphide ores of copper, and is sometimes found in sufficient quantities to be of importance as an ore, *e.g.* at Butte in Montana, and Copiapo in Chile. Covellite containing platinum (as the mineral sperrylite, PtAs₂) is mined in the Medicine Bow Mountains in Wyoming.

L. J. S.

COW TREE WAX *v.* WAXES.

COXPYRIN. Syn. for acetyl salicylic acid.

CRANBERRY, the fruit of *Vaccinium Oxycoccos* (Linn.).

American analyses give as the average composition of the berries :

Water	Protein	Fat	Carbohydrates	Ash
88·5	0·5	0·7	10·1	0·2

König gives :

Water	Protein	Free acid	Sugar	Other carbohydrates	Ash
89·6	0·12	2·3	1·5	6·3	0·15

The juice of cranberries was examined by Mach and Portele in 1888 (Landw. Versuchs. Stat. 1889, 38, 69), who found a litre of the fresh juice to contain (in grammes)

Invert sugar	Acidity (as malic acid)	Benzoic acid	Tannic acid	Ash	Nitrogen
87·1	19·0	0·75	2·2	3·0	0·11

The sp.gr. of the juice averaged 1·0591.

The juice will not ferment with yeast, owing, it is said, to the presence of benzoic acid, but this may be due to the poverty of the juice in nitrogenous matter, for Otto (Bied. Zentr. 1899, 28, 284) found that bilberry juice would only ferment vigorously with yeast after the addition of asparagine (about 0·6 gram per litre) or of ammonium chloride (about 0·3 gram per litre).

Rising (Bied. Zentr. 1915, 44, 163) found in cranberries, benzoic, isovaleric, malic and citric acids, fermentable sugars and a glucoside— *vaccinin* $C_6H_{11}O_5·Bz$. The amount of sugar varied from 5·7 to 10·4 p.c., and that of benzoic acid from 0 108 to 0·455 p c. The keeping qualities of the fruit are dependent upon the amount of benzoic acid present

The pigment of the cranberry consists of an anthocyanin—a compound of galactose with a cyanidin, the chloride of which has the composition $C_{15}H_{11}O_6Cl$ (Willstatter, Sitzungber. K Acad. Wiss Berlin, 1914, 12, 402).

Claassen (*ibid.* 16, 70) isolated a bitter substance from cranberries, to which he gave the name *oxycocin*, and which he found to give reactions similar to those of arbutin $C_{12}H_{16}O_7$, occurring in the leaves of the red bearberry, *Arctostaphylos Uva-ursi* (Spreng.).

The ash of cranberry juice contains about 3 p.c. of phosphorus pentoxide and 47 p.c. of potash.

H. I.

CREAM OF TARTAR *v.* TARTARIC ACID.

CREATINE, *Methylglycocyamine, Methylguanidoacetic acid* $H_2N·C(NH)NMe·CH_2·CO_2H, H_2O$ discovered by Chevreul (Annalen, 1835, 4, 293) in muscular flesh ($\chi\rho\epsilon as$=flesh), occurs in human flesh, in the flesh and blood of many warm and cold blooded animals and in urine (Liebig, Annalen, 1847, 62, 257 ; Gregory, *ibid.* 1848, 64, 105 ; Schlossberger, *ibid.* 1848, 66, 80 ; Voit, Z. Biol. 1868, 4, 77 ; Price, Chem. Soc. Trans. 1851, 3 ; Marcet, *ibid.* 1864, 2, 406 ; Folin and Denis, J. Biol. Chem. 1914, 17, 488 ; Rose, *ibid.* 1911, 10, 265) ; the amount varies with the species and the organ ; the flesh of fowl yields 3·21 p c. ; of pigeon, 0·825 p.c. ; of ox, 0·697 p.c. ; of ox heart, 1·375 p.c. ; of herring, 1·324 p.c. ; and of brill, 0·614 p.c. (Gregory, *l.c.* ; Beker, Zeitsch. physiol. Chem. 1913, 87, 28 ; according to Myers and Fine (J. Biol. Chem. 1913, 14, 9–12) it is constant for a given animal Okuda, 8th Int. Cong. App. Chem. 1912, 18, 275.

According to Folin (Amer. J. Physiol. 1905, 13, 45, 66, 117), van Hoogenhuyze and Verploegl (Zeitsch. physiol. Chem. 1908, 57, 161), Mellanby (J. Physiol. 1908, 36, 447), muscular creatine has its origin in the liver. This organ is continuously forming creatinine from substances carried to it by the blood from other organs, and in the developing muscle. This is changed to creatine, until the muscle is saturated with creatine, when the excess of creatinine is excreted by the kidneys. *Cf.*, however, Folin

and Denis (*ibid.* 493-496 and 500-501) who suggest that creatine is part of living vertebrate protoplasm and the creatine of muscles a post-mortem product, and that creatinine elimination is a measure of the total normal tissue metabolism and independent of any special function of the liver; *see also* Myers and Fine (*ibid.* 1913, 15, 283-285 and 301-304); Inooye (Zeitsch. physiol. Chem. 1912, 81, 71-79); Rieser (*ibid.* 1913, 86, 415-453, and 1914, 90, 221-235); Myers and Fine (*ibid.* 1913-14, 16, 169, and *ibid.* 1915, 21, 377); Rose and Dimmitt (J. Biol. Chem. 1916, 26, 345); Baumann and Hines (J. Biol. Chem. 1917, 31, 549) The creatine is presumably combined with the muscular protoplasm, for though a readily dialysable substance, it does not pass into the surrounding lymph or blood *in vitro*, nor is it readily obtainable by diffusion from muscular flesh (Urano, Beitr. Chem. physiol. Path. 1907, 9, 104). *Cf.*, however, Folin and Denis (J. Biol. Chem. 1914, 17, 499); Leo and Howe (Pro Amer. Soc. Biol. Chem. 1912-13, xliii. For the origin of urinary creatine, *see* Benedict and Osterberg (J. Biol. Chem. 1914, 18, 195), Myers and Fine (*ibid.* 1913, 15, 301)

In order to extract creatine, the flesh is heated with its own weight of water at 60°, and the juice expressed The flesh extract is then heated to coagulate the protein, and filtered; the filtrate is treated with basic lead acetate until no further precipitation occurs, and again filtered after removing the excess of lead from the filtrate by sulphuretted hydrogen, when it is evaporated until creatine separates on cooling; this is washed with alcohol and recrystallised from water (Neubauer, Zeitsch anal Chem. 1863, 2, 26; 1867, 6, 33). Creatine may be prepared by the decomposition of creatinine zinc chloride by means of calcium hydroxide (Benedict, J. Biol. Chem. 1914, 18, 186).

Creatine is prepared synthetically by heating sarcosine with cyanamide at 100°.

$$CN \cdot NH_2 + NHMe \cdot CH_2 \cdot CO_2H$$
$$= NH : C(NH_2) \cdot NMe \cdot CH_2 \cdot CO_2H$$
(Volhard, Z. Chem. N F. 1869, 5, 318; Strecker, J. 1868, 686); or, together with creatinine, by fusing sarcosine with guanidine carbonate (Paulmann, Beilstein Suppl. 1. 657).

Creatine forms colourless transparent monoclinic prisms, containing $1H_2O$, which it loses at 100°; it dissolves in 74·4 parts of water at 18°; or in 9810 parts of cold absolute alcohol, and is insoluble in ether (Liebig, Annalen, 1847, 62, 257). Heat of combustion at constant pressure is 4240 calories (Emery, Benedict, Amer J. Physiol. 1911, 28-307). The presence of urea, creatinine, or certain salts, raises the solubility of creatine in water and alcohol (Neubauer, *l.c.*). The aqueous solution is neutral, and has a bitter, harsh taste.

Creatine is decomposed by boiling baryta water into sarcosine, urea, and methylhydantoïn

$$NH:C(NH_2) \cdot NMe \cdot CH_2 \cdot CO_2H + H_2O$$
$$= CO(NH_2)_2 + NHMe \cdot CH_2 \cdot CO_2H$$

$$CO(NH_2)_2 + NHMe \cdot CH_2 \cdot CO_2H \rightarrow CO \begin{array}{c} NMe \cdot CH_2 \\ | \\ NH \cdot CO \end{array}$$
(Neubauer, Annalen, 1866, 137, 294); or by mercuric oxide and water into oxalic acid and methylguanidine; or by heating with soda-lime into ammonia and methylamine. Treated with mercuric acetate in presence of sodium carbonate it yields *α-methylguanidinoglyoxylic acid* $NH_2 \cdot C(NH) \cdot NMe \cdot CO \cdot CO_2H, 2H_2O$; glistening flakes, m.p. 203°-204° (Baumann and Ingvaldsen, J. Biol. Chem. 1918, 35, 277). When potassium hydroxide is added to an aqueous solution of creatine and silver nitrate until the white precipitate first formed just redissolves, the liquid solidifies to a transparent gelatinous mass immediately reduced on heating, or in the course of a few hours at the ordinary temperature. The addition of potassium hydroxide to a solution of creatine and mercuric chloride precipitates a white crystalline compound ($C_4H_8O_2N_3)_2Hg,HgO$ (Engel, Compt. rend 1874, 78, 1707; 1875, 80, 885) Creatine is converted into creatinine by heating with dilute mineral acids for some hours (Dessaignes, J. 1857, 544), or at 117° for 15 minutes (Benedict and Myers, Amer. J. Physiol. 1907, 18, 362); or by boiling down to dryness the solution of creatine to which has been added an equal volume of hydrochloric acid (Benedict, J. Biol. Chem. 1914, 18, 192); or by heating with water only in sealed tubes at 100° for 2-3 days (Neubauer, Zeitsch anal Chem. 1863, 2, 33). Smorodincev (J. Russ Phys Chem. Ges. 1915, 47, 1275-9) obtained a double salt of silver nitrate and creatinine, $C_4H_7ON_3 \cdot AgNO_3$ (decomposes 188°-191°) on treating pure creatine with silver nitrate in a slightly acid solution.

Creatine forms soluble normal salts with the mineral acids (Dessaignes, Annalen, 92, 409), and readily soluble compounds with zinc chloride $C_4H_9O_2N_3, ZnCl_2$; and cadmium chloride $C_4H_9O_2N_3, CdCl_2, 2H_2O$ (Neubauer, *ibid.* 137, 300).

Creatine is not usually estimated directly; it is converted into creatinine (*q.v.*), and estimated as such; for the estimation of creatine in urine, *v.* Benedict (J. Biol. Chem. 1914, 18, 192) and Walpole (J. Physiol. 1911, 42, 301), who makes use of the fact that a pale red colour is given by alkaline solutions of creatine and not by creatinine when a trace of diacetyl is added. For its estimation in blood *v.* Greenwald (Proc. Soc exp. Biol. Med. 1917, 14, 115).

α-Guaninopropionic acid, alacreatine

$$NH_2 \cdot C(NH)NH \cdot CHMe \cdot CO_2H$$

from alanine and cyanamide (Baumann, Annalen. 1873, 167, 83), an isomeride of creatine forms, sparingly soluble prisms.

The homologues of creatine are prepared by the action of cyanamide on the corresponding amino-acid in the presence of ammonia, *e.g.* *α-aminocaproycyamine*

$$NH_2 \cdot C(NH)NH \cdot CH(CO_2H)CH_2 \cdot CHMe_2$$

from leucine and cyanamide (Duvillier, Compt. rend. 1886, 103, 211; 1887, 104, 1290). According to Duvillier (*l.c.*) methyl- or ethylamino-acids yield with cyanamide the corresponding *creatinine*. The *creatine* is formed only in the case of methylglycocine and β-methyl-aminopropionic acid, the latter yielding *methyl-alacreatine* $NH_2 \cdot C(NH) \cdot NMe \cdot CHMe \cdot CO_2H$ (Lindenberg, J. pr. Chem. 1875, [2] 12, 253). This generalisation is not confirmed by Gansser (Zeitsch. physiol. Chem. 1909, 61, 16), who obtained the creatinine and not the creatine
from α-methylaminopropionic acid and cyanamide, but prepared β-*methylguaninopropionic acid* $NH_2 \cdot C(NH)NMe \cdot [CH_2]_2CO_2H, H_2O$, m.p. 201°–202°, from cyanamide and β-methylaminopropionic acid, and γ-*methylguaninobutyric acid* $NH_2 \cdot C(NH)NMe \cdot [CH_2]_3CO_2H$, m.p. 307°, from cyanamide and γ-methylaminobutyric acid.

Formaldehyde and creatine yield the *compound* $C_6H_{11}O_3N_3, 2H_2O$, decomposing at 250°, and forming a *dibenzoyl derivative* $C_6H_9O_3N_3Bz_2$, m.p. 265°–266° (Jaffé, Ber. 1902, 35, 2896).

Phthalyldicreatine

$$C_6H_4[CO \cdot NH \cdot C(NH) \cdot NMe \cdot CH_2 \cdot CO_2H]_2$$
has m.p. 212° (Urano, Beit. Chem. Physiol. Path 1907, 9, 183). *Diacetylcreatine*

$$NH \cdot C(NHAc)NMe \cdot CH_2 \cdot CO_2Ac$$

has m.p. 165° (Erlenmeyer, Annalen, 1895, 284, 50). M. A. W.

CREATININE, *Methylglycocyamidine*
discovered by Liebig in human urine (Annalen, 1847, 62, 268), the amount excreted being 26–30 mg. per kilo weight of body per diem (Koch, Amer. J. Physiol 1905, 15, 1), is also a constant constituent of the urine of horses, cows, dogs, pigs, and rabbits ; it is found in muscle (Shaffer and Reinoso, Proc Soc Biol. Chem. 1910, 7, xxx. ; Meyers and Fine, J Biol Chem. 1915, 21, 383) and occurs in small quantities in the flesh of fish, about 0 2 p c in the case of cod (Poulsson, Chem Zentr 1904, ii 30) ; for other estimations, *see* Okuda (8th Int. Cong. App. Chem, 1912, 18, 275) ; and traces (0·000098 p c , Cooper Colls, J. Physiol 1896, 20, 107) are found in the blood. According to Folin and Denis (J Biol Chem. 1914, 17, 487) normal human blood contains 1 mg creatinine and 6–8 mg. of creatinine and creatine per 100 grs. blood. In domestic animals it is about the same ; in birds 0 1 mg creatinine but 11 mg creatinine and creatine. It is probably a normal constituent of all soils (Shorey, J Amer Chem. Soc. 1912, 34, 99–107 ; Sullivan, J. Amer. Chem. Soc. 1911, 33, 2035–42) and vegetable matter (Oshima and Ariizumi, J Coll. Agric. Tohoku Imp. Univ. 1914, 6, 17–25).

Under normal conditions, the excretion of creatinine is constant from day to day and hour to hour (Shaffer, Amer. J. Physiol. 1908, 23, 1) ; it is not affected by diet or exercise (Folin, *ibid.* 1905, 13, 45, 66, 117 ; Pekelharing, van Hoogenhuyze Verploegh. Proc. k. Akad. Wetensch, Amsterdam, 1905, 8, 363 ; Klercker, Beit. Chem. Physiol. Path. 1906, 8, 59). It is now generally regarded as one of the end products of endogenous nitrogenous katabolism, the liver continuously forming creatinine from substances carried to it by the blood ; *cf.*, however, Folin and Denis (J. Biol. Chem. 1914, 17, 500–501) ; part of this creatinine furnishes the muscular creatine by the change it undergoes in the developing muscle, *v.* CREATINE ; the rest is excreted by the kidneys (Folin, *l.c.* ; Mellanby, J. Physiol. 1908, 36, 447 ; Lefmann, Zeitsch. physiol. Chem. 1908, 57, 476). In cases of fever or starvation, the amount of urinary creatinine is increased, the material wanted for contraction

being drawn from the muscular proteids (Pekelharing, van Hoogenhuyze Verploegh, *l.c.* ; Leathes, J. Physiol. 1907, 35, 205). In cancer of the liver, the urinary creatinine is diminished and the creatine is increased (Mellanby, *loc. cit.*).

Creatinine is extracted from urine by evaporating to one-third the original volume, decanting from the salts that crystallise out, precipitating with lead acetate and filtering, removing the lead from the filtrate and precipitating the creatinine as the sparingly soluble double salt with mercuric chloride. This is separated, decomposed by sulphuretted hydrogen, and the creatinine crystallised from the filtrate as the hydrochloride (Maly, Annalen, 1871, 159, 279) , or by precipitating it as creatinine potassium picrate with subsequent decomposition of the double salt (Folin, J. Biol. Chem. 1914, 17, 463–467 ; Benedict, *ibid.* 1914, 18, 184–190).

For extraction from the body tissues and fluids, *see* Costantino (Chem Zentr. 1915, 11, 287, from Arch farm. sper 1915, 19, 254–258.)

Creatinine bears the same relation to creatine as hydantoïn to hydantoïc acid
and is prepared by boiling creatine with dilute mineral acids for some hours (Liebig, Annalen, 1847, 62, 628) or by heating at 117° for 15 minutes under pressure (Benedict and Myers, Amer. J. Physiol. 1907, 18, 362), or by boiling down to dryness with an equal volume of hydrochloric acid (Benedict, J. Biol. Chem. 1914, 18, 192).

Creatinine can be prepared synthetically by heating guanidine carbonate with sarcosine at 140°–160° (Horbaczewski, J. Pharm. Chim. 1885, 86). A quantitative yield is obtained by heating N-methylglycocyamine with an organic acid (D. R. P. 281051, from J. Soc. Chem. Ind. 1915, 34, 637).

By heating creatinine with silver nitrate and baryta in excess on the water-bath for about an hour a nearly quantitative yield of methyl guanidine can be obtained (Ewins, Bio-Chem. J. 1916, 10, 104). By oxidation with mercuric acetate it yields α-methyl guanidinoglyoxylic acid (Baumann and Ingvaldsen, J. Biol. Chem. 1918, 35, 277).

Creatinine forms anhydrous monoclinic prisms soluble in 11·5 parts of water or 100 parts of absolute alcohol at 16° (Liebig, *l.c.*), and separates on slow evaporation of dilute solutions in square plates containing $2H_4O$ (Salkowski, Zeitsch. physikal. Chem. 1880, 4, 133). It is a weak base, displacing ammonia from its salts, and forming soluble salts with the mineral acids (Liebig, *l.c.*), the *picrate* $C_4H_7ON_3 \cdot C_6H_3O_7N_3$, m.p. 212°–213°, crystallises in sparingly soluble yellow needles ; the *acid picrate*

$$C_4H_7ON_3 \cdot 2C_6H_3O_7N_3$$
has m.p. 161°-166° (Mayerhoffer, Wien. Klin. Woch. 1909, 22, [3]); the *tartrate*

$$(C_4H_7ON_3)_2 \cdot C_4H_6O_6$$
decomposes at 207°-209°; the *oxalate*

$$(C_4H_7ON_3)_2 \cdot C_2H_2O_4$$
is sparingly soluble in alcohol (Poulsson, Chem. Zentr. 1904, ii. 30). Creatinine forms characteristic double salts with platinic chloride $(C_4H_7ON_3,HCl)_2 \cdot PtCl_4$, orange-red plates, m.p. 220°-225°; with auric chloride

$$C_4H_7ON_3 \cdot HCl \cdot AuCl_3$$
yellow crystals, m.p. 170°-174°; with potassium picrate $C_4H_7ON_3 \cdot C_6H_3O_7N_3 \cdot KC_6H_2O_7N_3$, lemon-yellow prisms, 100 parts of water dissolve 0 1806 part of the salt at 19°-20°; with zinc chloride $(C_4H_7ON_3)_2 \cdot ZnCl_2$, almost insoluble in alcohol (Heintz, J. 1847, 48, 883); with mercuric chloride $4(C_4H_5HgON_3 \cdot HCl) \cdot 3HgCl_2, 2H_2O$ (Johnson, Proc. Roy. Soc 1886, 43, 493).

Creatinine is converted into creatine by the action of cold dilute ammonia or calcium hydroxide solutions; or on treatment with iodine (Reichardt, Pharm. Zeit. 1911, 56, 922); boiling baryta solution converts it into ammonia and methyl hydantoïn; with alkaline oxidising agents it yields methylguanidine and oxalic acid, but is comparatively stable towards acid permanganate solutions (Jolles, Ber. 1902, 35, 160).

The presence of creatinine in dilute solution or in urine can be detected by (1) Maschke's test (Zeitsch. anal. Chem. 1878, 134), which consists in the formation of a sparingly soluble double compound of creatinine and cuprous oxide, when the suspected solution is heated at 50°-60° with Fehling's solution; as the cuprous oxide is formed by the oxidation of part of the creatinine, it is advisable to add a little glucose to the mixture; the test is sufficiently delicate to allow of the detection of $\frac{1}{10000}$ part of creatinine (2) Weyl's test (Ber 1878, 11, 2175) consists in the production of a ruby-red colouration, changing to yellow when, to a solution of creatinine, a few drops of 10 p.c. sodium nitroprusside and the same quantity of 10 p.c. sodium hydroxide or carbonate solution are added On acidifying the solution with acetic acid and boiling, the colour becomes emerald green, changing to blue, due to the formation of Prussian blue (Salkowski; Colasanti, Gazz. chim. ital. 1887, 17, 129). Guareschi (Ber. 1888, 21, Ref. 372) has shown that this reaction is given by other compounds than creatinine containing the $—CO \cdot CH_2—$ complex. (3) Jaffé's test (Zeitsch. physiol. Chem. 1886, 10, 399) is the production of a deep-red colour, when picric acid and an excess of sodium hydroxide solution are added to the liquid containing the creatinine. Chapman (Chem. News, 1909, 100, 175) has shown that the colour is due to the sodium salts of amino-dinitrophenol (picramic acid), and diamino-nitrophenol formed by the reduction of the picric acid by the creatinine; if the creatinine is present in excess, reduction to the colourless triaminophenol occurs.

The older methods for the estimation of creatinine were based upon the isolation of the base in the form of its sparingly soluble double salt with mercuric or zinc chloride, and either weighing the precipitate or estimating the metal

or the nitrogen in the compound (Neubauer, Annalen, 119, 35; Salkowski, Zeitsch. physiol. Chem. 1886, 10, 113; Grocco, Chem. Zentr. 1887, 17; Kolisch, *ibid.* 1895, i. 814; Ladd and Bottenfield, Amer. Chem. J. 1898, 20, 869). Edleson (Chem. Zentr. 1909, i. 108) recommends precipitating the sulphate in the presence of alcohol and ether, dissolving it in water, and titrating the solution with standard barium hydroxide solution, using phenol phthalein as indicator.

The method generally adopted for estimating creatinine in urine is Folin's colorimetric method, based on Jaffé's reaction (Zeitsch. physiol. Chem. 1904, 41, 223). N/2 potassium dichromate solution is placed to a height of 8 mm. in one tube of a Duboscq colorimeter; 100 c.c. of the urine is placed in a 500 c c. flask with 10 c.c. of a 1 2 p.c. solution of picric acid and 5 c.c. of a 10 p.c. solution of sodium hydroxide, left for a few minutes and made up to the mark. If x is the length of this solution in the second tube required to give the same colour effect as the 8 mm. of the standard dichromate solution in the first tube, then $8 \cdot 1 \times 10/x = mg$. of creatinine in the 10 c c. of the urine. If x is less than 5, only 5 c c. of urine should be used; if x is greater than 13, then 20 c.c. of urine should be used. If creatine is also present in the urine, the amount may be estimated by first determining the creatinine as above, then converting the creatine in another 10 c.c of the urine to creatinine by heating it with 5 c c. of N/2 HCl on the water-bath for 3 hours or for 15 minutes at 117° under pressure (Benedict and Myers, Amer. J. Phys. 1907, 18, 362), or by boiling down to dryness with an equal volume of hydrochloric acid (Benedict, J. Biol. Chem 1914, 18, 191-194), and estimating the total creatinine. The difference between the two results represents the amount of creatinine equivalent to the creatine originally present. (For precautions to be observed regarding temperature, time, and dilution, in applying this method for the estimation of creatinine, compare Chapman, Chem. News, 1909, 100, 175.) Folin and Morris (J. Biol. Chem. 1914, 17, 469-473) recommend the use of a standard solution of creatinine instead of a dichromate solution; *see also* Folin and Doisy (*ibid.* 1917, 28, 349-356); Gettler (*ibid* 29, 47). The presence of dextrose, acetone and aceto-acetic acid interferes with the final colour reaction and various suggestions have been made for overcoming the difficulty (Graham and Poulton, Proc. Roy. Soc. 1914, B, 87, 212; Greenwald, J. Biol. Chem. 1913, 14, 87; Rose, J. Biol. Chem. 1912, 12, 73-80). Morris, J. Biol. Chem. 1915, 21, 201-208, recommends the preliminary precipitation of creatinine as the double potassium picrate. *See* Bauman and Ingvaldsen (*ibid.* 1916, 25, 196-200) for the quantitative precipitation of creatinine with potassium picrate.

An isomeride of creatinine, *alacreatinine*,

NH —— CO

HN : C

NH —— CHMe
was prepared in 1873 (Ber. 6, 1371), and other isomerides have been described by Korndörfer, Arch. Pharm. 1904, 242, 620; Schenck,

ibid. 1910, 248, 376, and 1911, 249, 463; Schmidt, *ibid.* 1910, 248, 568; Johnson and Nicolet (J. Amer. Chem. Soc. 1915, 37, 11, 2417) obtained two methyl glycocyamidines isomeric with creatinine by the action of methylamine on the ethyl ester of benzoylpseudoethylthiohydantoic acid.

Two isomeric *nitrosocreatinines* were obtained by Dessaignes (Annalen, 1856, 97, 341) and Marcker (*ibid.* 1865, 133, 305) by passing the nitrous fumes from the action of nitric acid on arsenious oxide into an acid solution of creatinine The less soluble *α-nitrosocreatinine* $C_4H_8O_2N_4$ decomposes at 210°, forming a colourless liquid that quickly solidifies to a brown mass from which a new *base* $C_7H_{12}O_3N_{10}$ (?) can be extracted; it forms a crystalline *nitrate, hydrochloride,* and *platinichloride,* and yields the *bromoderivative* $C_4H_7O_2N_4Br$. The more soluble *β-nitrosocreatinine* $C_4H_8O_2N_4$ melts at 195° to a brown liquid and decomposes at 220°.

According to Kramm (Chem Zentr 1898, 1 37), the yellow colour formed by the interaction of sodium nitroprusside and sodium hydroxide on creatinine (*cf.* Weyl, Ber. 1878, 11, 2175), is due to the formation of a *nitrosocreatinine* $C_4H_6O_2N_4$, which can be isolated as a colourless crystalline precipitate by adding acetic acid to the yellow alkaline solution and shaking vigorously. According to Schmidt and Hennig (Arch. Pharm. 1912, 250, 345) this is an oxime, they find that on treatment with sodium nitrite in nitric acid solution creatinine yields a mixture of methyl hydantoin oxime, m p. 193° 194°, and creatinine oxime, which begins to discolour at 250° but does not melt.

The following *acyl-* and *alkyl-* derivatives of creatinine have been prepared : *Benzoylcreatinine* $C_{11}H_{11}O_2N_4$, pale yellow needles, m p. 187° (Urano, Beit Chem. Physiol. Path. 1907, 9, 183); *methyl, dimethyl* and *trimethyl creatinine* and *salts* (Korndorfer, Arch Pharm. 1904, 242, 641; Kunze, Arch. Pharm. 1910, 248, 578–93).

Methyl creatinine
$$HN : C \begin{matrix} NMe \cdot CH_2 \\ | \\ NMe \cdot CO \end{matrix}$$
gives an aurichloride, m.p. 170°–171°, and dimethyl creatinine gives an aurichloride, m. p. 128°–129°, and a platinichloride, m p. 177°–179°. According to Kunze the constitution of dimethyl-creatinine is
$$MeN : C \begin{matrix} NMe \cdot CH_2 \\ | \\ NMe - CO \end{matrix}$$
; it reacts as a

tertiary base; *ethylcreatinine*
$$C \begin{matrix} NH - CO \\ : NEt | \\ NMe - CH_2 \end{matrix}$$
(Neubauer, Annalen, 119, 50), *sec* Henzerling (Arch. Pharm. 1910, 248, 594 ; the *platinichloride* crystallises in monoclinic plates, m p. 197°–211°; *ethylcreatinine* hydriodide, m.p. 217°–219°; *diethylcreatinine* platinichloride 201°–202°); *methylamino-α-butyrocyamidine*
$$HN : C \begin{matrix} NMe \cdot CHEt \\ | \\ NH \cdot CO \end{matrix}$$
ethylamino-α-butyrocyamidine $HN : C \begin{matrix} NEt \cdot CHEt \\ | \\ NH \cdot CO \end{matrix}$

(Duvilher, Compt. rend. 1882, 95, 456; 96, 1583; 97, 1486; 100, 916; 103, 211; 104, 1290).—For *Xantho-, Cruso-,* and *Amphi-creatinine* v. *Xanthocreatinine.* M. A. W.

CREOLIN. A disinfectant consisting of an emulsion of coal tar cresols with soap.

CREOSOFORM. A condensation product of formaldehyde and creosote. Used as an internal antiseptic.

CREOSOL *v.* CREOSOTE, WOOD TAR.

CREOSOTAL (*Creosote carbonate*) is a mixture of carbonates of the phenols present in wood creosote, of which the chief are guaiacol and cresol.

It is produced by heating creosote with a benzene solution of carbonyl chloride (phosgene) under pressure (Heyden, Eng Pat 19074, 1890), but is generally prepared by passing phosgene gas through a solution of beechwood creosote in caustic soda solution The carbonate separates as an oil, and is washed with dilute caustic soda and finally with water,

Creosotal is a viscid yellowish liquid, insoluble in water, but soluble in alcohol, chloroform, benzene, &c (Aufrecht, Pharm. Zeit. 1908, 53, 480). When it is boiled with caustic potash, the odour of creosote is evolved. It is quite odourless, tasteless, and non-irritant in its action upon the mucous membrane, and is therefore much used as a substitute for creosote in the treatment of bronchial affections and pneumonia, especially in children (Weber, Pharm. J. 68, 115; Toff, *ibid* 73, 414) The dose for adults is about 60 grams daily, and it is usually given in an emulsion (Haefelin, Pharm. Zeit. 49, 141).

CREOSOTE or **KREOSOTE** (from κρέως, contracted genitive of κρέας, meat, and σωζώ, I save or preserve). Wood tar, and coal tar, when subjected to distillation, yield fractions technically known as ' creosote,' both of which, the latter more especially, find extensive and important uses in the industrial arts.

Reichenbach, in the year 1832, applied the term ' kreosote ' to a substance derived from wood tar, and which has been found to possess powerful antiseptic properties; shortly afterwards, Runge discovered carbolic acid in coal tar, and the two products were, for a considerable time, regarded as identical; similar compounds, however, have since been procured from other sources, and in order to prevent confusion, it has been suggested to restrict the use of the term 'creosote' to the use in a generic sense as referring to all the phenols and phenoloid bodies derived indifferently from coal, wood, coke-oven, blast-furnace, and shale-oil tars. The enormous extension of the use of creosote oil from coal tar for the preservation of timber has resulted in the terms 'creosote' and 'creosote oil' being used commercially as meaning the

heavier distillates from coal tar and coke oven-tar, the oils from blast-furnace tar being distinguished as 'blast-furnace creosote.'

Wood-tar creosote. The tar derived from the distillation of beechwood, when subjected to further distillation, yields certain fractions that are heavier than water, and which, after agitation with solution of caustic soda, and separation from insoluble oils, are boiled with free access of air in order to oxidise various impurities present; the alkaline solution thus obtained is decomposed with dilute sulphuric acid, the crude creosote which separates is again submitted to a similar alkaline and acid treatment, and the product finally distilled, reserving the fraction passing over between 200° and 220°.

This represents the ordinary 'wood-tar creosote' of commerce. It is a complex mixture of phenoloid compounds, the proportions of which are materially influenced by the method originally followed in distilling the beechwood from which it was obtained.

Wood-tar creosote, when freshly prepared, is a colourless, transparent liquid of an oily consistency, and which retains its fluidity at a very low temperature; its sp gr. varies from 1·037 to 1·087; it boils at 205°-225°, and dissolves in about 200 parts of water; its odour is strong and penetrating, resembling that of wood smoke, or rather of smoked meat; it refracts light powerfully and burns with a very sooty flame. Wood-tar creosote is powerfully antiseptic, but its power of coagulating albumen has been denied; nevertheless, it preserves animal substances as effectively as carbolic acid. It is less caustic than carbolic acid, and is not poisonous. Wood-tar creosote may be regarded as consisting of a mixture of compounds included in several homologous series, chiefly of acid methylic ethers of catechol, and the presence of the following bodies has been established:—

Name	Formula	Boiling point
1. Monohydric phenols ·		
Phenol, carbolic acid	C_6H_5OH	182°
Cresols, cresylic acid (1-2, 1-3, 1-4)	$\{C_6H_4(CH_3)OH$	203°
Xylenols or phlorols (1-3-4, 1 3 5)	$\}C_6H_3(CH_3)_2OH$	220°
Ethyl phenol (1-2)	$C_6H_4(C_2H_5)OH$	203°
2. Methyl ethers of dihydric phenols		
Guaiacol or methyl-catechol	$\{C_6H_4\{{OCH_3 \atop OH}$	200°
Creosol or methyl-homocatechol	$\{C_6H_3(CH_3)\{{OCH_3 \atop OH}$	219°
Dimethyl-homocatechol	$\}C_6H_3(CH)(OCH_3)_2$	214°–128°
Homocreosol or di-methyl guaiacol	$\{C_6H_2(CH_3)_2\{{OCH_3 \atop OH}$	230°
Ethyl-guaiacol(1-3-4)	$C_6H_3(C_2H_5)\{{OCH_3 \atop OH}$	—
Cœrullgnol or pro-pyl-guaiacol	$\{C_6H_3(C_3H_7)\{{OCH_3 \atop OH}$	241°
3. Methyl ethers of trihydric phenols:		
Dimethyl-pyrogallol	$C_6H_3\{{OCH_3 \atop {OCH_3 \atop OH}}$	253°
Dimethyl - methyl-pyrogallol	$C_6H_2(CH_3)\{{OCH_3 \atop {OCH_3 \atop OH}}$	265°
Dimethyl - propyl-pyrogallol (picamar)	$C_6H_2(C_3H_7)\{{OCH_3 \atop {OCH_3 \atop OH}}$	285°
Methyl-propyl-pyro-gallol	$C_6H_2(C_3H_7)\{{OCH_3 \atop {O \atop OH}}$	290°

Of these compounds, phenol is present in extremely small quantity, paracreosol in larger,

and phlorol in notable proportion, but the two principal constituents of creosote are guaiacol and creosol, although not equally present in all varieties; guaiacol, according to Allen, predominates in Rhenish creosote, whilst with Morson's creosote from 'Stockholm tar,' creosol is the chief constituent. Homocreosol and cœrulignol are present in small quantity only, but, according to Gratzel, the latter body possesses such energetic and astringent qualities that a single drop placed on the tongue causes bleeding; purified creosote should therefore be absolutely free from this compound, which may be detected by the blue colouration produced by barium hydroxide.

The less valuable portions of wood-tar creosote were found by A W. Hofmann to contain the methyl ethers of pyrogallol and its homologues; these bodies are of interest from the remarkable colouring matters (originally discovered by Runge) which may be derived from them by oxidation; thus, if the sodium derivative of dimethyl-pyrogallol be mixed with the sodium derivative of dimethyl-methyl-pyrogallol and excess of sodium hydroxide and heated in the air, a substance called *eupittonic acid* is formed, according to the following equation:—

$$(C_8H_{10}O_3)_2 + C_9H_{12}O_2 + 2O_2 = C_{25}H_{26}O_9 + 3H_2O$$
Eupittonic acid has the constitution of a hexamethoxyl aurin $C_{19}H_8(OCH_3)_6O_3$. Reichenbach's 'pittical,' called by Wichelhaus 'eupittone,' was a salt of eupittonic acid. Wood-tar creosote has been met with adulterated to a considerable extent with crude carbolic and cresylic acids, and from the fact that the reactions of these substances closely resemble those of wood creosote, the distinction between the two, especially when in admixture, is attended with some difficulty. Genuine beechwood tar is soluble in solutions of caustic alkalis, and forms a crystalline compound with potassium hydroxide, but not with sodium hydroxide; on the other hand, it is practically insoluble in strong ammonia.

An alcoholic solution should give no colouration whatever (blue or red) with baryta water; such colouring indicates the presence of cœrulignol and other impurities.

The composition of beechwood and oak creosotes, freed from hydrocarbons, is given by Béhal and Choay (Compt. rend. 1894, 119, 166), as follows:—

	Beech	Beech	Oak
Distillation temperature, °C.	200–220°	200–210°	200–210°
Specific gravity	1·085	1·085	1·068
Monophenols	39·0	39·0	55·0
Guaiacol	19·7	26·5	14·0
Creosols and homologues	40·0	32·1	31·0
Loss	1·3	2·4	—

Owing to the demand for guaiacol for pharmaceutical purposes, wood-tar creosote, as it occurs in commerce, is frequently found to have been deprived of part or the whole of the guaiacol it contained.

Methods for the determination of guaiacol in wood creosote are given by Béhal and Choay (Compt. rend. 1893, 116, 197); M. Adrian (Nouv. Rem. 13, 97); L. F. Kebler (Amer. J. Pharm. 1899, 409).

Wood-tar creosote is sharply distinguished from the coal-tar acids by its insolubility in absolute glycerol; it is also distinguished from the coal-tar acids by its reaction with an ethereal solution of nitrocellulose; shaken with half its volume of collodion, B.P., Calvert's No. 5 carbolic acid coagulates the gun-cotton. Morson's creosote does not precipitate the nitrocellulose from collodion, but mixes perfectly with the ethereal solution; when a mixture of equal volumes of Morson's creosote and Calvert's No. 5 acid is treated with the collodion, the precipitation is very marked.

Creosote from coal tar and other sources. In pharmaceutical circles the term 'creosote' is still retained for products of the carbonisation of wood, but, generally speaking, it is recognised in industry as applying to a mixture, consisting principally of hydrocarbons distilled from coal tar, the latter being either of gasworks origin, or from the carbonisation of coal in coke ovens. At the time when anthracene was a valuable commercial product, the fraction of coal tar containing this material was usually collected separately, the crude anthracene being removed by filtration, and the oil separated therefrom being placed on the market under the names 'anthracene oil,' 'green oil,' or 'heavy oil.' In more recent times many tar distillers have found the recovery of naphthalene unremunerative, and this is especially the case where the crude tar is of such a nature that an appreciable proportion of solid paraffinoid hydrocarbons appears. The whole of the anthracene fraction has therefore frequently found its way to the creosote storage. Other distillates of coal tar have also been passed into the creosote tanks at various works, including the 'sharp oil' separated during the recovery of crude naphthalene, and the 'middle oils' or 'carbolic oils,' after treatment for the removal of 'tar acids' (crude phenols). There is no very serious objection to this development, especially in view of the fact that inclusion of the anthracene fraction results in a mixture containing a large proportion of high-boiling constituents. Creosote of this nature is employed in the United States for railway work, and has been exported in recent times to that country in very large quantities by means of 'tankers.' But exception must be taken to the practice that has arisen in some cases whereby the creosote storage has largely assumed the character of a refuse pit for the disposal of various oils, and even tars, that are only marketable with difficulty, such as blast-furnace tar, blast-furnace creosote, water-gas tar, &c. It is probably most satisfactory to regard creosote as a fraction obtained during the distillation of coal tar, either of gasworks or coke-oven origin, collected between the light oil fraction and the anthracene fraction; it may or may not include the middle oils, or those portions of them remaining after partial or complete removal of tar acids or naphthalene.

Creosote from coal tar (gasworks). This consists, for the most part, of a mixture of liquid aromatic hydrocarbons with naphthalene.

The naphthalene may be present in such small quantities that the oils retain it entirely in solution, or there may be so much of it, say up to 40 p.c., or more, that the creosote exists as a solid mass at 15° C. Phenolic and basic constituents are also present, together with small amounts of paraffinoid hydrocarbons. The creosote produced from tar that is made in London and the southern districts of England, where Durham and other north country coals are largely carbonised, contains considerably more naphthalene, as a rule, than that obtained in more northerly districts, where Midland coals are retorted. On the other hand, the creosote obtained from Midland tar is far richer in tar acids than that made in London. So characteristic are these features that various creosotes are regularly known in the trade as 'Midland creosote,' 'ordinary London creosote,' &c. Scotch creosote will be dealt with later. The carbonisation of coal in gasworks has, during the last few years, developed in several directions. It was formerly the custom to work with 'light charges' of coal in the retorts, with the result that a relatively large free-space existed between the surface of the coal and the top of the retort. But about 1911 the practice was widely adopted of employing heavier charges, whereby the 'free space' was greatly reduced. The result of this change of procedure was that the volatile products of carbonisation experienced a much more rapid journey to the ascension pipes of the retort, and consequently the changes they underwent, due to thermal decomposition in the free space, were lessened. The effect of this change on the quality of the tar was very noticeable. The quality of the creosote seems to be very similar to that resulting from 'light charge' carbonisation, but there is more of it in the tar. The proportion of naphthalene in the creosote is lower, while the proportion of tar-acids is somewhat higher. The average yield of creosote from coal tar is roughly about 20 p.c. of the latter by volume.

Creosote being a mixture of many hydrocarbons, &c., it is not possible to give any definite figures for its physical and other constants, and the more so as it is highly improbable that any two makes are identical. When a sample of good quality is distilled in the laboratory, the main bulk of it usually passes over between 200° and 300° C., the bulb of the thermometer being immersed in the vapour. If the anthracene fraction be present there will be a considerable residue at the latter temperature. The calorific value is about 16,050 B.Th.U. The evaporating power (in actual practice, 'from and at 212° F.') is 12·0 lbs. The flash-point usually lies about 170°–180° F. (closed test). The refractive index of the higher fractions should be above 1·6 (Sage). Determination of the specific heat between 30° and 100° C. gave the figure 0·398. The co-efficient of expansion per °F. is about 0·000455. The specific gravity usually lies between 1·030 and 1·080. Creosote generally contains between 0·5 and 0·9 p.c. of sulphur.

Although these figures naturally differ with the various makes of creosote, and can therefore only be regarded as approximate, they, nevertheless, are frequently found useful in industry, and several serve as evidence of admixture of

adulterants of a paraffinoid nature, such as have already been mentioned in this article.

Creosote finds its largest application in the treatment of wood, especially railway sleepers, piles, and telegraph poles. Its employment as fuel is being very rapidly developed, chiefly in burners which serve to atomise the liquid, either by direct application of pressure, or by means of steam or air under pressure. Numerous patents have been granted for such burners, and for further information on the subject, consultation of such works as Brame's Fuel may be recommended. The employment of creosote as a fuel for Diesel engines, with or without pilot ignition, is extending, and the 'Diesel Engine Users Association' has recently issued a specification for the quality of oil considered to be best suited for that particular purpose. Creosote oil is (when freed from naphthalene) used in the preparation of disinfectants and sheep-dips. It is also employed for generating artificial light in specially designed lamps such as the 'Lucigen.'

Lamp-black is manufactured by partial combustion of creosote in a limited air supply. Recent experiments seem to indicate the possible value of creosote as a soil steriliser.

The best known methods of creosoting timber are perhaps those of Bethel, Boulton, Rüping, Curtis Isaacs, Lawry, Rutgers. In some of these processes the creosote is applied under pressure, occasionally after first placing the timber under a vacuum, and at other times the oil is employed at a temperature sufficiently high to boil the sap out of the wood *in vacuô.*

Many specifications for creosote considered to be best suited for this work have been published; probably the best known is that of Dr. Tidy. The advantages resulting from the creosoting of timber are summarised by Tidy as follows:—

Physical.—Choking of pores, and thus rendering the material non-absorbent of water.

Biochemical.—Inhibition of germ life.

Chemical.—Coagulation of albumen by the tar acids.

Probably most of the creosote sold for creosoting at the present time is subject to the American 'Maintenance of Way' specification. The most important feature is the insistence on a large proportion of high-boiling oils. It is estimated that in 1913, 35,000,000 gallons of creosote were exported to the United States from the United Kingdom. At various times emphasis has been given to one or more of the following properties of creosote for treatment of timber :

1. Maximum naphthalene content.
2. Minimum naphthalene content.
3. Tar acids.
4. Proportion of high-boiling constituents.

It is considered that the life of railway sleepers is increased five-fold by creosoting. Experiments by J. M. Weiss (U.S.A.) (*see* J. Soc. Chem. Ind. 1911, 1348), show that coal tar creosote is more efficient as a preservative than is that from water-gas tar, in the proportion of about 6 to 1. Creosote is used for the treatment of wooden paving blocks, for which purpose it is valuable both with phenoloid compounds, and also as a means of rendering the blocks impervious to

water, the absorption of which would give rise to expansion of the wood.

The following are among the tests commonly applied to creosote :—

1. Distillation.
2. Liquidity of residue left after distillation.
3. Water.
4. Solid matter (naphthalene, &c.) deposited at 60° F.
5. Loss on evaporation under specified conditions.
6. 'Absorbent spot '—a drop of the oil being placed on blotting-paper, and examination made for particles of ' free carbon ' indicative of adulteration by crude tars.
7. Tar acids.
8. Specific gravity.
9. Colour.
10. Fluorescence.
11. Refractive index—serving to indicate presence or absence of paraffinoid hydrocarbons, or tars containing them.
12. Flash point.
13. Matter insoluble in benzol.
14. Sulphonation.

(*Cf.* Sage, J. Soc. Chem. Ind. 1911, 588.)

Creosote from coke-oven tar is very similar to that from gasworks tar.

Oils from low-temperature processes of carbonisation. A great deal of work has been carried out in investigating the products of these systems. Some of the processes are worked under partial vacuum. The volatile products of carbonisation are not subjected to the secondary thermal decompositions that are incidental to high-temperature work in horizontal retorts, with the result that the proportion of aromatic hydrocarbons appearing in the oils is very much smaller, the specific gravity of those fractions corresponding to creosote being lower than 1·000. The content of tar acids is very much higher, though there is but little actual phenol. From the highest fractions solid paraffinoid hydrocarbons are frequently deposited. Work by Pictet and Bouvier, on the carbonisation of coal at low temperatures and in partial vacuum, points to the conclusion that the primary condensible products are similar to the constituents of certain petroleums, consisting to a considerable extent of terpenes and naphthenes. No solid aromatic hydrocarbons are present. On subjecting these low-temperature tars to heat by passage through a tube or over red-hot coke, benzene, naphthalene, anthracene, &c., are formed, the resulting oils being very similar to ordinary coal tar creosote. According to Wheeler, 'vacuum' tar is largely a mixture of ethylenic, naphthenic and paraffin hydrocarbons, and homologues of naphthalene, together with phenoloid compounds, chiefly cresols and xylenols. Aromatic solid hydrocarbons are generally absent. D. Trevor Jones concludes that the ordinary products of coal tar result from the action of heat on a tar which is formed in the first instance, and which is similar to that obtained under low-temperature conditions. The naphthenes, paraffins and unsaturated hydrocarbons are decomposed to produce olefines, which are at their maximum at 550° C. The olefines vanish at 750° with the simultaneous appearance of naphthalene and of large quantities of hydrogen. He further

concludes that acetylene plays an insignificant part in the formation of coal tar products. Low temperature carbonisation on the large scale yields a very oily tar amounting to 25 or more gallons per ton of coal. This tar is rich in those oils corresponding in distilling range to the creosote of normal tar. In the carbonisation of cannel coal by such processes as much as 50 gallons of tar is obtained.

Creosote from vertical retort tar is characterised by its low content of naphthalene, its high content of tar acids (chiefly higher homologues of phenol), and the large proportion of paraffinoid bodies present, the latter being sufficient to bring the specific gravity below 1·000.

West introduces steam during the process of vertical carbonisation, using continuous vertical retorts The yield of tar is increased very considerably and reaches 20 gallons per ton. The tar is of low specific gravity and gives a large ' creosote' fraction. The tars evolved during the carbonisation of coal in vertical retorts are not subject to such high temperatures as in the case of horizontal retorts. Consequently these tars resemble, to a certain extent, the low-temperature products already described. Similar remarks apply to the tars from blast furnaces and from power-gas producers, where coal is employed as fuel.

Blast furnace creosote. This is sometimes known as ' phenoloid.' It resembles vertical retort creosote in many ways. The specific gravity of the hydrocarbons is low, the proportion of tar acids is high, reaching 20–35 p.c., though there is little phenol. The phenoloids from blast-furnace tar, extracted by Watson Smith, contained only 1·33 p.c of real phenol, boiling at 182°, whereas the tar acids from Lancashire tars yielded 65 p.c. of crystallisable carbolic acid.

The fractions passing over between 210° and 230° contain phlorol and creosol, and those following at a higher temperature, viz 360°, furnish compounds allied to the cupittonic acid obtained from wood tar.

This creosote has a very strong and characteristic odour. Blast furnace creosote, which is sometimes even the crude tar from which it is distilled, is often mixed with coal tar creosote, and several of the tests generally applied to the latter are employed for the purpose of detecting this undesirable adulterant.

Blast-furnace creosote oil is now produced in large quantities in Scotland. It is employed to a certain extent for creosoting timber, in producing the ' Lucigen' light, and as a liquid fuel. It furnishes from 20 to 35 p.c. of phenoloid substances soluble in caustic soda, as against 4 to 7 p.c. in London coal-tar creosote, and about 16 p.c. for Midland and country make. Allen and Angus have secured by patent their use as an antiseptic under the name of ' neosote,' a word signifying ' new preserver' (Eng. Pat. 11689, August 29, 1887). Experiments have shown that the substance compares favourably with carbolic acid, whilst its caustic properties, when applied to the skin, are much less marked. When freshly prepared, the fluid is almost colourless, and bears a great resemblance to wood-tar creosote.

Creosote from producer tar. In cases where

bituminous coal is gasified a tar is formed, the creosote from which is similar in several respects to the blast-furnace oil. Tar acids and paraffinoids are present in large quantity.

Creosote from water-gas tar is characterised by the absence of tar acids. It is usually rich in paraffins, of low specific gravity, and may contain anthracene and naphthalene.

Scotch creosote is characterised by its large content of paraffinoid hydrocarbons and consequent low specific gravity.

Employment of creosote oils for lighting.— Creosote oil has long been employed as a source of light in the construction of harbours and outdoor work, where smoke was of little consequence or inconvenience ; but when it is wished to burn this oil to the greatest advantage and with the least possible amount of smoke and soot, it becomes necessary to employ lamps so constructed that a jet of air or steam, more or less superheated, may be introduced in such a manner as to ensure more perfect combustion. Hartmann and Lucke (D. R. P. 9195, Aug. 9, 1879) constructed a lamp specially intended for the consumption of creosote oils, in which the oil is automatically supplied to a dish-shaped receptacle, over which is placed a funnel-shaped cylinder. In the centre of the dish or receptacle receiving the oil from its attached reservoir, is placed a conical tube, reaching a little above the surface of the oil, and through which a jet of superheated or dry steam may be driven. In using the lamp, the dish or receptacle referred to is allowed to fill with oil ; it is then ignited at its surface, the funnel-shaped cylinder placed over it, and steam cautiously admitted through the conical tube. It will readily be seen that the arrangement closely resembles the ' Herapath blowpipe,' with the difference that the steam is forced through a body of combustible fluid, issuing just above its surface, in place of air forced through a body or envelope of combustible gas, and issuing at a point or position that may be called its surface.

The oil thus burns without wick or chimney, and affords a light of 180 standard candles, with an hourly consumption of a little over 2 lbs. of creosote.

An apparatus for a similar purpose has been patented by Lyle and Hannay, under the name of the ' Lucigen.' It consists of an oil tank or reservoir, fitted with a special burner at the top of a tube, which may be extended to any length ; into this reservoir compressed air is introduced by an indiarubber pipe, so attached as to make the ' Lucigen' portable. On the compressed air being admitted into the oil tank or receptacle, it forces the oil up through an internal tube, and, escaping at the same time with the oil in the burner, produces a spray which is set on fire. A light of about 2000 candle-power is given by the ' Lucigen.' The flame is large, the light well diffused, and the eyes are not dazzled by it. There is little or no smoke from the flame, and the lamp burns equally well under heavy rain or spray ; it requires no lantern, and has no parts which can be damaged by rough usage. In the ' Doty' and ' Wells' lights, pressure is brought to bear on the surface of the oil or creosote by means of an air pump, whereby the oil is forced through a coil surrounding the lower portion of the flame, and becomes distilled into gas.

Creosote oil has also been employed for the purpose of illuminating and heating, by direct conversion into permanent gas. A ton of creosote is capable of yielding 13,300 cubic feet of gas, with an illuminating power of 14 candles ; a yield of 29,300 cubic feet may be obtained, but of 8½ candle-power only ; the chief drawback to this method of utilisation is the high temperature necessary to decompose the oils, which results in the production of low candle-power gases.

Employment of creosote as fuel.—Creosote oil is extensively used as a fuel, both for marine and stationary purposes and especially. for furnaces for heating iron rods for the manufacture of bolts and rivets. From theoretical considerations, it would appear to be eminently adapted to the purpose, 1 lb. of coal-tar creosote, when effectively burnt, being capable of evaporating 11·24 lbs. of water, a result which is considerably in excess of that obtained from coal or coke.

Various methods have been devised for burning the oil to the greatest advantage. These may be briefly summarised under the following heads :—

1. Injection into the furnace by means of compressed air with ' atomising ' apparatus.

2. Injection into the furnace by means of steam with ' atomising ' apparatus.

3. Feeding into the furnace by simple gravitation, alone or in combination with coke.

G. F. Dexter (Journ. Gas Lighting, June 29, 1886, 1242-1244), in a table showing the relative calorific values of certain coal-tar distillates, refers to creosote, or heavy oils, as under :

Average formula $C_{14}H_{16}$; b p. 240° to 270° and upwards.

Proportionate weight of constituents :

| Carbon | . | . | . | 0·93913 |
| Hydrogen | . | . | . | 0·06087 |

Calorific value :

| Carbon units | . | . | . | 497 |
| Hydrogen units | . | . | . | 210 |

Employment of creosote oil as an antiseptic and for the purposes of a cattle wash and sheep dip (v. DISINFECTANTS).

Creosote oil is also now largely used to absorb benzene from coke-oven gas. The gas, after the extraction of the ammonia, is passed up towers or scrubbers down which a shower of creosote oil falls. The creosote oil takes up from 3 to 4 p.c. of benzene, and this is regained by distillation with steam, the creosote being used over and over again until, by the accumulation of dirt and tar, it becomes too viscid, when it is generally run into the tar well. This fact should not be lost sight of when estimating the proportion of creosote in coke-oven tars.

The heavier portions of creosote oil are also used to absorb naphthalene from coal gas : the gas is passed through washers containing the oil. As the oil tends to abstract some of the illuminants from the gas, it is best to add to the oil before use a small proportion of benzene sufficient to saturate the oil so that no more is absorbed from the gas.

The heavier oils are also used as a rough lubricant for brick-making machinery, and for

injecting into the brick kilns during the burning of the bricks to impart a superficial blue colour to them. The creosote acts as a reducing agent on the iron compounds in the clay, and the red colour is changed to blue.

A preparation of heavy creosote or anthracene oil with lime is used as a cart or axle grease.

Bibliography.—Lunge's Coal Tar and Ammonia ; Allen's Commercial Organic Analysis ; Warne's Coal Tar Distillation. W. H. C.

CREOSOTAL. Syn. for Creosol carbonate.

CRESATIN. Acetic ester of *m*-cresol.

CRESEGOL. Trade name for the mercury-potassium salt of cresol sulphonic acid.

CRESOL $C_6H_4(CH_3)OH$. The three isomeric cresols exist in coal tar (Williamson and Fairlie, Annalen, 92, 319 ; Ihle, J. pr. Chem. [2] 14, 442 ; Tiemann and Schotten, Ber. 11, 767, 783) in about the following proportions : orthocresol, 35 p.c. ; metacresol, 40 p.c. ; and paracresol, 25 p.c. (Schulze, *ibid.* 20, 410).

The cresols can be separated from the oily, non-crystallisable mother liquors obtained in the purification of crude phenol by fractionation and crystallisation, by dissolving them in soda lye, freeing the solution from naphthalene or other hydrocarbons by a current of steam, and then fractionally precipitating with sulphuric acid. The first fractions, owing to the greater acidity of phenol, contain chiefly cresols, and are further purified by distillation (Müller, Zeitsch. Chem. 1865, 270).

Various processes have been patented for obtaining meta- and para-cresol from crude cresol Raschig (Eng. Pat. 18334 ; D. R. P. 112545 ; J. Soc. Chem. Ind. 1900, 37), by repeated fractionation of the crude cresol, obtains a mixture containing 60 p.c. of meta- and 40 p.c. of para-cresol. This mixture is then sulphonated by means of concentrated sulphuric acid, in which *m*-cresolsulphonic acid is easily soluble, but the *p*- compound only with great difficulty. The mixture is allowed to stand for a week, and the crystals of the *p*-sulphonic acid are removed, or a soluble sodium salt, such as the sulphate, may be added in quantity sufficient to form the sodium salt of the *p*-cresolsulphonic acid. The latter is separated from the mother liquor, which consists of *m*-cresolsulphonic acid and a little sodium sulphate. The two cresols are obtained from their respective sulphonic acids by hydrolysis with superheated steam. In another process (Raschig, Eng. Pat. 25269 ; J. Soc. Chem. Ind. 1900, 1099) the mixture of the two sulphonic acids is subjected to the action of superheated steam at 120°-130°, the *m*-cresolsulphonic acid alone being hydrolysed under these conditions. The *m*-cresol distils off, and on raising the temperature to 140°-160°, the *p*-sulphonic acid is hydrolysed and *p*-cresol is obtained. *See also* Raschig, D. R. PP. 144903, 146752.

According to the Chem. Fabr. Ladenburg (D. R. P. 148703 ; Chem. Soc. Abstr. 1904, i. 312), separation of *m*- and *p*-cresols, by partial sulphonation, is incomplete. The process recommended is to heat crude cresol with sodium hydrogen sulphate at 100°-110°, dissolve the product in water, when *p*-cresol separates out as an oily layer, the *m*-cresol alone being sulphonated. Superheated steam, at 180°, is

passed in to obtain *m*-cresol, after the *p*-cresol has been separated.

Another process of the same firm (Eng. Pat. 1881; Fr. Pat. 339880; D. R. P. 152652; J. Soc. Chem. Ind. 1904, 759) consists in saturating the crude cresol with milk of lime, when the calcium salt of *m*-cresol, which is much less soluble than that of the *p*-cresol, separates out. This is filtered off, decomposed with acid, and relatively pure *m*-cresol is obtained. The crystals of the calcium salt, before decomposition with acid, may be washed with benzene to free them from the last traces of mother liquor. Reihm (D. R. P. 53307; Frdl. ii. 9) separates *m*-cresol from *p*-cresol by means of their barium salts.

Rütgers (Fr. Pat. 317512; D. R. P. 137584 and 141421; J. Soc. Chem. Ind 1902, 1410) treats the commercial mixture with anhydrous oxalic acid or an anhydrous acid oxalate. By this means, the oxalic ester of *p*-cresol alone is formed and separates out. This ester is separated and decomposed by water into *p*-cresol and oxalic acid; the *m*-cresol is obtained from the mother liquors.

Terrisse (D. R. P. 281054) sulphonates the mixture with acid of 60° Bé, at diminished pressure, neutralises with sodium carbonate and drives off the *p*-cresol in a current of steam. The residual sodium salts are decomposed by sulphuric acid and the *m*-sulphonic acid then heated with superheated steam; *see also* Hoffmann Laroche and Co., Fr Pat. 454534.

Synthetical preparation of ortho- and para-cresol.—Pure ortho- and para-cresol can be obtained by fusing the potassium salts of the corresponding toluenesulphonic acids with alkali (Engelhardt and Latschinow, Zeitsch. Chem. 1869, 620), or by diazotising the corresponding toluidines. For this purpose the toluidine (15 parts) is dissolved in sulphuric acid of sp gr. 1·8 (15 parts) diluted with 500 parts of water, treated with an aqueous solution of potassium nitrite (12 parts), and the product gradually heated with steam. The resulting cresol is then distilled with steam, the distillate treated with soda lye, then with sulphuric acid, and the liberated cresol extracted with ether and finally distilled in a current of carbon dioxide (Tiemann and Schrotter; Ihle (*loc. cit.*)).

Orthocresol can also be obtained from carvacrol by treatment with phosphorus pentoxide (Kekulé, Ber. 7, 1006). It is crystalline, sp.gr. 1·0512 at 15·5°, melts at 30° (T. and S.; Ihle; Béhal and Choay, Compt. rend. 118, 1211); boils at 188·5° (B. and C.), 188° (T. and S.) at 191° (corr.) (Perkin, Chem. Soc. Trans. 1896, 1182; Fox and Barker 191·8°), is soluble to the extent of 2·5 vols. in 100 vols. of water, and on fusion with caustic potash is converted into salicylic acid. When nitrated, it yields dinitroorthocresol (m.p. 86°-87°) (Nölting and Salis, Ber. 14, 987). Refractive index at 40° (μ_D) 1·53719.

Metacresol is prepared by heating thymol (100 parts) with half its weight of phosphorus pentoxide for 10–12 hours until propylene ceases to be evolved, adding the product to 115–120 parts of fused alkali, and further heating the fused mixture for 5–10 minutes to decompose the cresyl phosphate formed. The fused mass is then dissolved in water, treated with ether to

remove any undecomposed cresyl phosphate and other impurities, acidified with hydrochloric acid, and the separated metacresol extracted with ether, and finally distilled in a current of carbon dioxide (E. and L.; T. and S.).

Metacresol is also prepared from naphthalene 1.3.3´-, 1.3.6-, or 1.3.8- trisulphonic acids, from analogous hydroxy- or amino-naphthalene mono- or di-sulphonic acids or from trihydroxynaphthalene; *e.g.*1.3.3´- naphthalene trisulphonic acid together with half its weight of caustic soda and three-quarters of water, is heated for 5 hours at 280°. The product is poured into water, acidified, boiled to expel sulphurous acid, and filtered : *m*-cresol separates out on cooling (Kalle & Co. Eng. Pat. 16559; D R P. 81484; J. Soc. Chem. Ind. 1895, 1800; Hoffmann La Roche and Co. D. R. P. 247272). It is ordinarily a liquid of sp.gr. 1·0387 at 15·5°, but can be obtained in crystals, melting at 2·4° (Fox and Barker); it boils at 202° (corr.) (P.); and is soluble to the extent of 0 53 vol. in 100 vols. of water. Its aqueous solution is coloured blue by ferric chloride. When fused with caustic potash, it is converted into metahydroxybenzoic acid, and on nitration it yields a trinitro- derivative (m p. 105°-106°) (Nolting and Salis, Ber. 14, 987; 15, 1858). Refractive index at 40° (μ_D) 1·53322.

Paracresol crystallises in prisms, melts at 36° (Barth, Annalen, 154, 358 [B. and C.]), 36°-37° (T. and S.), and boils at 198° (I.), at 198°-199° (T. and S , B and C.), at 202° (corr.) (P.); and is soluble to the extent of 1·8 vols. in 100 vols. of water. Its aqueous solution gives a blue colour with ferric chloride. When fused with caustic potash, it is converted into parahydroxybenzoic acid, and on nitration it yields a dinitro- derivative (m p. 85°) (Richter, Annalen, 230, 313; Nolting and Salis, *l.c.*).

The crude cresol, as obtained from coal tar, is only slightly soluble in water, but its solubility in an aqueous solution of potassium cresol, renders its employment as an antiseptic possible. This solution is named *solveol* (Lacroix-Hunkiabéyendian, J. Pharm. Chim. 28, 34). The crude cresol is also frequently mixed with soaps, and is used in that form for disinfecting purposes (Dammann, D. R. P. 52129; Frdl. ii. 538; Holmers, D. R. P. 76133 and 80260; Frdl. iv. 1119 and 1120; Raschig, D. R. P. 87275; Frdl. iv. 1121; Engler and Dieckhoff, Arch. Pharm. 230, 561; 232, 351).

Oxidation with peroxides at a high temperature converts the cresols into the corresponding hydroxybenzoic acids (Friedländer and Löw-Beer, D. R. P. 170230; J. Soc. Chem. Ind. 1907, 434).

A mixture of nitro- derivatives, obtained by sulphonating coal-tar cresol and nitrating the sodium salt of the resulting cresolsulphonic acid with nitric acid of sp.gr. 1·2, has been employed, under the names 'Victoria yellow,' 'saffron surrogate,' as a dye for wool and silk; and, although poisonous (compare Weyl, Ber. 20, 2835; 21, 512), has been used as a colouring matter for butter, cheese, &c. By heating crude cresol with sulphur and alkali sulphide, or with alkalipolysulphides, or with a mixture of sulphur and alkalis, at a high temperature, brown sulphur compounds are obtained which are used for dyeing cotton (Farb. vorm.

F. Bayer & Co., D. R. P. 102897 ; Chem. Zentr. 1899, ii. 352).

CRESOLIN. A disinfectant composed of crude phenol and rosin soap.

CRESOLINE YELLOW v. AZO- COLOURING MATTERS.

CRESORCINOL v. PHENOL AND ITS HOMOLOGUES.

CRESOSTERIL. Acid-o-oxalic ester of m-cresol.

CRESOTIC ACID $CH_3\diagdown\ \diagup$ $\begin{matrix}OH\ CO_2H\end{matrix}$. A homologue of salicylic acid and obtained from o-cresol by similar methods to those employed in preparing salicylic acid from phenol; m.p. 163°–164°.

CRESYLIC ACID. The non-crystallisable, higher boiling portion of the phenols obtained in the purification of phenol (q.v.) is, after redistillation, known commercially as cresylic acid or liquid carbolic acid. It is a colourless, oily, refractive liquid, does not solidify at −80°, has a sp gr. 1 044, and consists of 40 p.c. metacresol, 35 p.c. orthocresol, and 25 p.c. paracresol (Schulze, Ber. 1887, 410). It is much less soluble than carbolic acid in water, ammonia, glycerol, or caustic soda, but more readily so in petroleum spirit. It boils at a higher temperature (about 185°–203°), gives a mixture of m-tribromo and o- and p-dibromo derivatives with bromine. It is even more readily acted upon by concentrated sulphuric and nitric acids than carbolic acid (Lunge, Coal Tar and Ammonia, ed. 1900, 182 ; v. also Allen, J. Soc. Chem. Ind. 1890, 141). Its antiseptic properties are more marked than those of carbolic acid or of either of the three cresols. Cf. CRESOL.

For a method of estimating phenol in commercial cresylic acid, see Fox and Barker (J. Soc. Chem. Ind. 1917, 842 ; 1918, 265 T.

CRESYL BLUE v. OXAZINE COLOURING MATTERS.

CRETAFORM. Oxymethyl cresol tannin.

CRISTOBALITE. A native form of silica (SiO_2) crystallising in the cubic system (pseudocubic). It was first recognised by G. vom Rath in 1886 as regular octahedra up to 2 mm. across, associated with tridymite, in cavities in andesite from the Cerro de San Cristóbal, near Pachuca in Mexico. It has since been found in volcanic rocks in the Rhenish district, Central France, and California, and in certain meteorites. The milk-white, translucent crystals are twinned and exhibit optical anomalies ; these disappear suddenly at a temperature of 175°, the crystals being then truly cubic ; on cooling, the birefringence reappears. Sp.gr. 2·34, hardness 6–7, refractive index 1·49, birefringence 0·0005.

Quartz when heated passes into β-tridymite at 870°, and this in turn passes into β-cristobalite (or metacristobalite, the cubic, optically isotropic modification) at 1470°. On cooling, the latter passes into the birefringent α-cristobalite at 180°–270°. The refractive index of this artificial cristobalite is about 1·484, being slightly higher than that of tridymite (1·477) ; m.p. 1710°. Cubic crystals of silica have also been obtained artificially by heating an aqueous solution of colloidal silica with hydrofluoboric acid at 200° under a pressure of 26 atmospheres. Cristobalite has also been detected in silica bricks. L. J. S.

CRITH. The weight of a litre of hydrogen at 0° and 760 mm. pressure—viz. 0·0896 gram.

CROCEIN, BRILLIANT, ORANGE, SCARLETS, v. AZO- COLOURING MATTERS.

CROCEINE ACID, 2-Naphthol-8-sulphonic acid. Used in making croceine scarlet and other dyes.

CROCIDOLITE. (*Krokydolith,* Ger.) A mineral of the soda-amphibole group, consisting of sodium and iron (ferric and ferrous) silicate, $NaFe'''(SiO_3)_2\cdot Fe''SiO_3$. It is known only in a finely fibrous form, its name, in fact, being from κροκύς, κροκύδος, wool. In the trade it is known as *blue asbestos,* and it is worked for the same purposes as the other varieties of asbestos (q v.). It is, however, more readily fusible (to a black magnetic glass) than are tremolite-asbestos and serpentine-asbestos. The mineral has been long known from the Asbestos Mountains near the Orange River in Griqualand West, South Africa, where it occurs abundantly as veins, 1 or 2 inches in thickness, in jasper-schists. The closely aggregated parallel fibres are arranged perpendicularly or nearly so to the walls of the veins ; and the material is extracted as slabs. It is now extensively mined for commercial purposes (H. F. Olds, Trans. Inst. Mining and Metall. 1899, vii. 122 ; G. E. B. Frood, The Cape Asbestos Industry, Ann. Rep. Govt. Mining Engineer, Dept. of Mines, S. Africa, 1915, and S. African Mining Journal, 1916).

Being an alkali silicate with ferrous iron, crocidolite is especially liable to decomposition when exposed to weathering ; sodium is removed, and the iron oxidised and hydrated to form limonite, while the silica is set free. There then results a ferruginous quartz possessing the finely fibrous structure of the original mineral ; or, in other words, a pseudomorph of quartz and limonite after crocidolite. This material is coloured a rich golden yellow, and displays a silky lustre, and being at the same time very hard, it is well adapted for ornamental purposes. When cut and polished with a convex surface, it displays a cat's-eye effect, and it is extensively used for making knobs, umbrella handles, beads, &c. Such material is known as *tiger-eye,* though, unfortunately, in the trade the name crocidolite is very frequently misapplied to it. The name *pseudo-crocidolite* would be more appropriate. In some stones there has been silicification without oxidation, and the indigo-blue colour of the original crocidolite has been preserved : material of this kind is known as *hawk's-eye.* The stones have sometimes been coloured artificially by the same processes as adopted in the staining of agate (q.v.).

L. J. S.

CROCOITE or **Crocoisite.** Lead chromate, $PbCrO_4$, crystallising in the monoclinic system. The name was originally given in the French form crocoise by F. S. Beudant in 1832, from κρόκος, saffron ; this was later changed to crocoisite, and afterwards to the more correct form crocoite. This mineral is the only chromate of any importance found in nature, and in it the element chromium was discovered. It is found usually as crystals which are bright hyacinth-red in colour with a brilliant lustre ; the streak is orange-yellow. On exposure to light the crystals soon deteriorate in translucency and

brilliancy. Sp.gr. 6·0, H. 2½–3. Crocoite is a mineral of secondary origin in veins of lead ore and is often associated with gold. It is found at Beresovsk in the Urals (where it was discovered in 1766), Congonhas do Campo near Ouro Preto in Brazil, Luzon in the Philippines, Umtali in Rhodesia, and as very fine crystals at Dundas in Tasmania. The mineral has been used as a pigment, being identical in composition with the artificial product chrome-yellow.

L. J. S.

CRONSTEDTITE v. THURINGITE.

CROOKESITE. A selenide of copper, thallium (Tl 16–18 p.c.), and silver forming compact masses with lead-grey colour and metallic lustre. Sp.gr. 6·9, H. 2½–3. It occurs embedded in calcite in the Skrikerum mine, Smäland, Sweden. Although a rare mineral it is of interest in being one of the few minerals containing thallium in considerable quantity. L. J. S.

CROPS. The composition of crops may be regarded from two points of view : (1) the materials they contain, which render them valuable either as food or as sources of some substance of commercial value ; (2) the materials they remove from the soil, which must eventually be replaced if the fertility of the land is to be maintained.

In Table I, the composition of some of the principal crops grown in the United Kingdom is set out, cereals being excluded because they are dealt with separately. The composition of each of these materials shows considerable variations, and the analyses given are either typical or the means of a small number of determinations.

TABLE I.—PROXIMATE COMPOSITION OF CROPS.

	Water	Crude fat	Protein crude	Carbo-hydrates	Crude fibre	Ash

Leguminous crops. The leguminous seeds are distinguished by their high protein content The proteins of the bean and pea and similar seeds have been studied by Ritthausen (Eiweisskörper der Getreidearten, Bonn, 1872) and Osborne (J. Amer. Chem. Soc. 1898, 20, 410 ; Amer. J. Physiol. (1908, 23, 180, &c.). The most abundant of these is the so-called legumin (q v.), which, according to Osborne, is a globulin containing lysine. Lentils contain a conglutin which has been hydrolysed, also some edestin.

The leguminous seeds grown in this country contain but a small proportion of oil, which has rot received any special examination ; the soya bean, however, yields oil up to 20 p c., and is extensively imported from Manchuria and pressed for oil (v. SOYA BEAN).

The only carbohydrate in beans, peas, &c., that has received any attention, is the starch, which is abundant and the granules of which possess characteristic shapes. The ash of leguminous plants is distinguished by a large proportion of lime, as may be seen from analyses 5–10 in Table II.

[1] Aitken, Trans. H. & Ag. Soc. 1884, 16.
[2] Wilson, *ibid.* 1886, 18.

Root crops. In these materials, the ether extract contains little, if any, true fat, the nitrogen-containing substances are also very far from being all protein ; usually one-half or more of the nitrogen present is combined in various non-protein forms.

Potatoes.—The characteristic carbohydrate is starch, of which there may be over 20 p.c. ; but sugars (both sucrose and reducing sugars) may be present up to 1 p c., and dextrins or amylans are also present in about the same amount. Amongst the nitrogen compounds there are both insoluble and soluble proteins, part of the latter being coagulable by heat or acids, and a large range of amino- bodies, among which tyrosin has been identified. The non-protein nitrogen may amount to more than half the total nitrogen. The darkening of the juice of a fresh potato is due to the black substance formed by the oxidation of the tyrosine under the action of an enzyme, also present in the cells. The darkening of boiled potatoes is due to some other cause (Ashby, J. Agric. Sci. 1905, i. 348). About two-thirds of the ash of potatoes consist of phosphoric acid and potash.

Mangolds.—The characteristic carbohydrate

present in the mangold is sucrose, which constitutes about 8 p.c. of the weight of the root, the total dry matter amounting to about 13 p.c. About 0·25 p.c. of reducing sugar is also present. The variation in the sugar content of mangolds has been examined by Wood (J. Agric. Sci. 1905, 1, 176), who gives the following table :—

Variety	Yield per acre—tons	Dry matter p.c	Sugar p.c.	Nitrogen p.c.
White-fleshed globe .	29 9	10·7	6·3	0·165
„ „ intermediate	27 4	12·0	7·1	0·168
Yellow-fleshed tankard .	24 6	13·1	8·0	0 186
„ „ globe. .	25 0	13·4	8·2	0 191
Long red . .	29 9	13·1	7·9	0·157

Of the nitrogen in mangolds, only 30–50 p.c. is in the protein form, 20–40 p.c. is combined as amide or amino- acid and is liberated on hydrolysis as ammonia, while 10 p.c. may be in the nitric form.

On storage, the mangold loses sugar by respiration, and some of the sucrose becomes changed into reducing sugar, a process which is much accelerated as soon as the temperature rises in the spring (*see* Miller, J. Roy Agric. Soc. 1900, 61 ; 1902, 63).

Sugar beet.—In the sugar beet, which has been derived from the same species of *Beta* as

the mangold, the characteristic carbohydrate is likewise sucrose, which may be present to the extent of 20 p.c. It is always accompanied by a certain proportion of reducing sugars (glucose and maltose), which, in well-grown roots, should not exceed 1 p.c. of the sucrose.

The variations in the amount and nature of the sugars in sugar beet have been subjected to very detailed investigation, for accounts of which the numerous technical works dealing with the beet-sugar industry, should be consulted. *V.* SUGAR.

The nitrogenous constituents resemble those of the mangold (*see* Lippmann, Ber. 1896, 29, 2645).

Swedes and turnips.— In these closely allied roots, the carbohydrates consist of sugars (chiefly reducing sugars, though few data exist) and pectic bodies yielding a mucilage on boiling with water. In Wilson's analyses, already quoted, the sugars averaged 4·72 p.c. The nitrogen compounds are also largely non-protein, only from 30 to 50 p.c. consists of protein. It is generally considered that swedes and turnips grown in the north and especially in the east of Scotland, possess a higher feeding value than the roots grown in the south ; analytical data to confirm this opinion are, however, lacking, though it is certain that much larger crops are usually grown in the cooler climate of the north, where the crop can be sown earlier with success.

Ash of crops. In Table II. are collected various analyses of the ash of the crops above mentioned.

TABLE II —COMPOSITION OF THE ASH OF FARM CROPS.

	Ash in dry matter	N in dry matter	Fe₂O₃	CaO	MgO	K₂O	Na₂O	P₂O₅	SO₃	Cl	CO₂	SiO₂

Analyses 8–16 are means taken from Wolff's Aschen-analysen, and have been recalculated to exclude the carbon dioxide present in the ash, as obtained after burning. Analyses 1–7 are selected from the Rothamsted records.

Materials removed from the land by average crops. Table III., compiled by Warington from Rothamsted data, shows the amount of the three important constituents—nitrogen, phosphoric acid, and potash, which would be contained in an average crop of the magnitude indicated, and therefore have been removed

from the soil by the crop, except in the case of the nitrogen contained in leguminous crops.

A comparison of these figures with the amount of fertilising material usually provided for the crops in question, or the effects of particular manures in field experiments, serves to show that the data contained in Table III. afford no guidance in deciding the appropriate manure for each crop.

The earliest theory of plant manuring, that of Liebig, supposed that the requirements of the plant can best be satisfied by applying to

TABLE III.—AMOUNT OF FERTILISING CONSTITUENTS PER ACRE REMOVED BY AN AVERAGE CROP.

—	Weight of crop, dry	Nitrogen	Potash	Phosphoric acid

the land exactly the constituents taken away by a good crop of that particular kind ; but the results of the Rothamsted experiments, confirmed by general farming experience, very soon showed that this view was incorrect, because it failed to take into account the enormous amount of plant food contained in the soil, more or less of which would reach the plant according to the method of cultivation and the plant's habit of growth. Moreover, in practical farming the supply of manure is largely determined by the place the crop occupies in the rotation and the treatment which has been given to the previous crops. To take an example, wheat and barley withdraw almost the same fertilising materials from the soil, yet all farming experience goes to show that the yield of wheat is chiefly determined by the supply of nitrogen If this element is present in sufficient quantity the wheat plant with its long period of growth is usually able to satisfy its requirements for phosphoric acid and potash from the soil. With barley, nitrogen is still a most important element in nutrition, but phosphoric acid also exerts a striking beneficial action and is a necessary element in the fertiliser. Neither for wheat nor barley need potash be supplied except on very light soils. A still more noteworthy example is provided by the swede turnip crop. The table shows that an average crop will take away from the soil about 100 lbs. of nitrogen, 20 lbs. of phosphoric acid and 80 lbs. of potash, yet the usual fertilisers applied to swedes consist almost wholly of phosphatic compounds, with a comparatively small amount of nitrogen and no potash. The majority of the swedes grown in this country receive from 50 to 100 lbs. of phosphoric acid (i.e. about 5 cwt. of superphosphate or basic slag), and the small quantity of nitrogen that would be provided by a light dressing of farmyard manure or half a hundredweight of sulphate of ammonia. The fertiliser requirements of a crop are in fact conditioned by its specific habit and by the soil (q.v.) rather than by its composition. Certain broad characters may be distinguished. Cereal crops possess considerable powers of obtaining the phosphoric acid and potash reserves in the soil provided they are well supplied with active forms of nitrogen. Leguminous crops rarely require a nitrogenous fertiliser, but respond to mineral fertilisers and particularly to potash, the soil also should be neutral and well supplied with lime. Cruciferous crops are particularly de-

pendent upon an abundant supply of phosphoric acid. Crops elaborating a considerable amount of carbohydrate, e.g. mangolds and potatoes, require potash. In general it may be said that nitrogen promotes leafy development, phosphoric acid maturity, and potash carbohydrate formation and continued growth.　　A. D. H.

CROTON OIL is obtained from the seeds of *Croton Tiglium* (Linn.), a tree belonging to the *Euphorbiaceæ*, indigenous to the Malabar coast, and cultivated in Southern Asia and China. The seeds contain 53–56 p c. of oil.

The oil has an amber-yellow, orange, or brown colour, according to its age ; it has a nauseous odour, a burning taste, and acts as a very powerful purgative. It blisters the skin and mucous membrane.

The chemical composition of croton oil differs so widely from that of all other oils, that its recognition, by means of the ' quantitative reactions ' (see OILS AND FATS), is easy. It contains a considerable amount of volatile acids ; its Reichert-Meissl value is about 13 ; its iodine value is 102–106. Saponification value, 210–215 ; and specific gravity, 0·940 to 0 960. Croton oil is strongly dextro-rotatory ($+14·5°$ to $16·4°$).

The variations in the recorded values are mainly attributable to different methods of extraction Croton oil contains the glycerides of tiglic acid, acid of butyric, caproic, lauric, myristic and palmitic acids, and probably also oleic acid. The vesicating principle is a resinous substance, $C_{13}H_{18}O_4$ (Dunstan and Boole, Proc. Roy. Soc. 1895, 58, 238).

CROWBERRY (*Empetrum nigrum*). The leaves of the crowberry contain a wax composed of ceryl cerotate, benzoic acid, urson, tannin, dextrose and probably rutin. The anhydrous urson $C_{16}H_{16}O$ is identical with that obtained from the leaves of *Uva Ursi*. *Empetrum nigrum* contains no alkaloids, andromedextrins or glucosides decomposed by emulsion (Van Itallie, Pharm. Weekblad, 1918, 55, 709).

CROWN GLASS v. GLASS.

CRUCIBLES. A perfect crucible should withstand the highest temperatures without fusion, should bear sudden changes of temperature without fracture, and should be unacted upon by the materials which are to be heated in it. A semi-automatic apparatus for moulding crucibles has been patented by Sims (Eng. Pat. 445, 1888).

[1] Wholly or in part derived from the atmosphere.

Clay crucibles are prepared from selected clay ; of the Stourbridge clay worked, only about 5 p.c. is available for this purpose. Its plasticity is much increased by exposure for some months in a moist condition to the air. During this process of ' weathering ' it becomes disintegrated, and the removal of foreign matter is thereby facilitated. The presence of iron pyrites is especially injurious ; furnace gases convert it into the oxide which acts as a flux and forms cavities in the crucible. Lime is also hurtful, except when in very small quantities and uniformly distributed. Potash and soda are invariably present in clay, and when in small quantity increase the coherence of the crucible without appreciably impairing its power of withstanding the action of heat.

In order to reduce the tendency to crack, and to increase its refractory character, the clay is usually mixed with sand, ground flints, burnt clay (old broken crucibles), graphite or coke These, which are either less fusible than the clay or altogether infusible, form a skeleton which upholds and prevents deformation of the crucibles at temperatures at which the clay would tend to fuse. The most refractory crucibles contain the largest proportion of silica

The clay, which should be of the greatest possible fineness, is well beaten to remove air bubbles and mixed with the proper quantity of the refractory material According to Berthier (Traité des Essais, 1, 66), when silica is used, it should not be too fine, as the tendency to combine with the clay and thus increase the fusibility would thereby be increased. Crucibles of fine grain are also more liable to fracture

Small crucibles are usually baked in a kiln, but the large casting pots of Stourbridge clay are not baked until immediately before use. When the temperature of the baking is high, the crucible is more liable to fracture on reheating.

All clay crucibles are more or less acted upon by litharge, but metals and most ores may be heated in them without danger. Berthier recommends a lining of such material as silica, alumina, or magnesia previously moistened. A lining of chalk renders a crucible less permeable to litharge.

Queneau recommends lining clay crucibles, before drying, with some substance which will resist the chemical reactions for which they are designed and then compressing strongly, drying, and firing (Fr. Pat. 354319 ; J. Soc. Chem. Ind. 1905, 1071).

Crucibles may be rendered non-porous by treating with ferrous sulphate solution and firing (Mitchell, U.S. Pat. 894845 ; J. Soc. Chem. Ind. 1908, 886) or by the addition to the clay of chromic oxide, chromates or chrome iron ore, which also renders them much more refractory (Bach, Eng. Pat. 24041, 1903 ; Klein, U.S. Pat. 787770 ; Seigle, Fr. Pat. 383593 ; and Placet, Eng. Pat. 28728, 1896).

The fracture of crucibles by expansion of solidifying metal can be prevented by lining with friable ferrous material (Colby, U.S. Pat. 830208 ; J. Soc. Chem. Ind 1906, 934).

Goldschmidt recommends that crucibles for the ' Thermit ' process should be lined with a mixture of magnesia or carborundum and soluble glass (Fr. Pat. 354597 ; J. Soc. Chem. Ind. 1905, 1114).

Very large crucibles may be built up from cylinders or annular rings of refractory material, provided arrangements are made for tapping the contents without moving the crucible (Reynolds, Eng. Pat 1004, 1901 ; Rousseau, Eng. Pat. 7451, 1902).

Stourbridge clay crucibles are made from a mixture of raw ground clay with about one-half its weight of powdered, sifted, old glass pots, from which all adherent glass has been removed, the mixture being made in a disc mill, and kneaded to the proper consistency. Percy gives the composition of the Stourbridge clay used for the best crucibles as silica, 79·25 ; alumina, 13 57, iron oxide, 1·38 ; lime, 0·08 ; magnesia, 0·42 ; water, 5 11.

The following analyses show the composition of certain varieties of crucibles. Nos. 1–7 are by Berthier, No 8 by Dick, Nos. 9–12 by Brand, and Nos 13–15 by Méne – -

	Silica	Alumina	Iron oxide	Magnesia	Lime	Potash	Sulphur	Carbon	Water

Hessian crucibles are composed of equal weights of Almerode clay and sand. They are usually triangular, of coarse texture, porous, rapidly destroyed by litharge, and liable to

fracture on sudden change of temperature, but will withstand a very high degree of heat.

French crucibles are made from a mixture of 1 part raw Ardennes clay and 2 parts of the same which has been burnt. They are refractory and of fine texture.

Cornish crucibles are largely used for copper assaying. They are round, of coarse grain, and of a mottled greyish-white colour. They are kiln-burnt, and withstand sudden changes of temperature, but cannot be heated to whiteness. Cornish crucibles are now made by the Morgan Crucible Company at Battersea.

London crucibles are of reddish-brown colour and close texture. They will not stand sudden change of temperature, but withstand the action of litharge fairly well.

Silica crucibles may be made of powdered silica, mixed with a highly absorbent substance, e.g. kieselguhr, saturated with water (Sankey, Eng. Pat. 3353, 1906; J. Soc. Chem. Ind. 1907, 96). Sand, mixed with a small proportion of cement and water, moulded, dried, and heated to the fusing-point of the sand, forms a very refractory material (Reppey, U.S Pat 905295; J. Soc. Chem. Ind. 1909, 24) A mixture of sand with a little lime may be used (Berglund, Fr. Pat. 366830; J. Soc Chem. Ind 1906, 1081).

White fluxing pots are made by the Morgan Company from a highly refractory fire-clay from Rouen. Crucibles containing carbon are now largely used. For very high temperatures, crucibles cut from a block of gas carbon or similar material may be employed. Clay crucibles may also be filled with a moist mixture of charcoal with starch, treacle, gum-water, or oil, or, for large crucibles, gas tar. The mass is forced with considerable pressure into the crucible and is then cut out, leaving a coating of about ½ inch in thickness, or the coating is put into the crucible and smoothed with a glass rod. The crucible is then filled with powdered charcoal and heated to redness.

Graphite crucibles. For the fusion of metals, plumbago or coke crucibles are of great value, but they are not largely used for assaying At the Battersea works, the following process of manufacture is employed : hand-picked Ceylon plumbago is ground, sifted, digested with dilute sulphuric acid to remove the greater part of the iron, and mixed and kneaded to a stiff paste, with about an equal weight of fine fireclay. The mixture is passed through a pug-mill, and is cut into blocks. When required for use, the blocks are again passed through the mill, and made by hand on a wheel or moulded by machinery. They are then dried and baked in saggars. These crucibles may be protected from oxidation by lining them with clay (Woolford, Eng. Pat. 24479, 1898; J. Soc. Chem. Ind. 1900, 52; McDonald, U.S. Pat. 828954; J. Soc. Chem. Ind. 1906, 911).

They are of fine grain, and will withstand the highest temperatures and repeated sudden changes. The graphite is slowly oxidised by metallic oxides or by the furnace gases. To minimise this, the crucible may be coated by dipping in a paste of clay and solution of borax. Any iron which is present in the graphite is liable to become introduced into the melt, and the carbon itself combines with iron or steel (v. Brand, Chem. Zentr. 15, 407; and Dingl. poly. J. 256, 227).

Tar, rosin, &c., may be used to bind the clay and graphite in manufacturing these crucibles (Putz, D. R. P. 181979; J. Soc. Chem. Ind. 1907, 1030). Digby recommends (Eng. Pat. 3661, 1893) the following composition :—

Plumbago, 17-mesh granules . 17 parts
Plumbago, 80- ,, ,, . 2 ,,
Russian clay . . . 5 ,,
China-stone. . . . 5 ,,
Gas carbon . . . . 2 .,

The last three ingredients are ground and mixed with water and then the plumbago is added and the crucibles formed, dried at 65° and baked.

Salamander crucibles, made by the Morgan Company, contain a much smaller proportion of carbon. They withstand sudden changes of temperature perfectly.

Lime crucibles are cut from blocks of well-burnt (preferably slightly hydraulic) lime.

Magnesia was introduced by Caron as a refractory basic material for making crucibles or for lining reverberatory furnaces for melting and dephosphorising steel Magnesia contracts considerably when heated ; it is therefore necessary, before making it into bricks or crucibles, to expose it to a higher temperature than that to which it will be heated. The strongly calcined magnesia is made into a paste with 15-30 p.c. of raw (slightly calcined) magnesia, and 10-15 p.c. of water, and is moulded, dried, and baked at a red heat. The highly heated magnesia would not cohere without admixture with the raw material. Magnesia crucibles are not injured by exposure to the atmosphere. Gaudin makes crucibles from a mixture of 1 part magnesia and 1 part bauxite. They may also be formed from a mixture of calcined magnesite with from 2 p.c. to 12 p.c. of a boron compound (according to the amount of calcium present), moistened, moulded, dried and fired at a high temperature (Rawson and Littlefield, Eng Pat. 16004, 1900 ; J. Soc. Chem. Ind. 1901, 992, and ibid. 1902, 52) The crucible is said to resist molten litharge. Porous crucibles for metal refining, are made from a similar mixture with the addition of sawdust (Dobell, Eng. Pat. 10715, 1897).

Alumina crucibles withstand sudden changes of temperature, and are not affected by the materials fused, even sodium being without action. According to Deville's process (Ann. Chim. Phys. [3] 46, 195), alumina precipitated at low temperature from ammonia alum solution is mixed with an equal weight of powdered marble, and is exposed to the highest temperature of a wind furnace. The mixture so produced, which may be considered as consisting of calcium aluminate, is mixed with its own weight of moist, precipitated alumina, and is made into a crucible, dried and baked (see also Caspar, U.S. Pat. 886111 ; J. Soc. Chem. Ind. 1908, 568). When the crucible is required to withstand higher temperatures, the amount of the calcium aluminate may be reduced, but the proportion of lime should not fall below 10 to 20 p.c.

Bauxite has been used to replace alumina. It is extremely refractory (v. Bauxite, art. ALUMINIUM).

Carborundum crucibles are infusible and

resistant to chemical action and have great solidity. They may be made from a mixture of commercial carborundum with sufficient clay to render it plastic (Velter, Fr. Pat. 376179 ; J. Soc. Chem. Ind. 1907, 1010 ; Engels, Eng. Pat. 14567, 1901).

A mixture of powdered silica rock or ganister with carborundum or amorphous silicon carbide, may be used. It is mixed with water-glass solution or glue, &c., compressed to shape and heated to the temperature of the electric furnace (Imray and Carborundum Co. Eng. Pat. 19493, 1902 ; 3308, 1903) (*see also* CARBORUNDUM).

(*See* further, Kerl, Handb. Thonvaaren Ind. 1879, 528–534 ; and Percy, Metallurgy (Fuel, &c.), 1875, 110–141).

CRUMPSALL YELLOW *v.* AZO- COLOURING MATTERS.

CRURIN. Trade name for quinoline bismuth thiocyanate, used as an antigonorrhoic.

CRYOGENIN. *m* - Benzaminsemicarbazide

$$H_2N—CO--\langle\bigcirc\rangle—NH·NH·CO·NH_2.$$ Used as
an antipyretic.

CRYOLITE.—(*Kryolith*, Ger.) A native fluoride of aluminium and sodium, found almost exclusively in Greenland, whence it has been sometimes called ' Greenland spar.' The name cryolite, or ' ice-spar ' (*Eisstein*) refers to the general resemblance of the mineral to ice ($\kappa\rho\nu\sigma$) and to its ready fusibility in a candle-flame. The mineral was discovered by the Danes in 1794, and described in the following year by Schumacher. Nearly all the cryolite of commerce is obtained from a single locality at Ivigtut (or Evigtok), on Arsuk-fjord in south-west Greenland. This locality was visited by Giesecké, and later by J. W. Tayler (Quart. Jour. Geol. Soc. 12, 140). The cryolite occurs as a large deposit in gneiss, and contains (especially near its junction with the enclosing rock) a number of metallic minerals, such as galena, pyrites, and chalybite (*v.* P. Johnstrup, N. Jahrb. f. Min. 1886, 1, Ref. 28 ; R. Baldauf, Zeitsch. prakt Geol. 1910, xviii. 432 ; O. B. Bøggild, Mineralogia Groelandica, Kjøbenhavn, 1905 ; O. B. Bøggild, Meddelelser om Grønland, 1912, 1 107, and Zeitsch. Kryst. Min., 1913, h. 591. C. P. Bernard, The Cryolite Mine at Ivigtut, Greenland, Mining Magazine, 1916, xiv. 202).

Cryolite is usually found in cleavable translucent masses, of snow-white colour, with a peculiar moist-looking vitreous lustre which renders the mineral easy of recognition. H. 2·5 ; sp.gr. 2·9–3. Crystals are rare, and their relations have been the subject of much discussion ; they are cube-like in habit, and belong to the monoclinic system. There are three perfect cleavages approximately at right angles to one another. Although cryolite is usually white, it is sometimes coloured brown or reddish, and is said to pass downwards, in the Greenland deposit, into a black mass. The black variety loses its colour when heated. Before the blowpipe cryolite fuses to a white enamel.

The composition of cryolite may be represented by the formula 3NaF·AlF₃ or Na₃AlF₆. This corresponds to 12·8 p.c. Al, 32·8 Na, and 54·4 F. An analysis of the Greenland cryolite by Chodnev yielded 13·23 p.c. Al, and 32·71 Na, with 0·83 of Mn₂O₃ and MgO (Verh. Petersb. Min. Ges. 1845–6, 209). Durnev found in the cryolite of Miask in the Urals, 13·41 p.c. Al, 32·31 Na, 0·55 Fe₂O₃ and Mn₂O₃, and 0·35 CaO (Pogg. Ann. 83, 587). Deville found in the Greenland cryolite 0·018 p.c, of vanadic acid and a small proportion of phosphoric acid. An analysis of cryolite from near Pike's Peak, Colorado, by Cross and Hillebrand yielded Al 12·9, Na 32·4, F 53·55, Fe₂O₃ 0·4, Ca 0·28, H₂O 0·3 (Amer. J. Sci. 1883, xxvi. 271).

Cryolite was formerly a rare mineral, but about 1855 it was introduced into Europe commercially, and at once found numerous applications in the arts. About 10,000 tons are exported annually from Greenland. By heating finely powdered cryolite with sodium or with magnesium, J. Percy and A. Dick obtained metallic aluminium (Phil. Mag. 10, 1855, 364). Deville found that fused cryolite is decomposed by the passage of an electric current, with elimination of free aluminium. At the present time, aluminium is prepared by the electrolysis of bauxite, but the addition of some cryolite is necessary to start the process and to keep it in continuous operation (*v. Aluminium*).

A wide range of applications was suggested when Julius Thomsen showed in 1850 that cryolite is readily decomposed by heating with calcium carbonate, and that sodium aluminate may be thus obtained :

$$Al_2F_6·6NaF+6CaCO_3$$
$$=3Na_2O·Al_2O_3+6NaF_2+6CO_3$$
If heated with quicklime, a similar decomposition is effected, of course without evolution of CO₂. The sodium aluminate has been used in the manufacture of alum, and in the preparation of caustic soda for soap making. By lixiviation, the aluminate is easily dissolved out ; and by the passage of CO₂ through the solution, Na₂CO₃ is obtained, while alumina separates in a gelatinous form. The decomposition of cryolite may also be effected by boiling the finely pulverised mineral with milk of lime. By adding an excess of powdered cryolite to the resulting solution, the aluminate is decomposed, the alumina being precipitated, while sodium fluoride remains in solution :

$$3Na_2O·Al_2O_3+Al_2F_6·6NaF=2Al_2O_3+12NaF$$
Cryolite can be readily decomposed by the action of sulphuric acid, with formation of sodium sulphate, which can be easily converted into carbonate ; but the process, after trial at Copenhagen, has been abandoned in consequence of the inconvenience arising from the evolution of hydrofluoric acid :

$$Al_2F_6·6NaF+6H_2SO_4$$
$$=Al_2(SO_4)_3+3Na_2SO_4+12HF$$
The manufacture of soda from cryolite is carried on at Oersund in Denmark, and at Natrona, near Pittsburg in Pennsylvania. The mineral is also employed in the preparation of enamels on iron and for the manufacture of an opaline glass, somewhat resembling porcelain. This glass may be formed by fusing together 100 parts of silica, 35 or 36 of cryolite, and 13 or 14 of oxide of zinc. C. Weinreb has investigated the cause of the milkiness of cryolite glass, and believes that it is due to the presence

of aluminium fluoride, which on the cooling of the fused mass, separates in a highly comminuted condition, and being distributed through the glass renders it more or less opaque (Dingl. poly. J. 256, 361).   L. J. S.

CRYOLITHIONITE. Fluoride of lithium, sodium, and aluminium, $Li_3Na_3Al_2F_{12}$, remarkable in containing a higher percentage of lithium (5·35 p.c.) than any other mineral. It occurs as large, colourless, rhombic-dodecahedra embedded in the cryolite deposit at Ivigtut in Greenland. Sp.gr. 2·77 ; H. 2½–3 ; n_{Na} 1·3395 ; m.p. 710°. The mineral dissolves in 1350 parts of water at 18°, and from this solution crystallises as cubes.   L. J. S.

CRYOSCOPY. So long ago as 1788 Blagden proved that the extent to which the freezing point of an aqueous solution lies below that of water—the depression of the freezing point, as it is called—is proportional to the concentration of the dissolved substance. Nearly a century later, the researches of de Coppet and Raoult showed that when equimolecular proportions of different substances are dissolved in equal quantities of a given solvent, the solutions so obtained have, in general, the same freezing point. It is on these facts that the use of the cryoscopic method of determining the molecular weights of dissolved substances is based.

In comparing the effects of different substances on the freezing point of a given solvent, it is obviously convenient, in view of de Coppet's and Raoult's results, to refer these effects to 1 gram molecule of solute and to some definite quantity of solvent : in practice, 100 grams of the latter are taken as the standard amount. The depression of the freezing point for such a concentrated solution as one containing 1 gram molecule of solute in 100 grams of solvent cannot be determined directly : it is calculated from the depression observed for a dilute solution, on the basis of the proportionality between depression and concentration. An example may be taken to illustrate this point. A solution containing 0·609 gram of ethyl alcohol in 100 grams of water freezes 0·243° below the freezing point of water ; from these data it follows, if proportionality between depression and concentration is assumed, that the depression for a solution containing 1 gram molecule of alcohol in 100 grams of water would be $\frac{0·243 \times 46}{0·609} = 18·4°$. Again, a solution of 4·276 grams of sucrose in 100 grams of water, freezes 0·237° below the freezing point of water ; from these data it follows, as above, that the depression for a solution containing 1 gram molecule of sucrose in 100 grams of water would be $\frac{0·237 \times 342}{4·276} = 19·0°$. If the depressions produced by 1 gram molecule of other non-electrolytes in 100 grams of water are similarly calculated from experimental data, values are obtained which are very close to the figures already quoted. The depression, therefore, for a solution containing 1 gram molecule of non-electrolyte in 100 grams of water is a constant, independent of the particular solute : the average value of the constant for water, deduced in the empirical way just described, is 18·5°.

For each solvent, a characteristic constant

(k) can be similarly deduced from experimental data. The evaluation of this constant—the 'molecular depression of the freezing point'—is effected, as illustrated above, by the formula $k = \frac{M}{g} \cdot \Delta t$, where Δt is the depression of freezing point observed for a solution containing g grams of solute in 100 grams of solvent, and M is the molecular weight of the solute.

It has been shown by van't Hoff that, on thermodynamical grounds, the molecular depression of the freezing point for any solvent is quantitatively related to the temperature of freezing and to the latent heat of fusion. The relationship in question is $k = \frac{0·0198T^2}{\omega}$, where T is the freezing point of the solvent on the absolute scale, and ω is the latent heat of fusion per gram of the solvent. The following table shows how far the values of the molecular depression, calculated for various solvents by van't Hoff's formula, are in agreement with those deduced empirically :—

Solvent			Empirical k	Calculated k
Water	.	.	18 5°	18·6°
Formic acid	.	.	28°	27·5°
Acetic acid	.	.	39°	38·5°
Benzene	.	.	50°	52°
Naphthalene	.	.	68 5°	69°
p-Toluidine	.	.	53°	51°
Phenol	.	.	75°	74°

The formula $k = \frac{0·0198T^2}{\omega}$ is based on the assumption that, when a solution freezes, it is the pure solid solvent which crystallises out. It is not surprising, therefore, that in cases where the crystals separating from the solution contain some of the dissolved substance, e.g solutions of thiophene in benzene, the empirical value for the molecular depression, deduced in the usual way, differs considerably from the normal value. In such cases the depression observed is smaller than it would be if the pure solid solvent separated out.

When the value of k for any solvent has been ascertained, either empirically by experiments with normal substances of known molecular weight, or indirectly by van't Hoff's formula, it may be utilised in determining the molecular weights of new substances. For this purpose, the formula $k = \frac{M}{g} \Delta t$ is employed, but now k is taken as known, and M is the quantity to be evaluated ; in view of this, the equation may be written $M = \frac{k \, g}{\Delta t}$.

It is evident that a determination of the molecular weight of a dissolved substance by the cryoscopic method depends, not on the absolute freezing temperature of the solution, but on the difference between the freezing point of the solvent and that of the solution. This difference can be determined with greater accuracy than can the freezing temperatures themselves. A thermometer with a very open scale, covering only 5°–6°, is employed, and it is convenient, as suggested by Beckmann, to have a reservoir attached to the upper end of the thermometer tube, so that the quantity of mercury in the bulb and stem may be varied according to requirements. This device permits

the use of one and the same thermometer at different temperatures, and therefore with various solvents. In Beckmann's thermometer, which is the one usually employed in cryoscopic investigations, the scale degree is about 4 cm. in length and is divided in hundredths : with the aid of a lens, preferably adapted for sliding up and down the stem, it is possible to estimate 0·001°. The form of the reservoir attached to the upper end of the ordinary Beckmann thermometer is shown in the accompanying sketch. When it is desired to adjust the thermometer for experiments with any given solvent, the bulb is immersed in water of the same temperature as the freezing point of the solvent. If the top of the mercury thread should reach a steady position on the upper half of the scale, no further adjustment is needed. Should the mercury, after sufficient time has been allowed, extend beyond the scale and into the reservoir, it is necessary to detach a portion. This is effected by putting the bulb in water 2°–3° higher than the required temperature, and then gently tapping the upper end of the thermometer until the mercury hanging at the top of the reservoir is separated from the thread. On cooling down again to the freezing temperature of the solvent, the top of the thread should now come to rest somewhere on the upper half of the scale If the quantity of mercury in the bulb and stem is too small, so that when the thermometer is immersed in water of the same temperature as the freezing point of the solvent, the thread does not reach the scale or appears only on the lowest part of it, the bulb is warmed until the mercury appears at the top of the reservoir. By a throwing movement, some of the mercury at the bottom of the reservoir is jerked up to the top, where it joins the end of the thread. The bulb is then immersed in water 2°–3° above the temperature required, and the final adjustment is carried out in the way already described.

FIG. 1.

The cryoscopic apparatus commonly employed for the determination of the molecular weight of dissolved substances is that known as Beckmann's. The accuracy of this method, as ordinarily applied, is not great, the error being of the order ±5 p.c. For most laboratory purposes, however, this is sufficient, and it is only when extreme accuracy is required, as in the investigation of very dilute aqueous solutions, that special forms of apparatus have to be employed.

The essential parts of Beckmann's apparatus are seen in the subjoined diagram. A stout glass jar, holding about 1½ litres, is provided with a metal top, at the side of which is a hole for a stirrer, and in the middle of which is another hole capable of holding a large stout test-tube. 3–4 cm. in diameter. The lid and the tube are held in position by springs, as will be evident from the diagram. By means of a cork, there is fitted in the tube another, narrower one, to hold the liquid under investigation. This tube should preferably have a flat bottom, while the part of it which projects beyond the outer jacket is provided with an auxiliary side tube, and is itself widened out at the upper extremity. The cork with which this inner tube—the freezing tube, as it may be called —is fitted carries the thermometer, and allows also free passage to a stirrer. The latter is best made of stout platinum wire, but silver or nickel may be used, provided that the possibility of chemical action is excluded. The thermometer must be fitted in an accurately central position, so that the stirrer may be moved up and down without grating.
When a determination of molecular weight is to be made, the freezing tube is charged with a weighed quantity of the solvent, usually 10–20 grams, and the jar is filled with water or a mixture of ice and salt kept at a temperature

FIG. 2.

4°–5° below the freezing point of the solvent under examination. The freezing tube, with thermometer and stirrer, is immersed directly in the jar, until the temperature has fallen almost to the freezing point It is then set in the jacket tube and the contents are stirred regularly, while the mercury in the thermometer falls slowly. The fall continues until the solvent is more or less supercooled. In the majority of cases, freezing sets in spontaneously before the supercooling exceeds 0·5°, and the liberation of heat results in a rise of the mercury in the thermometer up to a steady maximum position. This is the freezing point of the solvent—the temperature at which liquid and solid solvent are in equilibrium with each other. It is advisable, when the thread is rising towards its steady position, to tap the thermometer before taking a reading, and so avoid the possibility of the mercury sticking in the capillary. Should the supercooling exceed 0·5°, crystallisation ought to be initiated, either by stirring very vigorously for a few moments or by introducing a tiny crystal of the solid solvent. Whenever freezing has begun, the solvent must then be stirred with uniform regularity until the constant temperature has been reached.

The freezing point of the solvent having been determined two or three times in the manner just described, a weighed quantity of the solute, enough to give a depression of not less than 0·2°, is introduced, and the freezing point of the solution is then ascertained in the same way as that of the solvent. Subsequent additions of solute are made and the resulting depressions determined as before. One addition, it is true, yields sufficient data for the calculation of the molecular weight of the solute, but it is desirable

to ascertain also whether the concentration of the solute has any definite and notable influence on the value obtained for its molecular weight. It is advisable, further, to redetermine the freezing point of the solvent at the end of such a series of experiments, and so obtain a guarantee that the zero of the thermometer has not changed appreciably during the course of the work.

Various suggestions have been made from time to time with the object of rendering the simple Beckmann apparatus a more accurate instrument. Thus it has been proposed to stir the contents of the freezing tube mechanically instead of by hand. The access of atmospheric moisture to a hygroscopic solvent may be prevented by passing a current of dry air into the freezing tube during an experiment, or by using as stirrer an iron ring which is enveloped in platinum foil and is operated electromagnetically. In this latter case, obviously, communication between the contents of the freezing tube and the outside air can be completely cut off. The same end is attained by employing an ordinary stirrer with a mercury valve. (For a detailed description of these modifications and additions, *see* Beckmann, Zeitsch. physikal. Chem. 1891, 7, 323; 1896, 21, 239; 1897, 22, 616; 1903, 44, 169; *also* Ostwald and Luther's Physiko-chemische Messungen.)

For the determination of the freezing point of liquids which are obtainable only in small quantities—physiological fluids, for example— Beckmann's apparatus, in its ordinary form, is too large. Modifications of this apparatus, suitable for the investigation of blood, urine, &c., have been suggested by various authors (Guye and Bogdan, J. Chim. Phys. 1903, 1, 379; Burian and Drucker, Zentr. Physiol. 1910, 23, 772). In these instruments, only 1-2 cub.cm. of liquid is required, and it is claimed that the accuracy is of the same order as that attainable with the ordinary Beckmann apparatus. In this connection, mention ought to be made also of Eykman's apparatus (Zeitsch. physikal. Chem. 1888, 2, 964; 1889, 4, 497). This consists of a small flask, holding about 10 cub. cm., into the neck of which is ground a thermometer, graduated in tenths or hundredths of a degree. There is no separate jacketing vessel, but the procedure is similar to that followed in the case of the Beckmann apparatus.

As regards the preparation of the cooling bath required in the cryoscopic investigation of aqueous solutions, the usual mixture of ice and common salt solution may be replaced in some cases by a mixture of ice and a solid salt, which gives a steady eutectic temperature. Salts suitable for this purpose, with the eutectic temperatures obtained when they are mixed with ice, are alum, $-0.47°$; sodium sulphate, $-0.7°$; potassium dichromate, $-1.0°$; potassium sulphate, $-1.5°$; copper sulphate, $-2.0°$; potassium nitrate, $-3.0°$; zinc sulphate, $-5.0°$; barium chloride, $-7.0°$. Another kind of cooling bath was used by Raoult, who surrounded the jacketed freezing tube with ether, and passed through the latter a current of dry air (Compt. rend. 1896, 123, 476; Zeitsch. physikal. Chem. 1897, 27, 617). By careful regulation of the rate at which the air is forced through the ether, the bath can be adjusted to

any point between room temperature and $-15°$.

When it is desired to find the molecular weight of a new substance, the question of the most suitable solvent arises. The choice is frequently limited by the solubility of the substance; it may be appreciably soluble in only one or two of the more common solvents. Apart from this, however, there are other considerations which must be taken into account. Extensive investigation has proved that with certain combinations of solvent and solute, the cryoscopic method gives abnormal values for the molecular weight of the dissolved substance. Pre-eminently is this the case when the solvent is water and the solute is an acid, a base, or a salt, in short, an electrolyte; under these circumstances, the value found for the molecular weight of the solute is abnormally low. On the other hand, the influence of substances containing the hydroxyl group (alcohols, acids, phenols, oximes) on the freezing point of hydrocarbons (benzene) and allied indifferent solvents, is such as to lead to abnormally high values for the molecular weight. The cryoscopic investigation of solutions of acetic acid in benzene indicates that the formula of the acid is more correctly represented by $(CH_3 \cdot COOH)_2$ than by $CH_3 \cdot COOH$. Again, while the molecular weight of alcohol in benzene is nearly normal in dilute solution, the value increases rapidly as the concentration of the alcohol rises. The combinations of solvent and solute which lead to abnormally high values of the molecular weight have been studied in detail by various workers (Auwers, Zeitsch. physikal. Chem. 1893, 12, 689; 1894, 15, 33; 1895, 18, 595; 1896, 21, 337; 1897, 23, 449; 1899, 30, 300; 1903, 42, 513, 629; Biltz, *ibid.* 1899, 29, 249; Robertson, Chem. Soc. Trans. 1903, 83, 1425; 1904, 85, 1617; 1905, 87, 1574; 1906, 89, 567). It should be noted that in cases also where the dissolved substance crystallises out along with the solvent, the depression of the freezing point is abnormally small, and the value of the molecular weight calculated therefrom is correspondingly high.

For the cryoscopic determination of the molecular weights of dissolved substances a method of moderate accuracy is sufficient, and an experiment may be carried out with a comparatively small quantity of liquid. The case is different with the problem of finding the exact depression of the freezing point for very dilute aqueous solutions—a problem to which much attention has been devoted because of its bearing on the theory of solution. It was early evident that the cryoscopic investigation of very dilute solutions involves special difficulties, for the discrepancies between the results obtained by different workers were very considerable. Thus the molecular depression for water, based on experiments with sucrose in which the actually observed depressions amounted only to about $0.05°$, was found by Arrhenius to be $20.2°$, by Raoult, $20.7°$; by Jones, $21.8°$; and by Loomis, $18.1°$, instead of the theoretical value, $18.6°$. Subsequent investigations (Nernst and Abegg, Zeitsch. physikal. Chem. 1894, 15, 681; Abegg, *ibid.* 1896, 20, 207; Wildermann, Phil. Mag. 1895, 40, 119; Proc. Roy. Soc. 1896, 251; Raoult, Zeitsch. physikal. Chem. 1898, 27, 617)

have made it clear what conditions must be fulfilled if the freezing point depression for a dilute aqueous solution is to be determined with certainty to 0·001°. It will be sufficient here to indicate these conditions briefly.

As regards the thermometer, it is essential that a telescope be used for reading the position of the mercury, and that the bulb of the instrument be kept at about 0° during the whole of a series of experiments. The influence of alterations in the atmospheric pressure cannot be neglected, for it appears that a difference of 1 mm. mercury has about the same effect on a Beckmann thermometer as a temperature change of 0·0002°. On similar grounds, the thermometer must be immersed always to the same depth in solvent and solutions. It should be mentioned here that platinum resistance thermometers have been used in accurate cryoscopic work instead of the Beckmann instruments (*see* Chrustchoff, Compt. rend. 1900, 131, 883; 1901, 133, 955; Bedford, Proc. Roy. Soc. A, 1910, 83, 454). The difference between the freezing points of solvent and solution has also been determined thermoelectrically (Hausrath, Ann. Physik. 1902, [iv.] 9, 522; Jahn Zeitsch. physikal. Chem. 1907, 59, 31; Flugel, *ibid.* 1912, 79, 577; Adams, J. Amer. Chem. Soc. 1915, 37, 481). •

The temperature of the cooling bath is a matter which has to be carefully considered, if the freezing point depression for a dilute solution is to be correctly determined. Suppose that in an experiment with the ordinary Beckmann apparatus the aqueous solution in the inner tube cools without freezing, it is obvious that the lowest temperature to which the solution can fall must be higher than that of the cooling bath, because of the heat conducted from the air to the solution through the thermometer, stirrer, and tube, and because of the heat generated by the stirring. This lowest temperature, which the contents of the freezing tube tend to assume when no freezing takes place, is known as the *convergence temperature.* The difference between the convergence temperature and the temperature of the cooling bath varies, of course, with each apparatus; it decreases as the facility for heat exchange between the solution and the external air is lessened, and as the rate of stirring is diminished. Suppose now that the solution under examination has become supercooled, and that it has reached the convergence temperature. The introduction of a crystal of the solid solvent at this stage initiates the freezing process; heat is liberated and the temperature of the solution rises. Inasmuch, however, as the solution is no longer at the convergence temperature, there is an influence at work tending to lower the temperature of the solution, so that the latter never reaches its true freezing point: the maximum position reached by the mercury is only what may be called the *apparent* freezing point of the solution. Similarly, when the freezing point of the solution lies below the convergence temperature, an apparent freezing point is observed which is somewhat higher than the true freezing point. In both cases, the apparent freezing point lies between the true freezing point and the convergence temperature. In view of these considerations, it is necessary, in cryoscopic work

of the most accurate kind, either to adjust the cooling bath so that the convergence temperature and the freezing point are practically the same, or to apply a correction to the apparent freezing point (*see* Raoult, *l.c.*; Nernst and Abegg, *l.c.*).

The freezing point of a solution is the temperature at which the solution and the solid solvent are in equilibrium, and in order that this equilibrium, and therefore the freezing point, may be well defined, it is essential that a considerable quantity of solid should be in contact with the solution. In the case of aqueous solutions, this has generally been effected by supercooling to the extent of 0·5° or 1·0°, and then introducing a crystal (*see* Walker and Robertson, Proc. Roy. Soc. Edin. 1903, 24, 363; Richards, J. Amer. Chem. Soc. 1903, 25, 291; Jahn, Zeitsch. physikal. Chem. 1904, 50, 129; Roth, *ibid.* 1912, 79, 601; Adams, J. Amer. Chem. Soc. 1915, 37, 481; compare also Prytz, Ann. Physik. 1902, [iv.] 7, 882). In this method of procedure, equilibrium between the two phases is very rapidly established and the concentration of the liquid is ascertained by an analysis made subsequently to the determination of the freezing point.

It has already been pointed out that the freezing point depression is proportional to the number of dissolved units. The cryoscopic method may therefore be employed, not only in the determination of the molecular weights of dissolved substances, but also in the study of the question whether in a particular case a change in the number of dissolved units takes place. It is found, for instance, that the freezing points of potassium iodide solutions are not appreciably affected by the addition of iodine, which shows that the iodine must combine with the units already present in the solution (*see* Le Blanc and Noyes, Zeitsch. physikal. Chem. 1890, 6, 385; Paternò and Peratoner, Gazz. chim. ital. 1890, 21, 110). The cryoscopic method may similarly be employed in following the course of a reaction between dissolved substances which involves a change in the number of units, as for instance, the inversion of sucrose (*see* Kahlenberg, Davis, and Fowler, J. Amer. Chem. Soc. 1899, 21, 1).

CRYSTALLISATION. Crystals are often produced during the concentration of liquors in evaporating pans. Hand or mechanical scrapers are used for removing these crystals continuously. Such crystals are generally too

impure for sale and are redissolved in sufficient hot water to produce a solution, which, after clarification by subsidence or filtration, will yield, in the crystallising pan, bright and marketable crystals. The temperature and concentration of the solution, to yield the best result, have to be determined for every substance. The mother liquor is run off and the crystals transferred to drainers or centrifugal machines to be dried before packing. In some instances, several repetitions of this treatment are made, and the crystals are washed with water or liquor after each treatment. The crystallising pans are made of materials which give the best economic result; either they resist the mother liquors or, if attacked, do not spoil the product by discolouration or too much impurity. Cast-iron tanks about 2 feet deep with bottoms sloping to the outlet and rounded corners, are common. Wooden tanks unlined or lined with sheet lead, zinc, tin, or other metal, are used largely. Some manufacturers suspend roughened strips of metal in the pans, to which the crystals adhere. For rapid production, crystallisation by repose is now giving place in many industries to crystallisation in motion. The crystallising vessels are provided with circulating blades or with compressed air jets, so that the crystals as they form are prevented from adhering to the sides of the vessel, but remain suspended in the liquor, which, on complete cooling, flows directly to the centrifugal machines for the separation of the mother liquor. These crystals are purer and more convenient to handle than those obtained by repose methods. In the case of deliquescent substances and also in those instances where the mother liquor is sufficiently pure to make it unnecessary to purify by crystallisation, the liquor is concentrated in film evaporators so that only sufficient water remains in it to form the crystal. The liquor produced is run into drums, and forms on cooling, a solid block of crystals In some works, the liquor is run into a jacketed worm conveyor so that the crystals which form, leave the apparatus in a loose state.

The capacity of crystallising plant can be determined from a knowledge of the physical data involved. When crystallising by repose methods the rate of evaporation of the solution is given very closely by the utility formula :

$$W = \left(\frac{p_e - p_d}{50}\right)^{1\cdot2}$$

where W is the weight of water in kilograms evaporated per hour per square metre of surface of the liquid, p_e is the vapour pressure of the solution in mm. of mercury at the temperature under consideration, and p_d is the pressure of the aqueous vapour in the atmosphere of the factory. If a draught with a velocity exceeding (say) 1 metre per second is produced in the crystallising room, the figure given by the above formula will be low, and should be multiplied by a factor which is approximately the square root of the velocity in metres per second.

If the mother liquor is run into the crystallising vessels hot, then the time of cooling and evaporation can be determined by a graphical integration of the rates of cooling from the surface of the vessel and cooling from evapora-

tion from the surface of the liquid at a series of temperatures.

Many solutions will not produce bright crystals at temperatures above 20° C. ; in such cases, propeller fans are most useful in keeping down the temperature and increasing the output.

Substances which form hard cemented masses on the cool surfaces of the crystallising vessels may be most satisfactorily treated in vacuum evaporators, where the crystals form on the surface and then drop to the bottom of the vessel, unless a stirrer be provided to keep them in suspension. This method is most useful when crystallising from volatile solvents.

Crystals of uniform size are also most efficiently produced in this way, since the rate of evaporation and the temperature can be perfectly regulated. A mother liquor of suitable strength is produced in the pan and allowed to cool to saturation temperature. The solution is then 'sown' with a suitable quantity of finely powdered substance, and the heating coils and vacuum pump set to work at such a rate as to maintain the temperature and produce the required amount of evaporation, the liquid being stirred continuously As soon as the crystals are known to have reached the required size, the mass is discharged through strainers and the mother liquor returned to form a portion of the next charge. CUBA BLACK v. AZO- COLOURING MATTERS.

CUBEBS. *Cubebæ fructus*, B.P. The dried full-grown unripe fruits of *Piper Cubeba* (Linn. fil.).

CUBEBS CAMPHOR v. CAMPHORS.

CUBEBS, OIL OF, v. OILS, ESSENTIAL.

CUCUMBER. The fruit (really a berry) of *Cucumis sativus* (Linn.). König gives as the average composition :

Water	Nitrogenous matter	Fat	Sugar	Other carbo- hydrates	Fibre	Ash
95·36	1·09	0·11	1·12	1·09	0·78	0·45

According to Wittmann (1901), cucumbers contain about 0·2 p.c. of pentosans.

Heinze (Zeitsch. Nahr. Genussm. 1903, 6, 529) observed that large cucumbers contain a higher proportion of sugar than small ones, but less nitrogenous matter. He gives as the mean composition :

	Water	Pro- tein	Fat	Glu- cose	Cane sugar	Other carbohy- drates	Fibre	Ash
Small	96·6	0·81	0·09	0·00	0·10	1·44	0·58	0·34
Large	95·8	0·67	0·09	0·66	0·09	1·60	1·65	0·42

The ash of cucumbers contains :

K_2O	Na_2O	CaO	MgO	Fe_2O_3	P_2O_5	SO_3	SiO_2	Cl
51·7	4·2	7·0	4·5	0·8	13·1	5·7	4·3	9·2

CULM v. *Anthracite*, art. FUEL.

CUMENES. *Cumols.* The name *cumene,* originally applied to *iso*propylbenzene

$$C_6H_5 \cdot CH(CH_3)_2$$

to indicate its connection with *cumic acid,* from which it was obtained by distillation with lime, is frequently employed as a generic term to denote any of the isomeric benzene hydrocarbons of the formula C_9H_{12}. Theory predicts

the existence of eight of these, all of which have been found in coal-tar oil.

Propylbenzenes.

1. *Normal propylbenzene* (n- *cumene*)

$$C_6H_5 \cdot CH_2 \cdot CH_2 \cdot CH_3$$
Present in coal tar oil in fraction boiling at 153°–157° (Schultz and Perl, Ber. 1909, 3602). By the action of sodium on a mixture of bromobenzene and propyl bromide in ethereal solution (Fittig, Schäffer and König, Annalen, 149, 324). By the action of aluminium chloride on trimethylene bromide, propylbenzene and diphenylpropane (sym.) are formed, the latter of which, on further treatment, yields propylbenzene and cumene (Bodroux, Compt. rend. 132, 155). From benzene, aluminium chloride and propyl bromide, when kept at 0° (Heise, Ber. 1891, 768; Genvresse, Bull. Soc. chim. 9, [3] 219). From benzyl chloride, $C_6H_5 \cdot CH_2Cl$ and zinc-ethyl (Paternò and Spiza, Ber. 10, 294). Liquid boiling at 159° (corr), sp.gr. 0·867 at 15°/15° (Perkin, Chem. Soc. Trans. 1900, 274). Yields benzoic acid on oxidation with chromic acid.

Cumene, together with toluene, may be obtained from cymene by demethylation by the action of aluminium chloride in presence of benzene :

$$C_3H_7 \cdot C_6H_4 \cdot CH_3 + C_6H_6$$
$$= C_6H_5 \cdot CH_3 + C_3H_7 \cdot C_6H_5$$

(Bædlker· and Halse, Bull. Soc. chim. 1916, 19, 444).

2. *Isopropylbenzene* (*Cumene*)

$$C_6H_5 \cdot CH(CH_3)_2$$

Present in American petroleum (Maberry and Dunn, Amer. Chem. J. 18, 215). By distilling cumic acid $C_6H_4[CH(CH_3)_2]CO_2H(1, 4)$ with lime or baryta (Gerhardt and Cahours, Ann. Chim. Phys. [3] 1, 87). From benzal chloride $C_6H_5 \cdot CHCl_2$ and zinc-methyl (Liebermann, Ber. 13, 46). Phenyl magnesium bromide reacts with acetone to give methylethenylbenzene, which, on hydrogenation, yields cumene (Tiffeneau, Compt. rend 134, 845). From benzene and either isopropyl bromide or normal propyl bromide in presence of aluminium bromide (Gustavson, Ber. 14, 1251) Liquid boiling at 152·5°–153° (corr.); sp.gr. 0·8727, 7·9°/4° (Perkin, Chem. Soc. Trans. 1900, 275). Yields benzoic acid on oxidation with chromic acid.

Methylethylbenzenes (*Ethyltoluenes*). The three methylethylbenzenes are obtained by the action of sodium on a mixture of ethyl bromide or iodide with the corresponding bromotoluenes (ortho-, meta-, or para-).

1. *o-Methylethylbenzene*

$$C_6H_4(CH_3)(C_2H_5)(1, 2)$$
Liquid boiling at 158°–159° ; sp.gr. 0·8731 at 16°. Dilute nitric acid oxidises it to o-toluic acid $C_6H_4(CH_3)CO_2H(1, 2)$.

2. *m-Methylethylbenzene*

$$C_6H_4(CH_3)(C_2H_5)(1, 3)$$
Liquid boiling at 158°–159° ; sp.gr. 0·869 at 20°. Chromic acid oxidises it to isophthalic acid $C_6H_4(CO_2H)_2(1, 3)$.

3. *p-Methylethylbenzene*

$$C_6H_4(CH_3)(C_2H_5)(1, 4)$$

Liquid boiling at 161°·162° ; sp.gr. at 0·8652 at

21°. yields on oxidation p-toluic and terephthalic acids.

Trimethylbenzenes.

1. *Consecutive trimethylbenzene* (*Hemellitene* ; *Hemimellithene*) $C_6H_3(CH_3)_3(1, 2, 3)$. By heating the calcium salt of a-*isoduric* acid

$$C_6H_2(CH_3)_3CO_2H$$

with lime. Liquid boiling at 175° (Jacobsen, Ber. 15, 1857 ; 19, 2517).

2. *Unsymmetrical trimethylbenzene* (*pseudocumene*) $C_6H_3(CH_3)_3(1, 2, 4)$, occurs together with mesitylene in coal-tar (Beilstein and Kögler, Annalen, 137, 317), and is present in many petroleums (Poni, Chem. Zentr. 1906, i. 459). By the action of sodium on a mixture of either bromo-paraxylene or bromometaxylene with methyl iodide. In order to isolate it from coal tar, Armstrong recommends (Chem. News, 38, 5 ; Ber. 11, 1697) that the mixture of pseudocumene and mesitylene (v infra) boiling between 160° and 170°, obtained from coal tar by fractional distillation, should be converted by treatment with an equal volume of concentrated sulphuric acid into sulphonic acids. The mixture of sulphonic acids, which separates as an oily layer on carefully adding water to the sulphuric acid solution, is heated with concentrated hydrochloric acid in a sealed tube for 1 hour at 100°. In this way, the mesitylene sulphonic acid is decomposed, regenerating mesitylene, whilst the pseudocumenesulphonic acid is not attacked. After separating the mesitylene the pseudocumenesulphonic acid is precipitated from the hydrochloric acid solution by sulphuric acid, purified by recrystallisation from dilute sulphuric acid and finally decomposed by heating with hydrochloric acid at 140°-150°, when it breaks up into pseudocumene and sulphuric acid. Jacobsen (Ber. 9, 256) treats the mixture of sulphonic acids with barium or calcium carbonate, which removes the excess of sulphuric acid and converts the sulphonic acids into barium or calcium salts ; transforms these by double decomposition with sodium carbonate into sodium salts ; heats the latter with phosphorus pentachloride, with which they yield the sulphonic chlorides $C_9H_{11} \cdot SO_2Cl$; converts the chlorides into the sulphonamides

$$C_9H_{11}SO_2 \cdot NH_2$$
by the action of ammonia ; and separates the two isomeric sulphonamides by recrystallisation from alcohol, in which mesitylene sulphonamide is readily, pseudocumene sulphonamide only sparingly, soluble. The sulphonamides are then hydrolysed by heating with concentrated hydrochloric acid at 175°.

Another method proposed by Jacobsen (Annalen, 184, 199) is to separate the two sulphonic acids by fractional crystallisation ; pseudocumenesulphonic acid is soluble with difficulty in sulphuric acid and crystallises out. On heating to its melting-point (11C°) and passing in steam at a temperature of 250°, pure pseudocumene is obtained (see also Schultz and Herzfeld, Ber. 1909, 3602). Pseudocumene boils at 168·2°, and has sp.gr. 0·877 at 18° (Schultz and Herzfeld, l.c.). On oxidation with nitric acid, it yields two isomeric acids of the formula $C_6H_3(CH_3)_2CO_2H$—xylic acid and p-xylic acid

—and a small quantity of the isomeric methyl-isophthalic and methylterephthalic acids

$$C_6H_3(CH_3)(CO_2H)_2$$
(Bentley and Perkin, Chem. Soc. Trans. 1897, 165).

3. *Symmetrical trimethylbenzene* (*Mesitylene*) $C_6H_3(CH_3)_3(1, 3, 5)$. In coal-tar oil, in fraction boiling at 157°–162° (Fittig and Wackenroder, Annalen, 151, 292 ; Schultz and Perl, Ber. 1909, 3602), and in American petroleum (Maberry and Dunn, Amer. Chem. J. 18, 215). By distilling acetone with sulphuric acid

$$3CO(CH_3)_2 = C_6H_3(CH_3)_3 + 3H_2O$$
(Küster and Stollberg, Annalen, 278, 207 ; Meyer and Molz, Ber. 1896, 2831), or by dissolving allylene $CH_3 \cdot C \vdots CH$ in sulphuric acid and distilling with water $3CH_3 \cdot C \vdots CH = C_6H_3(CH_3)_3$ (Fittig and Schrohe, Ber. 8, 17). (On the isolation of mesitylene from coal tar and the method of separating it from pseudocumene, v. preceding paragraph.) Liquid boiling at 164·5° ; sp.gr. 0·8768 at 4°/4° (Perkin, Chem. Soc. Trans. 1896, 1193). Dilute nitric acid oxidises it to mesitylenic acid $C_6H_3(CH_3)_2CO_2H$ and uvitic acid $C_6H_3(CH_3)(CO_2H)_2$; with potassium permanganate it yields uvitic acid and trimesic acid $C_6H_3(CO_2H)_3(1, 3, 5)$.

CUMIDINES $C_9H_{13}N$. Of the sixteen isomeric cumidines which have hitherto been obtained, pseudo- and ψ-cumidine and mesidine are perhaps the most important. These bases are derivatives of pseudocumene and mesitylene respectively, the first of which is theoretically capable of yielding three isomeric ψ-cumidines, and the latter one cumidine only.

Pseudocumidine, *sym.-ψ-cumidine*

$$(CH_3)_3C_6H_2 \cdot NH_2[CH_3 : CH_3 : CH_3 : NH_2 = 1 : 2 : 4 : 5]$$

can be obtained by nitrating pseudocumene with fuming nitric acid in the cold, and reducing the nitro- compound (m.p. 71°) with tin and hydrochloric acid (Schaper, Zeitsch. chem. [2] 23, 1) The base is prepared technically by digesting xylidine hydrochloride with methyl alcohol in an autoclave at 280°–300°, converting the crude product into the nitrate, separating the sparingly soluble nitrates by means of a centrifugal machine, washing the product with water and finally treating with an alkali. The mixture of bases consisting of cumidines and xylidines is then fractionated, and the portion distilling between 225°–245° is allowed to crystallise, and finally freed from non-crystallisable bases by pressure (Aktiengesellschaft fur Anilin-fabrikation, D. R. P. 22265). The cumidine so obtained contains mesidine and other impurities (Hofmann, Ber. 17, 1912 ; Engel, *ibid.* 18, 2229), but consists chiefly of Schaper's pseudo-cumidine (*cf.* Hofmann, *ibid.* 15, 2895) which can be prepared in the pure state by digesting o-4-xylidine [$NH_2 : CH_3 : CH_3 = 1 : 3 : 4$] or para-xylidine with methyl alcohol under similar conditions (Nölting and Forel, *ibid.* 18, 2680).

Properties.—Pseudocumidine crystallises in large, lustrous prisms, melts at 63° (Hofmann), at 68° (Auwers, Ber. 18, 2661), and boils at 234°. It is insoluble in water, but readily soluble in alcohol. The nitrate is characterised by being very sparingly soluble in water. Its acetyl derivative crystallises in compact white needles, melts at 161° (Edler, *ibid.* 18, 629 ; Nölting and

Baumann), at 164° (Auwers) and boils above 360°. Pseudocumidine is used as a source of azo- dyes (D. R. PP. 3229, 1878 ; 22265, 1882).

as-ψ-cumidine [$CH_3 : CH_3 : CH_3 : NH_2 = 1 : 2 : 4 : 6$] has been prepared by Edler (*l.c.*). It melts at 36°.

ψ-**cumidine** [$CH_3 : CH_3 : CH_3 : NH_2 = 1 : 2 : 4 : 3$] is obtained by digesting o - 3 - xylidine hydrochloride [$NH_2 : CH_3 : CH_3 = 1 : 2 : 3$] with methyl alcohol in an autoclave at 300° (Nölting and Forel ; *cf.* Mayer, Ber. 20, 972). It boils at 240° (Nölting and Forel), 236° and does not solidify at −15° (Mayer). Its acetyl derivative melts at 186°.

Mesidine [$CH_3 : CH_3 : CH_3 : NH_2 = 1 : 3 : 5 : 2$] is obtained by treating mesitylene with nitric acid (sp.gr. 1·38) and reducing the nitro- derivative with tin and hydrochloric acid (Fittig and Storer, Annalen, 147, 3). It can also be prepared by digesting a-metaxylidine [$NH_2 : CH_3 : CH_3 = 1 : 2 : 4$] (Hofmann, Ber. 5, 715 ; 8, 61) or β-metaxylidine [$NH_2 : CH_3 : CH_3 = 1 : 2 : 6$] hydrochloride (Nölting and Forel) with methyl alcohol at 300°.

Properties.—Mesidine is a colourless liquid, which boils at 229°, and has a sp.gr. 0·9663. The acetyl derivative melts at 216° and crystallises in prisms.

Isocumidine [$CH_3 : CH_3 : CH_3 : NH_2 = 1 : 2 : 3 : 5$], prepared by digesting the hydrochloride of γ-metaxylidine

$$[NH_2 : CH_3 : CH_3 = 1 : 3 : 5]$$
with methyl alcohol, at 300° (Nölting and Forel ; Limpach, Ber. 1888, 644), melts at 67°–68°, boils at 245°, and yields an acetyl derivative melting at 163°–164°.

Para-aminopropylbenzene, formed by heating aniline, propyl alcohol, and zinc chloride at 280° for 8 hours (Louis, Ber. 16, 105 ; Francksen, *ibid.* 17, 1221), boils at 224°–226°. The acetyl derivative melts at 87°.

Orthoamino*iso***propylbenzene**, - *o* - **cumidine**, formed by heating aminocumic acid with baryta (Filetti, Gazz. chim. ital. 13, 379 ; *cf.* Constam and Goldschmidt, Ber. 1888, 1158), boils at 213·5°–214·5° at 732 mm. The acetyl derivative melts at 72°.

Para-amino*iso***propylbenzene, cumidine,** formed by heating *iso*propyl alcohol, aniline, and zinc chloride at 260°–280° (Louis, Ber. 16, 111 ; *cf.* Nicholson, Annalen, 65, 58), boils at 216°–218°. The acetyl derivative melts at 102°–102·5°. By oxidation with sodium chlorate and potassium ferrocyanide in hydrochloric acid solution, cumidine yields a dyestuff of the aniline black series (Kirptischnikow, Chem. Zentr. 1906, i. 829). By treatment with cyanogen chloride in pyridine solution, condensation is effected and a dyestuff is produced (König, D. R. P. 155782 ; Chem. Zentr. 1904, ii. 1557).

Ethylorthotoluidine, prepared by treating orthotoluidine in ethyl alcohol with zinc chloride at 270° (Benz, Ber. 15, 1650), boils at 229°–230°. The acetyl derivative melts at 105°–105·5°, and boils at 313°–315°.

obtained by passing acetylene over reduced copper heated above 180°, and treating the brown solid so formed repeatedly with acetylene until no further change occurs.

CUPRI-ADEPTOL. Copper m-phenol sulphonate.

CUPRISIN. Trade name for a preparation of cupric cyanide and potassium cyanide, used for the treatment of trachoma.

CUPRITE. Native cuprous oxide, Cu_2O, crystallising in the cubic system. Brilliant, transparent crystals of a ruby-red colour (hence the name ruby-copper-ore) are not uncommon; sp.gr. 6·0. In the variety called *chalcotrichite*, the crystals are capillary in form, being enormously elongated in the direction of one of the cubic edges, and are loosely matted together in plush-like masses Another variety, known as *tile-ore* (Ger. *Ziegelerz*), is earthy or compact and of a brick-red or brownish colour; it consists of an intimate mixture of cuprite and limonite, and has resulted from the alteration of copper-pyrites Cuprite is sometimes of importance as an ore in the upper oxidised portions of copper veins. L. J. S.

CUPROCITROL. Trade name for copper citrate.

CUPROL. A compound of nucleinic acid and copper.

CUPRONICKEL *v.* NICKEL.

CUPROSILICON, *Cuprous silicide* (*v.* COPPER)

CURARA. *Curare, Urari, Woorari, Woorah, Woorara.* Curara is the arrow poison of those tribes of South American Indians which inhabit the districts lying between the Amazon and the Orinoco. It was first brought to Europe by Sir Walter Raleigh, in 1595, and from that time to this its origin and preparation have been much discussed by travellers and botanists. A summary of the earlier observations of La Condamine, A. v. Humboldt and Bonpland, Waterton, Schomburgk, Castelnau, Weddell, Thiron, Jobert, Crévaux, and others is given by Planchon (Pharm. J. [3] 11, 469, 491, 529, 589, 693, and 754). It is shown that curara is an aqueous extract of a mixture of many plants, one of which is always a species of *Strychnos*, and gives to it the chief toxic power, whilst the remainder contribute those other qualities which render the extract suitable for the tipping of arrow heads. The method of preparation adopted by one tribe of Indians is described by Schomburgk (*ibid.* [3] 10, 646). The product differs somewhat with the locality in which it is prepared. Planchon distinguishes four varieties: the curara of the Orinoco, of the Upper Amazon, of French Guiana, and of British Guiana. The chief active ingredient in the preparation of the first is a *Strychnos* plant, closely allied to Schomburgk's *S. toxifera* (J. Pharm. Chim. [5] 5, 20), of the second, *S. Castelnæi* (Weddell), of the third, *S. Crevauxiana* (Baill.), and of the fourth, *S. toxifera* (Schomb.).

As seen in Europe, curara is a brown to black, nearly solid, or even brittle, extract. It has a bitter taste, and in its poisonous action it is related, though opposed, to strychnine. In medicine, it has been occasionally employed in the treatment of tetanus and hydrophobia, but it is not included in any pharmacopœia. Great care is necessary in its administration, and the solution should first be tested on animals.

For the earlier chemical investigations of curara, *see* Flückiger (Arch. Pharm. 1890, 228, 78). Our present knowledge is mainly due to Boehm (Chem. Zentr. 1895, ii. 1084; 1897, ii. 1078; Arch. Pharm. 1898, 235, 660), who showed that the alkaloids of curara can be divided into two classes: (1) compounds similar to curine, partly crystalline and partly amorphous, soluble in water with difficulty and precipitated from solution by ammonia, in which the characteristic toxic effect of curara is shown very slightly or not at all; (2) amorphous yellowish-red substances easily soluble in water as curarine, not precipitated by ammonia, and showing the most marked toxic action. Of most specimens of curara, about 70–90 p.c. is soluble in tepid water; sometimes, however, scarcely more than half is soluble. Para curara, which is imported in bamboo tubes and is the variety now usually met with in commerce, contains about 11–14 p.c. water, 12 p.c. ash, 12–15 p.c. *curine* $C_{18}H_{19}O_3N$, which is isolated by extracting the raw material with water, precipitating by aqueous ammonia and extracting with alcohol. It melts at 212°, and is obtained in crystals from benzene or alcohol with one molecule of the solvent or from methyl alcohol without alcohol of crystallisation. *Tubo-curarine (paracurarine)* $C_{19}H_{21}O_4N$ was obtained as a reddish-yellow substance which forms about 9–11 p.c. of raw curara. It is not identical with the previously known curarine, isolated from calabash curara. The latter kind, which was sent over from the Orinoco *via* Venezuela in small gourds, used to be the common variety, but is now seldom met with; it is much superior to tube curare, and seems to be derived from *Strychnos toxifera.* Earlier investigations, as a rule, refer to this. The active principle, *curarine* $C_{19}H_{26}ON_2$ (?), consists of hard glistening garnet-red laminæ, decomposing and giving off a smell of trimethylamine when heated to 150°. A minute quantity of a second alkaloid was found to be present.

A third variety of curara, from the Upper Amazon, occurs in the market in small jars of unburnt clay. This differs widely in respect to active principles from the other varieties. The following substances have been extracted from it: *protocurine* $C_{20}H_{23}O_4N$, colourless needles, which turn brown at 160° and melt, with decomposition, at 306°; *protocuridine* $C_{19}H_{21}O_3N$, colourless prismatic crystals, m.p. 274°–276°; and *protocurarine* $C_{19}H_{23}O_4N$ (?), an amorphous red powder, more poisonous than the other curarines.

The inert, or slightly active, curines appear to be tertiary bases, the curarines are quaternary ammonium bases, and in this connection it is noteworthy that, according to Crum Brown and Fraser (Proc. Roy. Soc. Edinburgh, 1869, 560), nearly all ammonium bases paralyse motor nerve endings and have a curare-like effect. In the case of curine and tubo-curarine, at least, there seems to be a close chemical relationship; both appear to be derivatives of methoxylated quinoline. Curine methiodide produces the typical curare effect and resembles tubocurarine. The colour reactions of curarine indicate a relationship to strychnine. Pure curarine is extremely active; $\frac{1}{10}-\frac{1}{20}$ mg. injected will paralyse a frog; given by the

mouth it is inactive. It paralyses the motor nerve endings, but, even in large doses, leaves other tissues unaffected. Hence it is much employed in physiological research (*cf. e.g.* Edmunds and Roth, Amer. J. Physiol. 1908, 23, 28, 46). G. B.

CURCAS OIL, purging nut oil, physic nut oil (*Oleum infernale*), is obtained from the seeds of *Jatropha curcas* (Linn.), (purging nut '), by hot expression. The seeds consist of 66 p.c. of kernels and 34 p.c. of husks. From the former there is obtained by extraction with ether 52 p.c. of oil of a pale colour, becoming yellow, with a reddish tint, on exposure to the air. Characteristic of the oil is its unpleasant odour, which assists in distinguishing curcas oil from other oils. Most prominent are the strong purgative properties of the oil, which are much more pronounced than those of castor oil. It may be distinguished from castor oil by its sparing solubility in alcohol, and ready solubility in petroleum spirit. The oil belongs to the semi-drying oils ; its liquid fatty acids consist of about equal proportions of oleic and linolic acids, as ascertained by the relative quantities of their oxidation products (viz. dihydroxy-stearic and tetrahydroxystearic acids). This oil is stated by Bouis to contain *isocetic* acid, but the existence of this acid is doubtful.

The recorded values show considerable variations, but genuine expressed oil has sp gr. 0·9204–0·9205 at 15·5° ; saponification value, 192–193 ; iodine value, 98–100 ; and acetyl value, 7·5–10.

In addition to its use as a medicine, curcas oil is also used in the manufacture of soap, and to a limited extent for burning.

Nearly related to the above-described oil are the oils obtained from the seeds of *Jatropha oligandra* (Mull.) and *J. multifida* (Linn.).

J. L.

CURCUMEÏNE *v.* Azo- colouring matters.

CURCUMIN *v.* Turmeric.

CURCUMINES *v.* Azo- colouring matters.

CURCUPHENINE *v.* Azo-colouring matters

CURINE *v.* Curara.

CUSCOHYGRINE *v.* Cocaine and the Coca alkaloids.

CUSPARIA BARK. *Angostura bark ; Carony bark. (Ecorce d'Angusture,* Fr. ; *Angostura-Rinde,* Ger.) The bark of the *Cusparia febrifuga* (Hiemb.) or *Galipea cusparia* (St. Hilaire), a tree inhabiting the mountain districts drained by the Orinoco (*cf.* Bentl. a. Trim. 43). Confusion has sometimes occurred between cusparia and nux vomica bark. The two barks may, however, be readily distinguished by treatment with a drop of nitric acid, which either deepens the colour of the cusparia or gives it a bluish shade, while nux vomica, similarly treated, exhibits a blood-red colour. Several other barks have, from time to time, been substituted for true angostura. (For these, and the mode of detecting them, *v.* Pereira (Mat. Med. 3rd. ed. 2, 1915) ; Maisch (Amer. J. Pharm. 1874, 50) ; Cazeneuve (Rép. de Pharm. 1874, 261) ; Oberlin and Schlagdenhauffen (Pharm. Zeit. 1878, 853).) For the bark of *Esenbeckia febrifuga,* which enters commerce under the name of angostura bark, *see* Hartwich and Gamper (Arch. Pharm. 238, 568). Cusparia

bark contains about four alkaloids, a little ethereal oil, a bitter principle, and a glucoside. Of total alkaloids there is 1·8 p.c. free and 0·6 p.c. in a combined state. By far the most abundant alkaloids are *cusparine* and *galipine,* discovered by Körner and Böhringer (Gazz. chim. ital. 1883, 13, 363). They are removed from the ethereal percolate of the bark by shaking with 20 p.c. acetic acid, which leaves small quantities of other bases behind. The separation of cusparine from galipine is effected by fractional crystallisation of the free bases, from ligroin, but principally by conversion into the oxalates ; cusparine oxalate is very little soluble in water, while galipine oxalate remains in solution (Tröger and Kroseberg, Arch. Pharm. 1912, 250, 494).

Galipine $C_{20}H_{21}O_3N$ forms colourless needles, m.p. 115° ; when pure the salts are colourless. Oxidation with permanganate yields veratric and methoxyquinoline carboxylic acids, whence Tröger and Kroseberg have suggested the following constitution :
Cusparine has, according to Tröger and Beck (Arch. Pharm. 1913, 251, 246), the composition $C_{19}H_{17}O_3N$, and not $C_{20}H_{19}O_3N$, as previously supposed. It is probably trimorphous, and may melt at 90°–91°, or at 110°–122°. Its salts, and particularly the oxalate, are sparingly soluble, and hence it is the easiest of the angostura alkaloids to isolate. Sulphuric acid gives a dull-red, rapidly changing to cherry-red, Frohde's reagent a deep-blue, colouration. On melting its salts with organic acids, it changes to *pyrocusparine* $C_{18}H_{15}O_3N$, m.p. 255°, which base gives well-crystallised salts. Like galipine, cusparine seems to be a quinoline derivative (Tröger and Beck). It is a tertiary base, and contains one methoxyl group. As protocatechuic acid is obtained by potash fusion, it is conceivable that it contains a methylenedioxy group instead of the two methoxy groups of galipine, which would be in accordance with the empirical formula. *Cusparine* $C_{18}H_{19}O_2N$, according to Tröger and Runne (Arch. Pharm. 1911, 249, 174), is extracted by light petroleum from the amorphous bases left after crystallisation of cusparine and galipine. It melts at 56°, distils almost without decomposition, contains two methoxy groups, and yields quinoline on zinc-dust distillation. Tröger and Runne also describe *galipoidine* $C_{19}H_{15}O_4N$, m.p. 233°, and Tröger and Beck (*l.c.*) yet another alkaloid $C_{16}H_{13}O_5N$ (?), m.p. 186°. Cusparidine and galipidine of Beckurts and Nehring are, according to Tröger and Kroseberg, merely mixtures of cusparine and galipine. Other papers on angostura alkaloids are by Tröger and Müller (Arch. Pharm. 1910, 248, 1 ; 1914, 252, 459), by Beckurts and Nehring (Arch. Pharm. 1891, 229, 591),·and by Beckurts and Frerichs (Arch. Pharm. 1905, 243, 470).

The *essential oil* (from *Cusparia trifoliata,* Engl.) is described in Schimmel and Co.'s Semi-Annual Report, April, 1913. The yield was

1·03 p.c. of the bark ; D_5^{15} 0·9285 ; $a_D^{20}-7·32°$; n_D^{20} 1·50744 ; colour, pale brown ; acid number, 1·8 ; ester number, 5·5 ; acetyl number, 35·7 ; the oil is not completely soluble even in 9 volumes of 90 p.c. alcohol.

Angosturin $C_9H_{12}O_5$, m.p. 58°, is a crystalline bitter principle, readily soluble in water and in alcohol, but not in ether (Beckurts and Nehring).

Angostura bark is a constituent of 'Angostura bitters,' and is used in medicine as a tonic in derangements of the alimentary canal, but it is not included in the B.P. nor in the U.S.P.

G. B.

CUSSO, KOUSSO, *v.* Kosin, art. RESINS.

CUSYLOL. Trade name for soluble copper citrate.

CUTCH. Considerable quantities of cutch are now prepared in Burma. It is obtained from the *Acacia Catechu*, the trees being felled while green, the bark taken off, and the timber chopped up and boiled in large cauldrons. The resultant liquid is drained off, and solidifies as it cools. In the better qualities of cutch only the heart-wood of the tree is utilised. Cutch is brought to the market in several forms, the three principal ones being : (1) tablets—small rectangular blocks weighing from 1 to 2 lbs. ; (2) blocks—more or less square blocks weighing from 28 to 56 lbs. ; (3) baskets—a soft cutch of a thick consistency. Tablet cutch is the best quality, and basket cutch the lowest. Block and basket cutch usually contain more impurities than tablet cutch. On arrival in Rangoon the cutch is packed in wooden cases (usually containing 1 cwt. net), and is then ready for export.

Cutch trees are found throughout the whole of Burma, but the principal producing districts are Prome, Thayetmo, Myingyan, Minbu, Pegu, Yamethin, and Pyinmana.

Cutch is used largely as a dye, and for tanning, and as a preservative, especially for preserving fishing nets and sails. *See also* CATECHU.

CYANACETIC ACID *v.* MALONIC ACID.

CYANELLAGIC ACID. Cyanellagic acid $C_{14}H_8O_{10}$ is prepared by heating ellagic or flavellagic acid with 100 p.c. sulphuric acid at 185°–230° (Perkin, Chem. Soc. Proc. 22, 114), or with arsenic and sulphuric acids at 130°. It crystallises from pyridine in small yellow prismatic needles, and is soluble in strong alkaline solutions with a green-yellow tint, changing to deep blue on dilution. The hexa-acetyl derivative $C_{14}O_{10}(C_2H_3O_6)$, forms colourless needles, melts at 330°–332°, and the hexabenzoyl compound, colourless needles, m.p. 343°–345°. Cyanellagic acid is most probably dihydroxyellagic acid, and in this case possesses the following constitution :—
It dyes mordanted fabrics more readily than ellagic acid. A. G. P.

CYANIDES. Compounds of the radical cyanogen CN. The history of the cyanid

industry begins with the discovery of Prussian blue by Diesbach in 1704 (H. Kopp, Geschichte der Chemie, 4, 369). While attempting to make Florentine lake by precipitating a mixture of cochineal infusion, alum, and ferrous sulphate with an alkali, he obtained a blue colour. The alkali used was potash, over which Dippel had distilled his animal oil, and Dippel recognised in this the source of the blue colouring matter. The new blue very quickly came into use in place of ultramarine, and in 1710 it was sold at one-tenth the price of the latter. The method of manufacture was a secret until 1724, when Woodward showed that the blue could be prepared by calcining blood with potassium carbonate and then treating the aqueous extract [1] with ferrous sulphate and alum, the greenish precipitate so obtained yielding Prussian blue when treated with hydrochloric acid.

This, in its essential features, was the method of manufacture which supplied the world's requirements of cyanogen compounds for nearly 150 years.

Macquer, in 1752, showed that alum is not required, and that Prussian blue, when boiled with an alkali, yields ferric hydroxide and a soluble salt from which the blue can be regenerated. This salt, potassium ferrocyanide, was first obtained in the crystalline form by Sage in 1772.

The brilliant researches of Scheele, 1782–3 (Chemical Essays, London, 1786), Berthollet, 1790 (Ann. Chim. Phys. 1790, 1, 30), and of Gay Lussac, 1815 (ibid. 1815, 95, 156), in the course of which the relationships of the ferrocyanides, hydrocyanic acid, cyanogen, and many of their derivatives were discovered, laid a firm scientific foundation for the industry.

Prussian blue was manufactured in Great Britain in 1770 by Bramwell & Co. of Newcastle ; it sold then at 2 guineas per lb. ; the price had fallen in 1815 to 10s. 6d., in 1820 to 2s. 6d., and in 1850 to 1s. 9d. Crystallised potassium ferrocyanide was first known in commerce about 1825, the price being 5s. per lb., although a solution had been sold previously (Graham, Reports of Juries, Exhib. of 1851, 1, 95).

The conversion of potassium ferrocyanide into potassium cyanide by fusion with potassium carbonate, was first described by F. and E. Rodgers in 1834 (Phil. Mag. 1834 [3] 4, 91), but the simple cyanides were not used in any considerable quantity until the process of electroplating with gold and silver, from a cyanide solution, was discovered by J. R. and H. Elkington in 1840 (Eng. Pat. 8447, of 1840).

An interesting application of potassium ferricyanide was discovered by Sir J. Herschel in 1842 (Phil. Trans. 1842). Paper, treated with a solution containing ferric ammonium citrate and potassium ferricyanide, becomes blue when exposed to light, owing to the reduction of the ferric salt and consequent formation of Prussian blue. Paper sensitised in this way is used for the reproduction of engineering drawings.

A very remarkable attempt was made by Possoz and Boissière in the year 1843, to manufacture cyanides from atmospheric nitrogen ;

[1] *Lixivium sanguinis* or blood-lye, whence the German name of potassium ferrocyanide, '*blutlaugensalz.*'

this is described under the heading POTASSIUM CYANIDE.

The year 1860 witnessed three important developments in the cyanide industry. Gautier-Bouchard (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59–63) began to produce prussiate from the spent oxide of the Paris gas works. A. Gélis (Eng. Pat. 1816, of 1860) synthesised it from carbon disulphide and ammonia; and Margueritte and de Sour-deval (Eng. Pat. 1171, of 1860) attacked the problem of the fixation of atmospheric nitrogen by means of barium oxide and carbon.

The existence of cyanogen compounds in coal gas was known in 1843, and possibly still earlier. E. Jacquemyns (Annalen, 1843, 46, 236), whose attention was drawn to them by H. Rose, says that he found none in gas lime, but obtained 0·75 gram of Prussian blue per litre from ammonia liquor. The purification of coal gas by means of iron oxide was introduced in 1847. Owing to the repeated use of the same quantity of oxide, the cyanogen compounds accumulate in it in a relatively concentrated form, and it was therefore naturally the first gas works product to be used in their manu-facture. Prussian blue, made from spent oxide, was exhibited by Gauthier-Bouchard at the London Exhibition of 1862.

Both the process of Gélis and that of Mar-gueritte and de Sourdeval were soon abandoned by their inventors; the recovery of cyanides from spent oxide, on the other hand, developed fairly rapidly, and, according to Dupré (Journ. für Gasbeleuchtung, 1884, 885), there were, in 1884, 10 works making prussiate by this means.

The competition of the gas works ferrocy-anide, the increasing cost of nitrogenous organic matters (which were being more and more used as fertilisers), and the diminished use of Prussian blue due to the competition of blue colouring matters derived from coal tar, led to the dis-appearance of the old process in Europe about this time.

In the United States of America, it appears to have held its own somewhat longer; the returns of the U.S. Census for 1900 (Bulletin No. 210, 31, 1902) show 18 works engaged in the manufacture of cyanides with a joint annual production of 2752 tons of yellow prussiate, almost entirely made from hoofs, horns, and scrap leather, only 1200 tons of spent oxide having been used.

Between 1875 and 1885, the sulphocyanides, especially the tin and aluminium salts, appear to have been used in calico printing instead of the acetates (Bertelsmann, Die Technologie der Cyanverbindungen, 303), and Gélis' synthesis was taken up and improved by Günzburg and Tcherniac (Eng. Pat. 1148, of 1878; 1359, of 1879; 1261, of 1881), but without financial success.

In 1887, J. S. MacArthur, R. W. and W. Forrest (Eng. Pat. 14174, Oct. 19, 1887; 10223, of 1888) patented their process for the extraction of gold and silver from their ores by means of a dilute solution of a cyanide. The process was carried out by allowing a solution containing 0·25 p.c. or less of potassium cyanide to perco-late through the ore, which was usually ground to pass a sieve with 40 or 60 holes to the linear

inch. The gold is dissolved in the form of potassium aurocyanide, and is recovered from the solution by passing it through a mass of zinc shavings. The process was first put into practice at Karangahake, New Zealand, in 1889, and near Johannesburg, Transvaal, in 1890. The success of these installations led to a very rapid adoption of the process in all the gold-producing countries of the world.

Prior to the introduction of this process, the cyanide industry was quite a small one. The world's consumption of potassium cyanide (produced exclusively from ferrocyanide by the Rodgers process) (F. Roessler, V. Internationaler Kongress für Angewandte Chemie, Berlin, 1903, 1, 638) did not exceed 50–70 tons per annum (G. Beilby, J. Soc. Chem. Ind. 1898, 134) and that of yellow prussiate was probably under rather than over 5000 tons (worth together about 325,000l.).

Ten years later, just before the Transvaal War, the European production of potassium cyanide was estimated by Beilby (V. Inter. Kongress Angew. Chem. Berlin, 1903, 1, 630) as 5500 tons, adding the American production of about 1000 tons (U.S. Census Bulletin, No. 210, 31, 1902), we arrive at a total production of 6500 tons.

The increased quantities of potassium cyanide required by the gold-mines were at first supplied by fusing potassium ferrocyanide with potassium carbonate, and very soon afterwards by E. Erlenmeyer's process (Ber. 1876, 1840), in which dry prussiate and metallic sodium are used : $K_4Fe(CN)_6 + 2Na = 2NaCN + 4KCN + Fe$. Synthetic processes producing cyanide direct without the intervention of prussiate, were also proposed in great numbers. The approximate numbers of patents connected with cyanide manufacture applied for were : 1889–1898, 104 ; 1899–1908, 129 ; 1909–1917, 106. The principal processes which have been worked with some measure of success, are :—

Process.	Where worked.	Began pro-duction in
Siepermann.	Stassfurt, Germany.	1892
Beilby.	Glasgow, Scotland	1892
British Cyanides Co.	Oldbury, England.	1895
Raschen.	Runcorn, England.	1898
Readman.	Leven, Scotland.	1899
Castner.	Germany, Scotland, U.S.A.	1899–1900
Bueb ('Schlempe').	Dessau, Germany.	1902

These, and others, are described fully below.

The recovery of cyanides from the products of distillation of coal was also improved by the introduction of special cyanide scrubbers during the decade 1890–1900 ; whereas the iron oxide purifiers had yielded but little more than one-half of the cyanogen in a useful form, the newer processes give an almost quantitative recovery.

About the year 1900 the fruit trees of Cali-fornia and the Southern States of America were threatened with extermination by a parasitic scale. The investigations of the Experiment Stations of the U.S. Department of Agriculture showed that this could be killed without injury to the trees by fumigation with hydrocyanic acid. The method, which was introduced

about 1903, is now very widely used, both in the United States of America and in other countries. It has also been extended in other directions, such as killing insects in hot-houses, and freeing railway carriages and houses from vermin (in South Africa). Details will be found under the heading *Hydrocyanic acid*. Statistics collected by George P. Gray show that the consumption of sodium cyanide for fumigating citrus trees during 1916 in the State of California alone exceeded 1300 tons (J. Ind. Eng. Chem. 10, 301, 1918).

Another application which may be mentioned is in case-hardening iron; immersion in fused cyanide produces a very hard skin on mild steel, and both cyanides and ferrocyanides have long been used for this purpose in ordinary workshop practice. According to J. E. Bucher (J. Ind. Eng. Chem. 9, 236, 1917), the reversible reaction $2NaCN \rightleftharpoons 2Na + 2C + N_2$ takes place in presence of iron; if pure iron is heated with sodium cyanide the latter is decomposed and the carbon combines with the iron; if, on the other hand, carbonised iron is heated with sodium and nitrogen, the carbon is removed from it, and cyanide formed.

Potassium cyanide, as used in electroplating, was a material having the appearance of unglazed porcelain, and containing from 30 to 70 p.c. of KCN, together with large quantities of carbonate and cyanate. The material supplied to the gold-mines in the early days of the gold-extracting process was a black mass containing some 75 p.c. of KCN, and all the iron and carbon liberated by the decomposition of the ferrocyanide. This was replaced by the pure white crystalline product of the Erlenmeyer process, which contained about 2 molecules of KCN to 1 molecule of NaCN, the cyanogen content being about 40 p.c., equivalent to 98-100 p.c. of KCN. The earlier produce of the Beilby process was in the form of cakes, which were coloured black by a small percentage of charcoal. Later, by filtration of the molten cyanide, the charcoal was removed, and the product was white or pale grey, and free from insoluble impurities. Shortly after the introduction of the Castner process, in 1900, solid cakes of pure white crystalline sodium cyanide, containing 97 p.c. to 98 p.c. of NaCN (equivalent to 129-130 p.c. of KCN), became an article of commerce, and this is at present the form in which the greater part of the cyanide employed in gold-extracting is used. Sodium cyanide, obtained by the evaporation of aqueous solutions, as in the Readman and 'Schlempe' processes, is compressed into briquettes, which contain about 90 p.c. of NaCN.

Potassium ferrocyanide has also been replaced to a very large extent by the sodium salt which is quite easily prepared by the more recent methods of extracting the hydrocyanic acid from coal gas by special cyanogen washers.

The rapid rate of increase in the world's consumption of cyanide which followed the introduction of the gold-extracting process has not been maintained. Since 1909 the annual value of the world's gold output has been almost stationary at a little more than 90,000,000*l*., and improvements in the process of extraction have everywhere tended to diminish the quantity of cyanide needed to produce this. On the Rand, where this tendency seems to have almost reached a limit, the average consumption of cyanide is 0·4 lb. KCN per ton of ore treated (H. A. White, J. Chem. Met. and Min. Soc. S. Africa, 1915, 16, 24). Increased use in the treatment of silver ores (much delayed, however, by political troubles in Mexico) and in agriculture have kept the world's consumption from 1910 to 1920 approximately constant at, in round figures, 20,000 tons per annum. In 1912 and 1913 Germany exported 6700 tons per annum (The Mineral Industry, 1917, 25, 882). The deficit caused by the cessation of these exports on the outbreak of war in 1914 has been covered by increased production in Great Britain; a temporary shortage in the United States was soon overtaken by the American makers.

Manufacture of Potassium and Sodium Ferrocyanides.—(1) From nitrogenous organic matter.

The method of manufacture from nitrogenous organic matter is now only of historical interest.

The sources of nitrogen were horn, dried blood, hair, waste wool, and feathers (15-17 p.c. N), woollen rags (10-16 p.c. N), pigs' bristles (9-10 p.c. N), and old leather (4·5-7 p.c. N). These materials were sometimes charred before use, about 80 p.c. of the nitrogen being driven off in the form of ammonia, hydrocyanic acid, and a complicated mixture of nitriles and organic bases.

The process was carried out at first in pear-shaped, cast-iron muffles, which were replaced later by reverberatory furnaces, the beds of which were formed of cast-iron pans, 5 feet long, 3 feet wide, 4 inches deep, and about 2 inches thick. A charge of 2 cwt. of potash (usually made up of 2 parts of the 'blue salt' recovered in a later stage of the process, and 1 part of fresh potash) was put into the pan and fused with 18-20 lbs. of iron turnings; 2 cwt. of the dry nitrogenous materials were then stirred in gradually (2·5 to 3 cwt. of charred material could be added without making the mass too pasty). The temperature was then raised in order to complete the reaction, and the melt ladled out into iron moulds. After solidification, it was broken up and digested for 24 hours with water at 50°-60°, and finally extracted completely with boiling water. The solution obtained contained potassium ferrocyanide, sulphocyanide, carbonate and sulphide. It was evaporated to sp.gr. 1·28, and allowed to crystallise. Further evaporation yielded a second crop of impure crystals, the mother liquor of which was evaporated to dryness, leaving a mixture of potassium carbonate and sulphide, known as 'blue salt' which was returned to the fusion pan.

The black insoluble residue left from the extraction of the 'metal,' as the product of the fusion, was called, contained considerable quantities of potassium, mainly in the form of potassium ferrous sulphide and of double potassium, calcium, and aluminium silicates.

The quantity of 'metal' produced was very little greater than the weight of potash used, and 4 charges were put through in 24 hours, but practice varied considerably: C. Karmrodt (Wagner's Jahresber. 1857, 3, 139) speaks of

6 charges of 500 lbs. each as the normal output of a pan in 24 hours.

The yield of ferrocyanide was seldom more than 20 p.c. of the quantity theoretically obtainable from the nitrogen in the materials used when they were not previously charred. Using charred materials, as much as 57 p.c. of the remaining nitrogen was converted into ferrocyanide, corresponding with a yield of about 12 p.c. on the nitrogen originally present.

The quantity and composition of the black residues varied greatly with the kind of organic matter used. The main constituents were carbon (4–9 p.c.), ferrous sulphide, iron, and inorganic substances derived from the ash of the animal matters and adhering dirt, the principal being silica, lime, alumina, and phosphoric acid. The quantity of potassium combined with these substances in an insoluble form was considerable. According to Karmrodt (Wagner's Jahresber. 1857, 3, 139), 100 parts of ‘ metal ’ made (1) from horn gave 18·7 p.c. of dry residue, containing 12·2 p.c. of K_2O ; (2) from rags, 28·3 p.c. of residues, with 16·7 p.c. K_2O ; (3) from leather, 35·1 p.c. of residue, with 10·2 p.c. K_2O. These quantities represent about 4½, 9, and 7 p.c. of the potassium contained in the original charge, and since only some 10 p.c. of this is converted into ferrocyanide at each operation (R. Brunquell, Wagner's Jahresber. 2, 102, 1856), the loss of potash in the residues appears to have been from 45 to 90 p.c. of that usefully employed. Potash was also carried away with the flue gases. The iron pans survived several hundred operations.

The theory of the process was first given by Liebig (Annalen, 1841, 38, 20). Scheele (Chemical Essays, London, 1786 ; reprinted 1901) had already shown that *lixivium sanguinis* is essentially a solution of potassium cyanide and that the addition of a ferrous compound is necessary to convert it into prussiate. Liebig confirmed this by extracting the ‘ metal ’ with alcohol, which dissolves out potassium cyanide, leaving a residue from which no ferrocyanide can be obtained. He attributed the formation of the cyanide partly to the action of ammonia (formed by destructive distillation of the organic matter) on carbon, $C + NH_3 = HCN + H_2$, and partly to the action of potassium on the nitrogenous residue of carbon. It may be remarked that the temperature of the fusion could not have exceeded 1000°, since cast iron melts about 1100°, and the pans withstood some hundreds of fusions. The temperature, too, was lowered by the addition of the organic matter, occasionally sufficiently to cause the charge to solidify, so that the reaction between ammonia and carbon, which requires a temperature of about 1000°, could not have occurred to any great extent. The direct action of ammonia on potassium carbonate would, however, take place, although, the ammonia being evolved on the surface of the mass, the conditions were not favourable to it. As to the second of Liebig's reactions, the writer has found that potassium is not formed in appreciable quantity from a mixture of charcoal and potassium carbonate below about 1200°, certainly not at 1000°, so that the greater part of the cyanide must have been formed by the action of potassium carbonate itself on the unknown carbon-nitrogen com-

pounds contained in the charred organic matter. That cyanide may be formed in this way is indicated by the fact that carbazol, when heated to redness with caustic potash, yields considerable quantities of it (G. Kraemer, Eng. Pat. 16529, of 1894). The rôle of sulphur in the process was explained by Liebig thus : potassium sulphate, which is always present in the potash, is reduced by carbon to sulphide, carbonate, and polysulphide. The latter dissolves iron, forming a double sulphide of iron and potassium which, when the product is lixiviated, dissolves in the potassium cyanide solution thus :

$$6KCN + FeS = K_4Fe(CN)_6 + K_2S$$
If insufficient iron is present in the fusion, the polysulphide is not entirely decomposed, and potassium sulphocyanide is also formed. R. Hoffmann (Annalen, 1860, 113, 81) investigated the behaviour of the sulphur compounds in the process in some detail, and found that the sulphur of potassium sulphide is rapidly and completely removed by iron alone in the fusion process, and that the same is true of potassium sulphate in presence of carbon. When organic matters are added to the sulphur-free melt, however, sulphocyanide is produced in proportion to the quantity added. Hoffmann, therefore, attributes its formation to the organic matter.

The behaviour of potassium sulphocyanide in the fusion is not clearly understood. Hoffmann found that it is completely decomposed by fusion with excess of potassium carbonate, yielding cyanate and sulphide ;[1] but if the mixture is again heated with carbon, the sulphocyanide is regenerated. It appears, therefore, that, under the conditions of the process, sulphocyanide is not decomposed. The reaction between iron and sulphocyanide is described below.

A part of the sulphide of iron formed is present in the form of a potassium ferrous sulphide, $FeS \cdot xK_2S$, which dissolves in hot water to a dark-green, colloidal solution which is coagulated by cooling or by adding excess of potassium carbonate. Another part is probably present in the form of the crystalline potassium ferric sulphide $K_4S \cdot Fe_2S_3$, obtained by K. Preis (J. pr. Chem. 1869, 107, 10), by fusing together finely divided iron, potassium carbonate, and sulphur. He found that the crystalline sulphide was formed at very high temperatures, and the amorphous one, yielding the green solution, at lower temperatures.

The reaction between potassium cyanide and ferric sulphide

$$13KCN + Fe_2S_3 = 2K_4Fe(CN)_6 + KSCN + 2K_2S$$
would give a ratio of cyanogen in the form of sulphocyanide to cyanogen in the form of ferrocyanide of 1 : 12, whilst Hoffmann, in 10 experiments, found ratios varying from 1 : 5 to 1 : 18.

The improvements in the process which were proposed aimed at saving the ammonia evolved in the early stages by distilling the organic matters separately and passing the ammonia

---

[1] I can confirm the accuracy of this observation. Equal molecules of potassium carbonate and sulphocyanide were fused together in a closed aluminium crucible at 500°–580° for 1½ hours, a little more than half of the materials had reacted in accordance with the equation $KSCN + K_2CO_3 = KCNO + K_2S + CO_2$.—T. E.

through a red-hot mixture of potash and charcoal (Brunquell, Wagner's Jahresber. 1856, 2, 102), or a similar mixture with iron added (Karmrodt, *ibid.* 1857, 3, 139), or over red-hot charcoal forming hydrocyanic acid which was to be absorbed, together with the unchanged ammonia, in a solution of ferrous sulphate (Brunquell). These proposals, unfruitful at the time, are interesting as foreshadowing processes which came into successful operation nearly half a century later.

The belief, which prevailed until about the end of the nineteenth century, that cyanogen compounds are more easily produced from potash than from soda, is not entirely in accordance with the older experimental evidence. The truth appears to be that equally good results can be obtained with sodium carbonate under suitable conditions, but the conditions are not so easily realised.

L. Possoz (Compt. rend. 1858, 47, 209) obtained, under manufacturing conditions, 5 parts of sodium prussiate, instead of 25 parts of the potassium salt, from 100 parts of horn. R. Hoffmann (Annalen, 1860, 113, 81), using a very high temperature and sodium carbonate, got the equivalent of 11 parts of potassium ferrocyanide from 100 parts of woollen rags, against 10 to 14 parts with potash, and S. Tanatar (Dingl. poly. J. 1880, 237, 234) obtained the results tabulated below, as the means of 3 to 5 experiments :—

Blood charcoal	K₂CO₃	Na₂CO₃	NaCl	CaCO₃	Prussiate obtained
10	25	—	—	—	2·15
10	—	25	—	—	0·2
10	—	5	25	—	2 17
10	—	5	25	3	2·3

Manufacture of Potassium and Sodium Ferrocyanides.—(2) *From the products of distillation of coal.* The coal used in the manufacture of illuminating gas may be taken to contain from 1 to 1·9 p.c. of nitrogen (Drehschmidt, Journ. für Gasbeleuchtung, 1904, 677 ; J. McLeod, J. Soc. Chem. Ind. 1907, 26, 137). When the coal is distilled, a part of this nitrogen passes into the gas in the form of ammonia, hydrocyanic acid, and free nitrogen, a small part is found in the tar, and the remainder in the coke. The distribution of the nitrogen between these products varies considerably, being influenced by the nature of the coal, the amount of moisture in it, the temperature of distillation, and the kind of retort used. The following table indicates the magnitude of the quantities involved when the coal is distilled dry :

No.	Kind of coal	P.c. of the total N of the coal in				
		Coke	NH₃	HCN	Tar	Gas
1	Durham .	48·7	14·5	1·6	—	35·2
2	Westphalia	50	12–14	1·8	1·5	30·0
3		48	15	2	—	35
4	Scottish .	58·3	17·1	1·5	3·9	19·5

1. Foster, J. Gas Lighting, 1882, 1081.
2. Knublauch, J. Soc. Chem. Ind. 1896, 15, 106.

3. Chief Inspector of Alkali Works, 43rd Report, 1906, 58.
4. J. McLeod, J. Soc. Chem. Ind. 1907, 26, 137 ; and Alkali Works, 44th Report, 1907, 215.

The effect of temperature on the distribution of the nitrogen has been investigated by O. Simmersbach (J. Soc. Chem. Ind. 1915, 34, 895), using a Silesian coal containing 1·396 p.c. of N. The following table contains some of his results :

Temp.	P.c of the total nitrogen				
	as NH₃	as HCN	in tar	as N₂ in gas	in coke
600	7·81	0·25	2·12	18·13	71·69
800	21·28	0·87	3·47	10·73	63·65
1000	23·15	1·23	4·11	21·53	49·98
1200	22·84	1·42	4·21	· 45·10	26·43

Even the ammonia liquor from low temperature carbonisation retorts working at 427°–455°• contains traces of cyanogen compounds (Alkali Works, 45th Report, 1908, 52).

Hydrocyanic acid is converted into ammonia by water vapour at the temperature of distillation used in gas works and coke ovens

$$HCN + H_2O = NH_3 + CO$$
(Carpenter and Linder, J. Soc. Chem. Ind. 1905, 24, 63). The gas from coke ovens distilling coal with some 12 p c. of moisture therefore contains about two-thirds of the quantity of hydrocyanic acid found in the gas made from almost dry coal in gas works.

The gas leaving the retorts contains the whole of its cyanogen in the form of hydrocyanic acid (Alkali Works, 43rd Rep. 1906, 33), the fate of this depends on the process of purification adopted. In common practice about one-third of it is condensed along with the ammonia in the virgin liquor and ammonia scrubbers in English works (Alkali Works, 43rd Rep. 1906, 61), but less in many German works, where less water is used in the scrubbers (Bertelsmann, Technologie der Cyanverbindungon, 171). The greater part of this is converted into sulphocyanide, and escapes finally in the effluent from the ammonia stills. From 50 to 70 p.c. is caught in the iron oxide purifiers, the remainder passing away with the gas, where it is a source of damage to meters and gas-holders. A more complete recovery is obtainable when one of the cyanide washers described below is placed before the ammonia scrubbers. Up to 1908 attempts to recover cyanogen compounds from coke-oven gases had been unsuccessful (Alkali Works, 44th Rep. 1907, 40).

The total quantity of cyanogen compounds formed during the destructive distillation of coal is very considerable. In 1912 the world's production of ammonium sulphate was 1,144,000 tons. In Great Britain over 70 p.c. of the production came from gas works and coke ovens in which roughly one molecule of hydrocyanic acid accompanies ten molecules of ammonia. Assuming the same conditions in other countries, it appears probable that hydrocyanic acid equivalent to 80,000 tons of KCN is formed annually ; only a small part of this is actually recovered.

Formation of HCN from Ammonia and Carbon.

—The earliest synthesis of hydrocyanic acid was effected by Clouet (Ann. de Chim. 1791, 11, 30), by passing dry ammonia over wood charcoal heated to bright redness in a porcelain tube. This reaction has been studied quantitatively by E. Bergmann (Journ. für Gasbel. 1896, 39, 117), D. Lance (Compt. rend. 1897, 124, 819), G. A. Voerkelius (Dissertation, Hannover, 1909), and Carpenter and Linder (Alkali Works, 45th Rep. 1908, 26 ; 46th Rep. 1909, 21). The formation of hydrocyanic acid begins at about 700°, and the best yields, calculated on the ammonia used, are obtained at temperatures between 1000° and 1100°. The reaction $NH_3 + C \rightleftarrows HCN + H_2$ is reversible, and should lead to an equilibrium between ammonia, hydrocyanic acid, and hydrogen ; the equilibrium, however, cannot be realised, because both ammonia and hydrocyanic acid are unstable at the temperatures required. The final result depends, therefore, on the rates of decomposition of ammonia and hydrocyanic acid and on the rate of reaction between ammonia and charcoal. Even at 1000°, the rate of decomposition of hydrocyanic acid in presence of charcoal is small, but in presence of other substances it may be large. Voerkelius, for example, passed a mixture of hydrocyanic acid and hydrogen through an unglazed porcelain tube at 1000°, and found that over 70 p.c. of it was decomposed, but, after a layer of carbon had been deposited on the tube the decomposition fell to 19 p.c. The rate of decomposition of the ammonia is even more variable ; for example, at 720°, 28 p.c. of the ammonia survived 6 minutes' contact with fresh finely ground wood charcoal, whilst 82 p.c. were unchanged when the charcoal was in the form of lumps which had been already used. The rate of decomposition of the ammonia is diminished by diluting it with an indifferent gas.

In the 66 experiments recorded by Voerkelius, the ammonia (diluted with hydrogen) was in contact with the charcoal for from 16 to 360 seconds ; within these limits, the ratio between the numbers of molecules of ammonia and of hydrocyanic acid in the product is roughly independent of the time of reaction, but the quantity of ammonia decomposed into its elements increases with the time of contact. The following table is calculated from the figures given by Voerkelius. The figures show the influence of the quality of the charcoal on the result :—

Temperature		P.c. NH₃ in gas used	Mols. HCN in product
			Mols. NH₃
720° charcoal A		50	6·7–13·4 mean 9·80
,, B		50	29–45 ,, 37·7
sugar charcoal		50	71 ,, 71
1020° charcoal C		13–15	0·64–0·92 ,, 0·76
,, D		13–15	0·90–1·80 ,, 1·40
,, C		43–47	0·50–0·90 ,, 0·61
1120° ,, D		13·4	0·44–0·48 ,, 0·46

Nernst's thermodynamic theorem (Application of Thermodynamics to Chemistry, London) 1907, and Theoretische Chemie, 5th and 6th ed. has been applied to this reaction by v. Wartenberg (Zeitsch. anorg. Chem. 1907, 52, 299). Since the reaction $NH_3 + C = HCN + H_2$ absorbs 39,500 cals. per molecule, the equilibrium must

lead to the formation of more hydrocyanic acid at higher temperatures, the calculation indicates that the ratio of the partial pressures (in atmospheres) of the gases in equilibrium should have the following values :—

Temperature	$\dfrac{p_{NH_3}}{p_{HCN} \times p_{H_2}}$
500°	632
800°	0·27
1100°	0·003
1400°	0·0002

In the experiments tabulated above, the final mixture of gases usually contained nearly 95 p.c. of hydrogen, the partial pressure of which was therefore almost 1 atmosphere. The molecular ratio of ammonia to hydrocyanic acid is, therefore, almost the same as the ratio of the partial pressures. A comparison of the experimental values with those calculated shows that equilibrium is never even approximately attained. They agree in indicating 700° as the lowest temperature at which appreciable quantities of hydrocyanic acid can be formed.

Carpenter and Linder's independent investigation yielded results in close agreement with those obtained by Voerkelius. It seems fairly certain that the greater part of the hydrocyanic acid found in the products of destructive distillation of coal is formed by the reaction which has just been discussed. The presence of small quantities of HCN in the products formed at temperatures below 600° indicates, however, that it may be, in part, a primary product of the decomposition.

Spent oxide. The hydrated oxide of iron first used in gas purification was made by mixing ferrous sulphate and slaked lime, sawdust being added to increase the porosity (Laming, Eng. Pat. 11944, of 1847); natural iron ores were introduced by Howitz in 1870. Sulphuretted hydrogen is absorbed, yielding a mixture of ferrous and ferric sulphides which is regenerated by exposure to air and moisture, free sulphur and ferrous and ferric hydroxide being produced. Ferrocyanide is formed from the ferrous hydroxide and ammonium cyanide, and then converted into Prussian blue by interaction with the ferric iron. Sulphocyanides are also formed in very variable amount, doubtless by the interaction of hydrocyanic acid and ammonium polysulphide. Since ammonia, sulphuretted hydrogen, and free sulphur are always present in the purifiers, it is obvious that polysulphides of ammonium can always be formed ; it appears to be generally allowed, however, that sulphocyanide is only produced in large amount when the mixture becomes warm, as, for example, when the regeneration proceeds rapidly in a large mass of material. The spent oxide finally contains 30 to 40 p.c. of sulphur (or more), soluble ammonium salts and Prussian blue, in addition to tar and iron oxides. Good material contains 11 to 12 p.c. of Prussian blue, calculated on the air-dried substance, whilst ammonium sulphocyanide varies from traces to 10 p.c.

As already mentioned, prussiates were first produced from spent oxide by Gautier-Bouchard about 1860. Ammonium salts were first removed by washing with water ; the residue was then mixed intimately with sufficient lime to

convert the Prussian blue into calcium ferro-cyanide and the mixture submitted to systematic lixiviation with cold water. This operation must be done in the cold, because otherwise calcium polysulphide is produced from the lime and free sulphur, and this converts the ferro-cyanide into sulphocyanide. The calcium ferro-cyanide was converted into the potassium salt by means of potassium carbonate, and the sulphur in the extracted residue burned to sulphur dioxide and converted into sulphuric acid (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59–63). This process contains the essential features of all those which have since been worked successfully.

T. L. G. Bell (Eng. Pat. 257, of 1868) proposed to extract the sulphur with carbon disulphide, and, after removing soluble ammonium salts with water, to boil the residue with lime. In order to obtain a pure product, the solution was then acidified and precipitated by the addition of ferric chloride, the Prussian blue being then converted into potassium ferro-cyanide. The preliminary extraction of the sulphur has occasionally been carried out, but it is difficult to separate the sulphur from the tar which is extracted along with it. In spite of the great difficulty of filtering and washing Prussian blue, this method of purification appears to have been fairly generally used up to the year 1883, when Kunheim and Zimmermann (Eng. Pat. 3342, of 1883) described two new methods.

In the first, the ammonia is only partially removed from the spent oxide by the preliminary washing, enough being left behind to produce the double salt $Ca(NH_4)_2Fe(CN)_6$. The extraction with lime then yields an ammoniacal solution of calcium ferrocyanide, which, when neutralised with hydrochloric acid and heated to 80°, deposits the very sparingly soluble calcium ammonium ferrocyanide, which is comparatively easily filtered and washed.

By the second method, the solution of calcium ferrocyanide, obtained by following Gautier-Bouchard's original procedure, is treated with a solution of potassium chloride which precipitates the double salt $CaK_2Fe(CN)_6$ in minute crystals, which are very readily washed and are then converted into potassium ferro-cyanide by boiling with potassium carbonate. By this means one-half of the potassium carbonate is replaced by the cheaper chloride, and a very pure product is obtained (Franz Bössner, Die Verwerthung der Ausgebrauchten Gasreinigungsmassen, 1902). From the calcium ammonium salt, sodium ferrocyanide is readily obtained.

During the decade 1885 to 1895, the spent oxide of the gas works was the principal source of prussiates; its importance, however, has been diminished by the introduction of the more efficient wet methods of recovering the hydrocyanic acid.

Cyanide Washers.—The first practicable proposal of this kind was made by O. Knublauch (Eng. Pat. 15164, of 1887). Coal gas was to be scrubbed with a solution of the oxide, hydroxide, carbonate, or sulphide of ammonium, or of an alkali or alkaline-earth metal containing the hydroxide or carbonate of iron, zinc, or manganese in suspension. The process did not succeed

at the time, probably for commercial reasons. The very similar process of Foulis (Eng. Pat. 9474, of 1892; Foulis and Holmes, Eng. Pat. 15168, of 1895) has since been introduced at several gas works with satisfactory results. In this process, the reagent required is prepared by precipitating a ferrous salt with sodium carbonate. The washed precipitate (a partially oxidised mixture of ferrous carbonate and hydroxide) is suspended in a solution of sodium carbonate and the gas passed through it in a rotary scrubber. Foulis wished to obtain the whole of the ferrocyanide in the form of a solution of the sodium salt, and therefore placed the cyanogen washer after the ammonia scrubbers because, in presence of ammonia, an insoluble ammonium ferrous ferrocyanide is formed which is only decomposed by sodium hydroxide, but not by the carbonate. At the Hague gas works, however, this order was reversed in order to catch the hydrocyanic acid which is otherwise condensed along with the ammonia (Rutten, Journ. of Gas Lighting, 1902, 80, 879; Jorrisen and Rutten, Journ. für Gasbeleuchtung, 1903, 716). The saturated liquor from the cyanide washer contains Prussian blue and potassium and ammonium ferrous ferrocyanides in suspension and potassium ferrocyanide and ammonia in solution (potassium carbonate is used instead of the sodium salt). This mixture is filter-pressed and the solution distilled to separate the ammonia and then evaporated *in vacuó* and crystallised. The press cake is boiled with caustic potash and the ammonia collected, the residual iron oxide returning to the cyanide washer, and the solution of ferro-cyanide going to the evaporating plant.

In another set of proposals, the use of an alkali other than the ammonia of the gas is dispensed with, the crude coal gas being simply washed with a solution of ferrous sulphate. Since ammonia and sulphuretted hydrogen are present in much larger quantities than hydrocyanic acid, the ferrous sulphate is soon converted into a suspension of ferrous sulphide in a solution of ammonium sulphate, and the subsequent changes may be regarded as due to the action of a solution of ammonium cyanide on ferrous sulphide. If a large excess of the latter is present, the main product is ferrous ferro-cyanide $Fe_2[Fe(CN)_6]$; as the ferrous sulphide is used up, ammonium ferrous ferrocyanide $(NH_4)_2Fe[Fe(CN)_6]$ is formed in increasing quantities, and finally, when but little FeS remains, ammonium ferrocyanide is found in solution (Feld, Journ. für Gasbeleuchtung, 1904, 132).

The earlier patentees of processes based on these reactions attempted to obtain the ferro-cyanide in a soluble form by using a dilute solution of a ferrous salt, and so having a large excess of ammonia present (Rowland, Eng. Pat. 22347, of 1891; Lewis and Cripps, Eng. Pat. 20883, of 1896; Schröder, Eng. Pat. 19849, of 1898; Teichmann, Eng. Pat. 12485, of 1899), but since insoluble compounds are always formed to some extent, it appears to be easier to obtain all the ferrocyanide (or the greater part of it) in the insoluble form by using a saturated solution of ferrous sulphate, and so having a large excess of iron present as first proposed by Bueb (Eng. Pat. 9075, of 1898). Bueb's process

has been adopted by a considerable number of gas works. It is said to absorb 98 p.c. of the hydrocyanic acid in the gas, yielding a mud containing 6-7 p.c. of ammonia and cyanogen compounds, equivalent to 18-20 p.c. of yellow prussiate of potash. A small part of the ferrocyanide is in solution. This is precipitated by boiling the mixture with ferrous sulphate; the precipitate is then filtered off and treated with lime, the calcium ferrocyanide solution obtained being worked up in the way already described when dealing with spent oxide.

As already mentioned, part of the hydrocyanic acid in coal gas is always converted into sulphocyanide owing to liberation of free sulphur by the action of atmospheric oxygen on sulphuretted hydrogen. By suitable means the whole of the hydrocyanic acid may be fixed in the form of sulphocyanide, which is then converted into ferrocyanide by one of the processes described in the next section.

In 1877 W. Marriott (Eng. Pat. 3311, of 1877) proposed to scrub gas with a solution of sodium polysulphides, and in 1888 Campbell and Boyd (Eng. Pat. 10186, of 1888) proposed the use of manganese dioxide suspended in water. This liberates sulphur from a part of the sulphuretted hydrogen in the gas, and this free sulphur combines with ammonium sulphide to form polysulphide, which converts the cyanide into sulphocyanide. The final step, which led to a successful and economical process, was made by H. Wood Smith (H. Wood Smith, Gidden, Salamon, and Albright, Eng. Pat. 13658, of 1901) by simply scrubbing the gas through a suspension of sulphur, whereby the hydrocyanic acid is removed quantitatively, and a solution containing as much as 200 grams of ammonium sulphocyanate per litre may be obtained. This process is in use at several gas works, and yields practically the whole of the sulphocyanides made at present.

Manufacture of Sodium and Potassium Ferrocyanides.—(3) *From Sulphocyanides.* A. Gélis (Eng. Pat. 1816, of 1860) was the first to manufacture potassium ferrocyanide by heating dry potassium sulphocyanide with iron, made by reducing the oxide, at a dull-red heat, in a closed vessel. He states that too high a temperature leads to considerable loss. The fusion process yields a mixture of potassium cyanide and ferrous sulphide which gives potassium ferrocyanide, when treated with water in the same way as the 'metal' of the old process (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59–63). Sir G. Beilby has informed the writer that he made considerable quantities of potassium ferrocyanide by this process in the years 1873–1876. Potassium sulphocyanide was heated with iron turnings in air-tight iron retorts and, after cooling sufficiently, the product was extracted with water in the retort itself, without coming in contact with air. In this way the only serious difficulty of the process, which is due to the extreme proneness to oxidation of the fusion product, is avoided and satisfactory yields obtained.

The process was taken up again in 1878 by Günzburg and Tcherniac (Eng. Pat. 1148, of 1878; 1359, of 1879; 1261, of 1881). They dried the sulphocyanide by fusing it at 300°, and then mixed it intimately with the oxide-free

iron by grinding them together. The mixture was heated in iron boxes with closely fitting covers at 445°, the vapour of boiling sulphur being used to obtain a constant temperature. After working for two or three years, the process was given up, but it was revived for the third time in 1894 by the United Alkali Co., Ltd. (Hetherington and Muspratt, Eng. Pat. 5830, of 1894), and by the British Cyanides Co., Ltd. (Crowther, Rossiter, Hood and Albright, Eng. Pat. 8305, of 1894). The patent specifications of Hetherington and of Crowther add but little to the information given above. In both cases, some 20 to 30 p.c. excess of iron is used, and the temperature is almost the same as that recommended by Günzburg and Tcherniac. Crowther says that mere fusion is insufficient to dry the sulphocyanide; a current of an indifferent gas must be passed through it for some time. Conroy (J. Soc. Chem. Ind. 1896, 15, 12) was able, in a small scale experiment, to convert 76·8 p.c. of the sulphocyanide used into ferrocyanide (leaving 18·2 p.c. unchanged) by means of Hetherington's method. The process has been worked by the British Cyanides Co. at Oldbury since 1894 (Brussels Exhib. 1910, Catalogue of British Chem. Section, 155).

The conversion of sulphocyanides into ferrocyanides is also possible in aqueous solution. Sternberg (D. R. P. 32892, of 1882), found that by heating a solution of potassium sulphocyanide with double the theoretical quantities of iron filings and ferrous hydroxide under pressure at 110°-120°, about 80 p.c. of the material could be converted into ferrocyanide in accordance with the equation

$$6KCNS + 6Fe + Fe(OH)_2 = 6FeS + K_4Fe(CN)_6 + 2KOH$$
G. R. Bower (Eng. Pat. 361, of 1896) succeeded in removing the sulphur from ferrous sulphocyanide by means of copper in a similar way: $Fe(CNS)_2 + 2Cu = 2CuS + Fe(CN)_2$. Conroy (Conroy, Hurter, and Brock, Eng. Pat. 3867, of 1896; J. T. Conroy, J. Soc. Chem. Ind. 1898, 17, 98) then found that a mixture of a soluble sulphocyanide and a ferric or ferrous salt would do as well as pure ferrous sulphocyanide, and also that the sulphur is more rapidly removed by finely divided iron than it is by copper. Using very finely divided iron, the reaction takes place quantitatively in 5 to 6 hours at a temperature of 135°-140° and a pressure of 50 to 60 lbs. per square inch, in accordance with the empirical equation $Fe(CNS)_2 + 2Fe = Fe(CN)_2 + 2FeS$. (Sodium or potassium sulphocyanide is acted on by iron under similar conditions very slowly and incompletely.) The black mud produced is either boiled with caustic alkali to decompose the ferrous ferrocyanide, or the ferrous sulphide is first dissolved in hydrochloric acid. The latter course is to be preferred, owing to the fact that ferrous sulphide combines with the alkalis, each 3 or 4 equivalents of it rendering 1 equivalent of either caustic soda or potash insoluble, a difficulty with which the manufacturers of ferrocyanide from nitrogenous organic matter had long been familiar.

PROPERTIES OF THE FERROCYANIDES.

The principal characteristics of those salts which possess some technical interest are described here; further information is to be

found in Cyanogen Compounds, by H. E. Williams, 1915, or in the text-books of inorganic chemistry.

Ammonium ferrocyanide is readily prepared in aqueous solution from the free acid and ammonia, or from barium ferrocyanide and ammonium sulphate. The solid salt

$$(NH_4)_4Fe(CN)_6,3H_2O$$
is obtained by evaporating the solution *in vacuô*, or by precipitation with alcohol. The salt crystallises with difficulty in very pale yellow plates, which are isomorphous with potassium ferrocyanide (Bunsen, Pogg. Ann. 1835, 36, 404). The aqueous solution decomposes when boiled, yielding ammonium cyanide and an insoluble residue, which possibly consists of more or less oxidised ammonium ferrous ferrocyanide

$$2(NH_4)_4Fe(CN)_6 = (NH_4)_2Fe[Fe(CN)_6] + 6NH_4CN$$
From solutions containing much ammonium chloride a double salt of the formula

$$(NH_4)_4Fe(CN)_6 \cdot 2NH_4Cl + 3H_2O$$
crystallises very readily in well-formed orange-yellow rhombohedra, which were at one time mistaken for the ammonium salt (Bunsen, *l.c.*).

Barium ferrocyanide $Ba_2Fe(CN)_6,6H_2O$ is precipitated when strong solutions of barium chloride and sodium ferrocyanide are mixed; it separates in the form of a light yellow, crystalline powder. Its solubility (grams of anhydrous salt per 100 grams water) is 0·34 at 15·5°, and 1·01 at 100° (Williams). The water of crystallisation is not quite completely driven off even at 160° (Drechsel, J. pr. Chem. 1880, [2] 21, 77). The dried salt, when heated *in vacuô*, or in an atmosphere of nitrogen, begins to decompose at about 500°, nitrogen, carbon, iron, and barium cyanide and cyanamide being formed. When oxygen is completely excluded the product contains about 2 molecules of cyanamide to 1 of cyanide (Ewan and Napier, J. Soc. Chem. Ind. 1913, 32, 467).

Barium potassium ferrocyanide

$$BaK_2[Fe(CN)_6],3H_2O$$
is precipitated as a pale yellow, crystalline powder when solutions of barium chloride and potassium ferrocyanide are mixed in equivalent quantities. Its solubility in water (grams anhydrous salt per 100 grams water) is 2·1 at 15·5°; 6·08 at 100°.

Calcium ferrocyanide $Ca_2Fe(CN)_6,12H_2O$ is extremely soluble in water; highly concentrated solutions are very viscous and crystallise with difficulty, yielding small yellow triclinic crystals of sp.gr. 1·68, which effloresce when exposed to the air and lose 11½ molecules of water at 40°. H. G. Colman (Journ. of Gas Lighting, 1910, 583) finds that the whole of the water is removed by heating the salt in a current of air. The dry salt begins to decompose (in absence of oxygen) at 500° yielding calcium cyanamide thus

$$Ca_2Fe(CN)_6 = 2CaCN_2 + Fe + N_2 + 4C$$
(unpublished experiments made by the writer).

Calcium ammonium ferrocyanide

$$Ca(NH_4)_2Fe(CN)_6$$
is a white, minutely crystalline powder, which becomes coloured on exposure to light; it is anhydrous; 100 grams of water, at 15°–17°, dissolve 0·258 gram of the salt (J. Campbell Brown, Chem. Soc. Trans. 1907, 91, 1826)

Calcium potassium ferrocyanide $K_2CaFe(CN)_6$ is a white powder consisting of small quadratic prisms which becomes slightly cream-coloured on exposure to light. It contains no water of crystallisation and, at 15°–17°, 100 grams of water dissolve 0·41 gram of it (J. Campbell Brown, *ibid.* 1907, 91, 1826).

According to Williams (*l.c.*), the solubilities of these salts are rather larger, viz. 0·35 at 15°, and 0·39 at 100° for the ammonium salt; and 0·72 at 15°, and 0·80 at 100°, for the potassium salt.

Cupric ferrocyanide $Cu_2Fe(CN)_6 \cdot 11H_2O$ is a red-brown, amorphous substance, obtained by adding a solution of calcium ferrocyanide or hydroferrocyanic acid to excess of cupric chloride solution. In general, when solutions of a cupric salt and of a soluble ferrocyanide are mixed, an insoluble substance is produced, in which only a part of the four valencies of the ferrocyanogen ion is saturated by copper, the remainder being occupied by the metal of the ferrocyanide employed. A very large number of these substances have been described. Colloidal membranes formed of one or other of these copper ferrocyanides have been much used in the study of osmosis. The precipitate formed from potassium ferrocyanide and a cupric salt $K_6Cu_4[Fe(CN)_6]_3$ was used as a pigment under the name Hatchett's brown. The black, silver deposit in an ordinary photographic 'bromide' print may be converted into a red one, consisting of a copper ferrocyanide, by immersing the print in a solution containing 6·6 grams of copper sulphate crystals, 88 grams of potassium citrate, and 5·8 grams of potassium ferricyanide per litre (Ferguson, Photographic Journ. 1900, 133).

Cuprous ferrocyanide $Cu_4Fe(CN)_6 \cdot xH_2O$ is a white precipitate, which differs from most of the ferrocyanides in evolving the whole of its cyanogen as hydrocyanic acid when boiled with dilute sulphuric acid. J. Dewrance and H. E. Williams (Eng. Pat. 28074, 1908) utilise this property in order to obtain complete decomposition of alkali ferrocyanides by distilling them with acid in presence of a small amount of cuprous chloride.

Hydroferrocyanic acid $H_4Fe(CN)_6$ is prepared by adding concentrated hydrochloric acid to a saturated solution of potassium ferrocyanide (both should be free from dissolved oxygen) and then enough ether to saturate the solution. The acid crystallises out in colourless scales which are washed with water saturated with ether (A. W. Williamson, Annalen, 1846, 57, 225; A. Joannis, Ann. Chim. Phys. 1882, [5] 26, 484), and dried over sulphuric acid. It may be purified by dissolving in alcohol and precipitating with ether; it obstinately retains ether, which is removed by heating at 100° in a current of dry hydrogen (Browning, Chem. Soc. Trans. 1900, 1234). A solution of the acid, saturated at 14°, contains 150 grams per litre. The solution is readily oxidised by atmospheric oxygen, especially at higher temperatures, forming a blue substance which is usually assumed to be Prussian blue. This reaction is utilised in calico printing for the production of blue patterns.

Ferrous ammonium ferrocyanide

$$Fe(NH_4)_2Fe(CN)_6]$$
is formed when a solution containing ammonium ferrocyanide and excess of an ammonium salt is exactly precipitated by a ferrous salt, oxygen being excluded. It is also formed when ammonium ferrocyanide is distilled with an acid in absence of air.

Ferrous cyanide $Fe(CN)_2$ is formed when a solution of hydroferrocyanic acid is boiled, $H_4Fe(CN)_6 = 4HCN + Fe(CN)_2$, or when the dry acid is heated at 300° in an atmosphere of hydrogen (Addie and Browning, Chem. Soc. Trans. 1900, 158; Browning, *ibid.* 1900, 1234).

Ferrous potassium ferrocyanide (Everitt's salt) $K_2Fe[Fe(CN)_6]$ is formed in a similar way if potassium salts are present, as, for example, in the preparation of hydrocyanic acid by distilling a mixture of potassium ferrocyanide and dilute sulphuric acid. Everitt's salt is a pale-yellow crystalline powder which is not identical with the white precipitate obtained by mixing solutions of potassium ferrocyanide and ferrous chloride, although this precipitate has the same composition.

The iron in these ferrous salts is displaced by treatment with caustic alkalis, but not by alkali carbonates.

Ferric ferrocyanides. The blue compounds of iron and cyanogen are all amorphous substances, which yield colloidal solutions in pure water. It is therefore extremely difficult to prepare them in a pure condition. Owing to the well-known tendency of colloids to adsorb other substances from solutions, the precipitates require very prolonged washing to free them from adhering salts, and during this process their composition may, and very often does, change, owing to atmospheric oxidation or to hydrolysis. On the other hand, the method of determining the composition of a precipitate by mixing known quantities of the reagents and estimating the excess left in the supernatant liquid, is open, in this case, to the objection that the precipitate is not a pure substance because it has adsorbed some of the salts in the solution in contact with it. This method has been used by E. Müller and by P. Woringer. (E. Müller and T. Stanisch, J. pr. Chem. 1909, [ii] 79, 81; *ibid* 1909, [ii] 80, 153; E. Müller, G. Wegelin, F. R. Treadwell, and O. Diefenthaler, *ibid.* 1911, [ii] 84, 353; E. Müller, *ibid.* 1914, [ii] 90, 119; P. Woringer, ibid. 1914, [ii] 87, 51.) K. A. Hofmann and his collaborators (K. A. Hofmann, O. Heine, and F. Höchtlen, Annalen, 1904, 337, 1; K. A. Hofmann and F. Resensheck, *ibid.* 1905, 340, 267; 1905, 342, 364; Hofmann, Arnoldi, and Hiendlmaier, *ibid.* 1907, 352, 54), have investigated more especially the composition and properties of the substances which remain after exhaustive purification.

The freshly prepared blue precipitates contain indefinite quantities of water, but the whole of it cannot be removed by drying *in vacuo* over phosphorus pentoxide until a constant weight is attained (which usually requires from 2 to 5 months). This residual water must be regarded as constitutional, because when the precipitates are heated to temperatures a little above 100°, they lose hydrocyanic acid, but not water. The formulæ of the dry substances given in what follows refer to the very thoroughly washed substances after complete drying over P_2O_5 in the way mentioned above.

When cold neutral solutions of one molecule of a ferric salt and one molecule of potassium ferrocyanide are mixed together, a precipitate of ordinary soluble Prussian blue is formed. The dry substance has the composition

$$2[KFe^{III}(Fe^{II}Cy_6)] + 3\tfrac{1}{2}H_2O$$
The same compound is obtained by mixing equal molecular quantities of a ferrous salt and potassium ferricyanide. This was first proved by Skraup (Annalen, 186, 371, 1877).

When a cold solution of potassium ferrocyanide is added gradually to a cold neutral (or $\tfrac{1}{2}$ p.c. hydrochloric acid) solution containing an excess of a ferric or of a ferrous salt, or when soluble Prussian blue is digested with a solution of ferric chloride, precipitates are formed which, after the prolonged exposure to air involved in washing them completely, are identical in composition and properties. The dry substance is normal ferric ferrocyanide

$$Fe_4^{III}(Fe^{II}Cy_6)_3 + 10H_2O$$
usually referred to as Prussian blue. Turnbull's blue, obtained by precipitating a solution of potassium ferricyanide with an excess of a ferrous salt, is, after exhaustive washing and exposure to air, identical with ordinary Prussian blue.

The composition of the unwashed precipitates initially formed depends, as Müller has shown, on the relative quantities of reagents employed. Setting out from potassium ferrocyanide and ferric chloride, Prussian blue is precipitated when the ratio mols. $K_4Fe(Cy_6)$/mols. $FeCl_3$ is less than 0·75; for values between 0·75 and 0·92 the precipitate contains increasing quantities of $KFe^{III}[Fe^{II}Cy_6]$, and when the ratio exceeds 0·92 the substance
$$K_2Fe^{II}[Fe^{II}Cy_6]$$

is also present. Setting out from potassium ferricyanide and ferrous chloride a precipitate of the composition $KFe^{II}Fe_5^{III}[Fe^{II}Cy_6]_5$ is obtained when the ratio, mols. K_3FeCy_6/mols. $FeCl_2$ is less than 0·714. Between 0·714 and 0·75 a substance $KFe^{II}Fe_3^{III}[Fe^{II}Cy_6]_3$ is formed, which Müller regards as ordinary Turnbull's blue; from 0·75 to 0·9 increasing quantities of $KFe^{III}[Fe^{II}Cy_6]$ are present, and finally, when the ratio exceeds 0·9 ordinary Prussian blue appears. According to Müller, Turnbull's blue and Prussian blue are interconvertible

$$Fe_4^{III}[Fe^{II}Cy_6]_3 + K^{\cdot} + Fe^{\cdot\cdot}$$
$$\rightleftarrows KFe^{II}Fe_3^{III}[Fe^{II}Cy_6]_3 + Fe^{\cdot\cdot\cdot},$$
although a very large excess of ferrous salt is required to convert an appreciable amount of Prussian blue.

It is obvious that the reactions involved in the formation of the blues are not simple double decompositions; mutual oxidations and reductions take place, and adsorption phenomena are superadded, so that, in general, the precipitates first produced are mixtures either of definite insoluble compounds, as Müller supposes, or if insoluble substances with soluble constituents adsorbed from the solutions.

The precipitates obtained from hot acid solutions differ more or less from those formed at ordinary temperatures in their properties, and appear even when washed to be mixtures of different substances.

Both the soluble and insoluble Prussian blue, above described, are ferric ferrocyanides, and not ferrous ferricyanides. This is proved by the fact that they can be made by the action of hydrogen peroxide on a solution containing a ferric salt and potassium ferricyanide in suitable quantities. As Schönbein (J. pr. Chem. 1866, 98, 65) showed, hydrogen peroxide reduces ferricyanide to ferrocyanide, but has no action on a ferric salt, so that ferrous ferricyanide could not be produced by this reaction.

Blue compounds, which are not identical with those described above, are also obtained by the oxidation of ferrous ferrocyanides.

(a) By adding a cold neutral solution of 1 molecule of a ferrous salt to a solution of 1 molecule of potassium ferrocyanide, and then oxidising the white precipitate by means of atmospheric oxygen, which is greedily absorbed (or better by hydrogen peroxide), a blue compound of the composition $KFe^{III}(Fe^{II}Cy_6)+H_2O$ is obtained. This differs from ordinary soluble blue in being insoluble in oxalic acid solution. It is referred to in the table of properties of the blues as K. A. Hofmann's blue.

(b) By proceeding exactly as in (a), except that the solutions contain 1 p.c. of sulphuric acid, a white precipitate is obtained, $Fe^{II}K_2(Fe^{II}Cy_6)$, which is rather less readily oxidised to a blue of the same composition as before :

$$Fe^{III}K(Fe^{II}Cy_6)+H_2O$$

but possessing rather different properties. Like ordinary soluble Prussian blue, it is soluble in water and oxalic acid, but differs from it in being much more stable to ammonia solution. This compound is referred to as 'stable soluble blue.'

(c) When a solution of potassium ferrocyanide, containing about 10 p.c. of sulphuric acid, is heated in an atmosphere devoid of oxygen, one half of the hydrocyanic acid is evolved and a pale-yellow crystalline powder of Everitt's salt $K_2Fe^{II}Cy_6)$ remains behind. This salt is very much less readily oxidised than the precipitate obtained by mixing solutions of potassium ferrocyanide and a ferrous salt ; it is not completely oxidised by several weeks' exposure to the air. It is readily oxidised by warm dilute nitric acid (A. W. Williamson, Ann. Chem. Pharm. 1846, 57, 225), but a homogeneous product is prepared most certainly by suspending it in 1 p.c. sulphuric acid and adding about 10 times the theoretical quantity of hydrogen peroxide. The substance thus obtained is Williamson's blue (sometimes called violet), and it also has the composition

$$KFe^{III}(Fe\ Cy_6)+H_2O$$
Its properties are, however, totally different from those of the isomeric substances already described.

PROPERTIES OF THE BLUE IRON-CYANOGEN COMPOUNDS.

Reagent	Ordinary soluble Prussian blue (Turnbull's soluble blue).	Insoluble Prussian blue	K. A. Hofmann's blue	Stable soluble blue	Williamson's blue or violet
Pure water .	Soluble, reddish-blue solution	Insoluble	Soluble, greenish-blue solution	Soluble	Insoluble, turbid greenish-blue suspension
10 p.c. oxalic acid	Soluble, blue solution	Soluble, blue solution	Insoluble	Soluble	Insoluble
4 p.c. ammonia	yields red-brown ferric hydroxide	In a few seconds	In 10 seconds	In a few seconds	In 6 to 7 minutes	After some hours
Ferric chloride	Precipitates insoluble Prussian blue	No change	(?)	Gradually coagulated in unchanged condition	No change
1 to 1½ p.c. H_2SO_4	Slowly precipitated ; moist precipitate soluble in water	No action	Quickly precipitated ; insoluble in water	Precipitated, insoluble in water	No action
Appearance of dry solids	Deep-blue with coppery lustre	Deep-blue purple lustre	—	—	Purple-red

For comparison, the distinguishing properties of the different blues are tabulated above. The isomerism of these substances may be due to differences in the linking of the atoms—of the kind familiar in organic chemistry—or it may be due to differences in the size of the molecules ; the data available do not appear to be sufficient to decide these questions with any degree of certainty.

In accordance with the commonly accepted view, the blues have been formulated as ferro-

cyanides. P. Woringer, in 1914 (l.c.), however, advanced certain arguments in favour of the ferricyanide structure. He confirmed an observation, made by A. W. Williamson in 1846, that when ferric chloride acts on an excess of ferrocyanide the solution contains ferricyanide ; he also states that Prussian blue, when decomposed by ammonium carbonate, yields 90 p.c. of ferricyanide. As E. Müller pointed out in 1909, it is easy to show, from the well-known oxidation potentials of solutions of ferrous

and ferric ions and of ferro- and ferri-cyanogen ions that, if these four ions could coexist in solution the ratio of their concentrations $[Fe]\cdot\cdot[FeCy_6]\cdot\cdot\cdot]/[Fe][Fe\cdot\cdot\cdot Cy_6\cdot\cdot\cdot\cdot]$ would be about 10^6, that is, ferrocyanide would be oxidised practically completely by ferric salts.

Williamson, however, showed that the reverse reaction also takes place, ferricyanide being partly reduced by ferrous salts. It appears thus that ferri- and ferro-cyanogen ions can coexist in approximately equal concentration, so that, in equilibrium, the concentration of ferric ion must be very small compared with that of ferrous ion. These concentrations are determined by the solubilities of the precipitates formed, about which very little appears to be known; the mode of formation of a blue affords, therefore, no certain clue to its structure. The same is true of its decomposition by strong alkalis, since alkaline ferricyanide solution oxidises ferrous hydroxide very readily. Hofmann's methods of preparation by means of hydrogen peroxide appear at present to be the best evidence available in favour of the ferrocyanide structure.

It is of interest that precipitation from hot acid solutions always tends to produce substances (or mixtures) of a more stable type, approaching Williamson's blue more or less closely in properties, and also that all the blue iron cyanogen compounds contain both ferrous and ferric iron. The compounds which contain only ferrous or only ferric iron are colourless or (compared with the blues) feebly coloured. Solid pieces of ordinary Prussian blue assume a coppery lustre when rubbed on a smooth, hard surface. The blue solution in oxalic acid was formerly used as an ink. Prussian blue is reduced by hydrosulphurous acid, $H_2S_2O_4$, or its sodium salt to white ferrous ferrocyanide (M. Rohn, Zeit. Anorg. Chem. 1906, 49, 443). Chlorine turns a suspension of Prussian blue in water green; the solution contains ferric chloride; the blue colour is restored by washing with water. Concentrated sulphuric acid unites with Prussian blue to a white paste from which the original blue is obtained by diluting with water. It is slowly decomposed by concentrated aqueous hydrochloric acid, but dissolves to a colourless solution in alcoholic hydrochloric acid; the solubility increases with the molecular weight of the alcohol used. Water precipitates unchanged Prussian blue from these solutions. By dissolving impure Prussian blue in a solution of hydrochloric acid in propyl alcohol, filtering, and reprecipitating with water, it may be separated from all commonly occurring impurities, such as barium sulphate, kaolin, alumina, and starch (C. Coffignier, Bull. Soc. chim. 1904, 391). Potassium, sodium, and calcium hydroxides decompose Prussian blue into ferric hydroxide and a ferrocyanide; alkali carbonates act more slowly. Tissues dyed with Prussian blue gradually lose their colour in sunlight, but regain it in the dark. When heated to 170° in the air, it burns like tinder leaving a brown ash.

Colloidal solutions of Prussian blue (0·2 to 2 p.c.) may be prepared by dialysis of the oxalic acid solution. The colloidal blue is negatively charged and is coagulated by cathions; hydrogen is especially active, otherwise the usual increase of activity with valency obtains (W. Pappadà, Gazz. chim. Ital. 1911, 41, ii. 454). K. A. Hofmann (Annalen, 1905, 340, 267) also observed that his soluble blue carried a negative charge, and did not depress the freezing-point.

Commercial blues are usually mixtures of the compounds already described. J. G. Gentele (Lehrbuch der Farbenfabrikation, 2nd ed. 1880) says that the best blues are obtained by precipitating a ferrous salt with potassium ferrocyanide, and then oxidising the precipitate. *Paris blue* (the finest quality of commercial Prussian blue) is made as follows : 50 kilos. of potassium ferrocyanide are dissolved in 250 kilos of boiling water ; 42·5 to 45 kilos. of green vitriol are dissolved in about the same quantity of water, preferably in the presence of scrap iron to prevent formation of ferric salt. The clear solutions are then run simultaneously into 250 kilos. of water. The almost white precipitate is allowed to settle and then drained on a cloth filter. The oldest method of ' blueing ' the paste was to heat it to boiling in a basin, transfer it to a wooden tub, and add 25·5 kilos. of nitric acid (sp.gr. 1·23) and 18 kilos. of sulphuric acid (1·84 sp.gr.). Sometimes, red fumes were evolved only after some hours, but in presence of excess of green vitriol, they were always evolved at once and this gave the best colour. After standing for 24 hours, the mixture was suspended in a large quantity of cold water and allowed to settle. The washing by decantation was continued until the blue was free from sulphuric acid. It was then collected on linen filters, pressed into thin cakes, and cut up into cubes which were dried in the air and finally at 30°-40°. The yield was 39 to 39·5 kilos. of finished blue.

Another method was to treat the heated paste of ferrous ferrocyanides with ferric chloride, instead of with nitric acid, until the solution contained ferric in addition to ferrous salts, but according to Gentele, the cheapest and best method is to acidify the paste slightly with hydrochloric acid and pass chlorine gas into it until the solution shows a distinct ' ferric ' reaction with ferrocyanide.

From these descriptions it is clear that commercial Paris blue must contain, in addition to ordinary insoluble Prussian blue, one or more of the potassium ferric ferrocyanides. The presence of potassium appears to be of importance, a less satisfactory colour being produced when sodium ferrocyanide is used in its preparation. H. E. Williams says that potassium may be replaced by ammonium with satisfactory results. A. Eibner and L. Gerstacker (J. Soc. Chem. Ind. 1912, 31, 1041) state that the blues with a high potassium content possess the technically desirable greenish shade, those poor in potassium being dull with a violet tinge. They have found 12 p.c. K and 5·5 p.c. H_2O in ' steel-blue ' and ' bronze blue ; ' 9 p.c. K and 10·5 p.c. H_2O in ' Paris blue,' the lowest value found in a commercial blue being 1·5 p.c. K and 24 p.c. H_2O. In the commercial pigments, Paris blue is diluted with starch, heavy spar, gypsum, zinc white, or burned and finely ground kaolin. The white admixture, after having been ground very finely by itself, is added to the Paris blue paste, and along with it passed through a colour mill. Very low qualities of

blue are faced by rotating the dry cubes in a cask with the fine dust of pure Paris blue.

Potassium ferrocyanide (yellow prussiate of potash, *Blutlaugensalz*, Ger.) crystallises from aqueous solutions in large, well-formed, orange-yellow tetragonal pyramids of the composition $K_4Fe(CN)_6,3H_2O$; sp.gr. 1·86. The crystals do not change when exposed to the air at ordinary temperatures. They begin to lose water at 60°, and the finely powdered salt may be completely dehydrated at 100°, forming a white powder which begins to decompose, in absence of oxygen, slightly below a red heat to a mixture of potassium cyanide, carbon and iron, nitrogen escaping. The powder takes fire at a considerably lower temperature when heated in contact with air. It is insoluble in alcohol. The soluble ferrocyanides are completely decomposed by boiling with mercuric oxide

$$K_4Fe(CN)_6+3HgO+2H_2O$$
$$=3Hg(CN)_2+FeO+4KOH$$
They are also decomposed by aurous cyanide, hydroxide, and even by finely-divided gold in the presence of oxygen

$$3Au+K_4Fe(CN)_6+2H_2O+O_2$$
$$=3KAu(CN)_2+Fe(OH)_3+KOH$$
(E. Beutel, Zeitsch. anorg. Chem. 1912, 78, 141). According to Etard (Ann. Chim. Phys. 1894, [7] 2, 546), the solubility, expressed in grams of anhydrous salt dissolved by 100 grams of water, is 14·5 at 0°, 24·5 at 20°, 36 at 40°, 49·5 at 60°, 64 at 75°, 70 at 80°, 72 at 89°, 74 at 98°, and 88 at 157°. The salt is much less soluble in solutions of potassium salts. The specific gravity of the aqueous solutions is given below (Schiff, Annalen, 1860, 113, 199) :—

Grs. $K_4Fe(CN)_6,3H_2O$ per 100 grs. of solution	1	5	10	15	20
Sp.gr. at 15°	.	1·0058	1·0295	1·0605	1·0932 1 1275

Sodium ferrocyanide crystallises in large lemon-yellow monoclinic prisms or rhombohedra of the composition $Na_4Fe(CN)_6,10H_2O$ (Conroy, J. Soc. Chem. Ind. 1898, 17, 103), which are permanent when exposed to the air at the ordinary temperature, but are completely dehydrated at a little above 100°. The behaviour of the dry salt, when heated, resembles that of the potassium compound. The solubility in water (Conroy, J. Soc. Chem. Ind. 1898, 17, 103): grams anhydrous salt dissolved by 100 grams of water, is at 20°, 17·9; at 30°, 23·5; at 40°, 29; at 50°, 35·5; at 60°, 42·5; at 70°, 51·5; at 80°, 59·2; at 90°, 61; and at 100°, 63.

Zinc ferrocyanide $Zn_2Fe(CN)_6,6H_2O$ is a white amorphous substance obtained by the action of calcium or hydrogen ferrocyanide on an excess of zinc chloride in aqueous solution. With other soluble ferrocyanides the precipitate contains more or less of the metal of the ferrocyanide used, a fact referred to in more detail in the analytical section of this article. It is insoluble in dilute acids, completely soluble in caustic alkalis to a mixture of ferrocyanide and zincate, and only partially decomposed by alkali carbonates.

Potassium ferricyanide, red prussiate of potash, $K_3Fe(CN)_6$, was discovered by Leopold Gmelin in 1822. He prepared it by passing chlorine into a solution of potassium ferro-

Vol. II.—*T*.

cyanide until it no longer gave a blue colour with a ferric salt :

$$2K_4Fe(CN)_6+Cl_2=2K_3Fe(CN)_6+2KCl$$
The salt is always manufactured by this reaction; the ferrocyanide is sometimes used in the form of a dry powder, in which case a mixture containing potassium chloride is obtained. Most commonly, a cold 10 p.c. solution of potassium ferrocyanide is treated with chlorine until conversion is just complete. A little Prussian green is always formed by the action of chlorine on the ferricyanide, and as this passes through any filter it spoils the appearance of the product. The difficulty may be avoided by evaporating the solution to crystallisation and then adding a little caustic potash which decomposes the green into ferric hydroxide, which is easily removed by filtration, and potassium ferrocyanide, which is apt to crystallise out along with the ferricyanide. The yield of ferricyanide, in this process, is 85 to 90 p.c. of the theoretical quantity.

A. W. Williamson (Annalen, 1846, 57, 225) found that potassium ferric ferrocyanide (Williamson's blue), when boiled with potassium ferrocyanide, gives potassium ferricyanide and Everitt's salt

$$K_4Fe^{II}(CN)_6+KFe^{III}[Fe^{II}(CN)_6]$$
$$=K_3Fe^{III}(CN)_6+K_2Fe^{II}[Fe^{II}(CN)_6]$$
Since Everitt's salt is readily oxidised to Williamson's blue by warming with dilute nitric acid, the process might (as Dittmar suggested) be utilised to complete the conversion of ferro- into ferricyanide, chlorine being used up to the point at which Prussian green begins to be formed.

Many other oxidising agents have been suggested in place of chlorine, such as bromine, lead peroxide, calcium plumbate, potassium permanganate and persulphate, and electrolytic oxidation (*see* Bertelsmann, Technologie der Cyanverbindungen).

Potassium ferricyanide crystallises from water in magnificent, deep-red, monoclinic prisms which may be very large. It is anhydrous; sp.gr. 1·845. The aqueous solution has an intense yellow colour. The solubility (grams of anhydrous salt dissolved by 100 grams of water) is 33 at 4·4°, 36 at 10°, 40·8 at 15·5°, 58·8 at 37·8°, 77·5 at 100°, and 82·6 at 104·4° (Wallace, Dingl. poly. J. 1856, 142, 52). Specific gravity of the solutions at 15° (Schiff, Annalen, 1860, 113, 199) :—

Per cent. $K_3Fe(CN)_6$	1	5	10	15	20	25	30
Sp.gr.	1·0051	1·0261	1·0538	1·0831	1·1139	1·1462	1·1802

The aqueous solution is decomposed by light, potassium ferrocyanide being formed. The caustic alkaline solution is a strong oxidising agent which decolourises indigo instantaneously. The alkaline solution is also reduced by hydrogen peroxide, oxygen being evolved.

Ferric ferricyanide. The dark-brown solution, formed when solutions of a ferricyanide and of a ferric salt are mixed, contains ferric ferricyanide in the form of a highly disperse colloid. Ultramicroscopic examination show that the particles gradually increase in size, a green substance ultimately separating out

2 G

(R. Haller, Kolloid Zeit. 1917, 20, 76). The formation of a green substance by the action of chlorine on potassium ferricyanide was first noticed by Pelouze (Ann. Chim. Phys. 1838, [2] 69, 40). Green ferric ferricyanides are also obtained by boiling Prussian blue with strong nitric acid or by precipitating potassium ferricyanide containing a little ferrocyanide with ferric chloride (H. E. Williams).

Potassium carbonylferrocyanide

$$K_3[Fe(CN)_5CO]H_2O$$
is formed by the action of carbon monoxide on an aqueous solution of potassium ferrocyanide at 135°

$$K_4Fe(CN)_6 + CO + 2H_2O$$
$$= K_3Fe(CN)_5CO + NH_3 + KHCO_2$$
(Müller, Ann. Chim. Phys. 1889, [6] 17, 94). Carbonylferrocyanides are found in the cyanide mud and spent oxide of the gas works, in which from 2 to 5 p.c. of the cyanogen (exceptionally as much as 20 p.c.) is present in this form (H. G. Colman, Analyst, 1908, 33, 261). When the caustic soda extract of these materials, mixed with 4 to 5 times its volume of methylated spirit, is allowed to stand for some hours, the sodium ferrocyanide crystallises out completely, leaving the carbonyl ferrocyanide in solution. It is isolated, in the form of the amorphous, deep-violet ferric salt, by adding ferric chloride to the acidified solution. The deliquescent calcium salt $Ca_3[Fe(CN)_5CO]_2,8H_2O$ is obtained by boiling the ferric salt with milk of lime. The carbonyl ferrocyanides resemble the corresponding ferrocyanides, but are paler in colour and more soluble in water. The copper salt, is a green precipitate soluble in excess of ammonia, is characteristic.

Sodium nitroprusside

$Na_2[Fe(CN)_5NO]\cdot2H_2O$ was first prepared by Lyon Playfair (Phil. Mag. 1850, [3] 36, 197) by the action of dilute nitric acid on a solution of a ferrocyanide. The primary products of the change, hydroferricyanic acid and nitric acid, react thus: $H_3Fe(CN)_6 + NO = H_4Fe(CN)_5NO + HCN$. The salt is also formed by adding a concentrated solution of ferrous sulphate to a solution containing equal parts of sodium nitrite and potassium cyanide. It crystallises in dark-red prisms, soluble in 2½ parts of water at 16°. The solution is not precipitated by a ferric salt, and gives a deep violet colouration with alkali sulphides.

### Sodium aquopentacyanoferroate

$$Na_3[Fe(CN)_5H_2O],5H_2O$$
is obtained by the action of reducing agents, such as phenylhydrazine or hydroxylamine, or of oxidising agents, such as potassium hypobromite and hydrogen peroxide on a solution of sodium nitroprusside at temperatures below 0°. The action of hydrogen peroxide is analogous to its behaviour with a ferricyanide

$$2K_3Fe(CN)_6 + H_2O_2 + 2KOH$$
$$= 2K_4Fe(CN)_6 + O_2 + 2H_2O$$
The salt crystallises in reddish-yellow needles, giving an intensely yellow solution, which does not yield a violet colouration with alkali sulphides.

Sodium aquopentacyanoferriate

$$Na_2[Fe(CN)_5H_2O]$$
is obtained by oxidising the foregoing compound with bromine. It is a deep violet-blue substance,

and Cambi has shown that the potassium perferricyanide obtained by Bong (Bull. Soc. chim. 1875, [2] 24, 268) and Skraup (Annalen, 1877, 189, 368) by the action of potassium chlorate and an acid on a solution of potassium ferricyanide, is the potassium salt of the same acid. It is also obtained by the action of excess chlorine on potassium ferricyanide, a deep violet solution being formed, from which the salt is precipitated by alcohol.

A series of pentacyano iron compounds has also been prepared, which may be regarded as derived from the aquo-compounds just described by the replacement of the H_2O group in the anion by one of the groups NO_2, AsO_2, SO_3, NH_3, or substituted ammonias.

Hexamethyl carbylamine ferro salts

By the action of methyl sulphate on dry potassium ferrocyanide or of methyl iodide on silver ferrocyanide, E. G. J. Hartley has obtained a series of salts of the general formula $[Fe(CNCH_3)_6]R_2$, R being a univalent acid radical, in which the iron cyanogen complex plays the part of cathion. When heated with concentrated sulphuric acid, or boiled with aqueous caustic soda, these salts are decomposed, the whole of the nitrogen appearing in the form of methylamine, or of methyl carbylamine, which proves that all the nitrogen atoms are linked to methyl.

Tetramethyl ferrocyanide $\left[Fe\frac{(CNCH_3)_4}{(CN)_2}\right]$ is

formed when hexamethylcarbylamine ferrochloride $[Fe(CNCH_3)_6]Cl_2$ is heated at 140°–150° in a vacuum for 6–9 hours, methyl chloride being split off. Two isomeric forms, with the same molecular weight, have been separated from the reaction product. The α-isomer is much more readily soluble in water, alcohol, and chloroform than is the β-isomer, and from water it crystallises with two molecules of water of crystallisation, the β-isomer combining with six. They also differ in their behaviour towards methyl iodide, with which the α-compound combines at 100°, yielding hexamethylcarbylamine ferroiodide, the β-compound remaining unchanged. No method of converting the one form into the other has been discovered (E. G. J. Hartley, Chem. Soc. Trans. 1910, 1066 and 1725; *ibid.* 1911, 1549; *ibid.* 1912, 705; *ibid.* 1913, 1196).

Constitution of the Iron Cyanogen Compounds. —When dissolved in water these compounds dissociate electrolytically into a complex ion containing the iron, cyanogen, and other groups; the sign and magnitude of the electric charge of this ion depend on the nature of its constituent groups of atoms. The ions $Fe(CN)_6'''$, $Fe(CN)_6''''$, $Fe(CN)_5CO'''$, $Fe(CN)_5NO''$, $Fe(CNCH_3)_6''$ are examples of this. These ions possess considerable stability, and are probably dissociated to a very small extent. For example, the ferrocyanogen ion is supposed to dissociate thus, $Fe(CN)_6'''' \rightleftharpoons Fe'' + 6(CN)'$ (F. Haber, Zeit. Elektrochem. 1905, 11, 846; Foster, Chem. Soc. Trans. 1906, 912). In the dark the concentration of ferrous ion is too small to produce

a precipitate of FeS with an alkali sulphide, but the complete decomposition of the ferrocyanogen complex by mercuric oxide shows that the minute concentration of (CN)′ in a solution of a ferrocyanide is greater than that in a solution of mercuric cyanide. The dissociation of the ferrocyanogen ion is increased by light, especially the ultra-violet rays, so that in alkaline solutions, oxygen produces a precipitate of ferric hydroxide. The increased dissociation is, however, so small that no appreciable increase in the conductivity of the solution can be detected.

Measurements of the osmotic pressure and electrical conductivity of solutions of the ferrocyanides of calcium and strontium have been made by the Earl of Berkeley, Hartley and Stephenson (Phil. Trans. 1909, 209A, 319), the results of which are incompatible with the assumption of a molecule $Ca_2[Fe(CN)_6]$ dissociating into three ions, it is suggested that the undissociated molecules may be double. The non-electrolyte, tetramethyl ferrocyanide, exists as single molecules in aqueous solution, and, from measurements of the freezing-point, Buchböck (Zeitsch. phys. Chem. 1897, 23, 157) arrived at the same result in the case of tetraethyl ferrocyanide.

Several cases of isomerism have been recorded. Locke and Edwards (Amer. Chem. J. 1899, 21, 193 and 413) observed that the ordinary anhydrous, red potassium ferricyanide is converted into a greenish-yellow modification, crystallising with 1 molecule of water by treatment with acids. This β-ferricyanide gives no precipitate with bismuth nitrate, the ordinary α-modification giving a straw-coloured precipitate. The β-ferricyanide is converted into the α-salt by treatment with alkalis. Briggs (Chem. Soc. Trans. 1911, 1019) describes similar behaviour on the part of the ferrocyanides. Faintly acid solutions deposit more deeply coloured crystals of the β-isomer, which are readily converted into the α-form by treatment with potassium cyanide or alkalis. The *l*-menthyl ammonium salts of the two isomers have different specific rotatory powers in alcoholic solution, otherwise only minute differences in density and solubility were observed. Bennett (Chem. Soc. Trans. 1917, 490) finds that the α- and β-ferrocyanides are crystalographically identical, and explains the difference of colour by slight decomposition of the acid solutions.

In addition to the isomeric tetramethyl ferrocyanides already mentioned, Hartley (Chem. Soc. Trans. 1914, 521) has recorded the existence of two isomeric trimethyl cobalticyanides $Co(CNCH_3)_3(CN)_3$ (attempts to prepare the ferricyanide derivative were unsuccessful), which differ considerably in solubility.

The synthesis of ferrocyanides from a ferrous compound and of ferricyanides by boiling excess of ferric hydroxide with an alkali cyanide (Skraup, Annalen, 1877, 189, 376), show that these compounds and their direct derivatives contain divalent and trivalent iron respectively. It is to be remembered that the iron cyanogen compounds here considered form one group of a great family of complex salts. Substances of the general formulæ
$$[M(CN)_6]R_3 \text{ and } [M(CN)_6]R_4$$
are known in which the metal is Co, Cr, Mn, Ru, Rh, Ir, and Os, and in which the CN group may be replaced by SCN. These are closely related in structure and chemical behaviour to large groups of metal ammonia and halogen complex salts. Under the circumstances, Werner's formulation of these salts, although it lacks the definiteness of the structural formulæ of organic chemistry, appears to be the best available. A. Werner (Neuere Anschauungen auf den Gebiete der anorganischen Chemie, 3rd ed. 1913) regards the complex salts as built up by the co-ordination of a maximum number of six groups of atoms round a central atom; carbon, nitrogen, and boron are exceptional, their maximum co-ordination number being four. The six groups are arranged symmetrically; at the angles of a regular octahedron, they are attached to the central atom, partly by the ordinary principal valencies, partly by secondary valencies. The nucleus so formed acts as a more or less stable whole, which may still be able to combine with other atoms at a greater distance from the centre or on an outer sphere. These more loosely held atoms dissociate electrolytically when the substance is dissolved; whether they are attached to the nucleus as a whole or to any particular atom in it is left undecided, although Werner inclines to the former view. The number and nature of the ionogenic groups depends on the nature of all the atoms included in the nucleus. For example, among the compounds described, we have :—

Ferro-series	Ferri-series	Complex forms
$[Fe(CN)_6]K_4$	$[Fe(CN)_6]K_3$	anion
$\left[Fe\genfrac{}{}{0pt}{}{(CN)_5}{CO}\right]K_3$	$\left[Fe\genfrac{}{}{0pt}{}{(CN)_5}{NO}\right]K_2$	anion
$\left[Fe\genfrac{}{}{0pt}{}{(CNCH_3)_4}{(CN)_2}\right]$	$\left[Co\genfrac{}{}{0pt}{}{(CNCH_3)_3}{(CN)_3}\right]$	not dissociated
$[Fe(CNCH_3)_6]Cl_2$		cathion

A further consequence of the theory is that complexes of the formulæ $\left[M\genfrac{}{}{0pt}{}{R_4}{R'_2}\right]$ and $\left[M\genfrac{}{}{0pt}{}{R_3}{R_3}\right]$ should exist in the two stereoisomeric forms represented by :

for the first and

for the Second

Possibly Hartley's isomeric tetramethyl ferrocyanide and trimethylcobalticyanides are examples of these forms of isomerism. Werner classifies the (somewhat uncertain) isomerism of the ferro- and ferricyanides as unexplained; but as Briggs has remarked (Chem. Soc. Trans. 1908, 1564), they would also come under the above heading if the potassium atoms are supposed to be attached to definite CN groups in the nucleus.

Manufacture of Potassium and Sodium Cyanides.—The methods of manufacture of these salts are most conveniently described together, since most of the processes used may equally well

be applied to making either salt. The most important technical processes have already been mentioned in the introduction to this article.

*Manufacture from Yellow Prussiate.*—Potassium cyanide was first prepared by Berzelius's method, which consists in heating dry potassium ferrocyanide to redness, when it decomposes thus : $K_4Fe(CN)_6 = 4KCN + Fe + 2C + N_2$. The loss of cyanogen, which occurs in this way, is partly avoided by fusing the ferrocyanide with potassium carbonate, as first described by F. and E. Rodgers (Phil. Mag. 1834, [3] 4, 91). Liebig showed that the product contains cyanate, formed thus :

$$K_4Fe(CN)_6 + K_2CO_3 = 5KCN + KCNO + Fe + CO_2$$
The fused salt is allowed to stand until the iron and carbon have settled out, and is then poured off into moulds. The comparatively small quantities of cyanide, which were used in electro-plating and for other purposes up to about 1890, were made by this process. The product was sold in white, porcelain-like cakes, containing from 30 to 70 p.c. of KCN.

In 1876, E. Erlenmeyer (Ber. 1876, 9, 1840) pointed out that a very pure product, containing on the average 40 p.c. of CN (equivalent to 100 p.c KCN), was obtained by fusing dry prussiate with metallic sodium in the proportions required by the equation

$$K_4Fe(CN)_6 + 2Na = 4KCN + 2NaCN + Fe$$
This process was taken up first by the Deutsche Gold and Silber Scheide-Anstalt (F. Roessler, V. Inter. Kongress für Angewandte Chemie, Berlin, 1903, 1, 638) in Frankfort-on-Main, in 1890 ; they obtained a practically quantitative yield by filtering off the spongy iron from the fused cyanide and pressing the iron while red hot. The cyanide so obtained is cast in cakes and forms a pure white crystalline mass. Since about 1905, sodium ferrocyanide has been used in this process in place of the potassium salt, and the product is almost pure sodium cyanide. The excess of the gas works ferrocyanide over that required in the colour industries is converted into sodium cyanide in this way.

It has been proposed to distil ferrocyanides with acids and to absorb the hydrocyanic acid in solutions of caustic alkalis. Grossmann (Eng. Pats. 36 and 4513, of 1903 ; J. Soc. Chem. Ind. 1903, 22, 1327) distils sodium ferrocyanide with 20 p.c. sulphuric acid in lead stills. the Everitt's salt remaining is re-converted into sodium ferrocyanide by boiling it with caustic soda in a current of air. The use of calcium ferrocyanide, which readily yields two-thirds of its hydrocyanic acid, was proposed by J. H. Paul (Eng. Pat. 72 of 1903). W. Feld (Eng. Pat. 24920 of 1901) converts insoluble ferrocyanides into mercuric cyanide, and then distils this with an acid. Dewrance and Williams (Eng. Pat. 28074 of 1908) distil the ferrocyanide, either soluble or insoluble, with 2-3 p.c. of its weight of cuprous chloride and a small excess of sulphuric acid, the whole of the hydrocyanic acid being evolved. None of these proposals is at present of technical importance.

The processes of Siepermann and Beilby were the first synthetic processes to produce cyanide in large quantities ; they are most conveniently considered together because, although they differ widely in the methods adopted in carrying them out, they are both based on the same chemical reaction which was also used by Scheele in the first synthesis of a cyanide ever made.

In Siepermann's process (D. R. P. 38012, March 10, 1886 ; Eng. Pat. 13697 of 1889 ; 9350 and 9351 of 1900) a dry mixture of about 2 parts of charcoal and 1 part of potassium carbonate—that is, a sufficient excess of charcoal to keep the mixture in the form of a dry unfused mass throughout the process—is heated in the upper part of a vertical iron tube to a dark-red heat and treated with dry ammonia gas, which is taken up, forming potassium cyanate. The product is then allowed to fall into the lower end of the tube, which is heated to bright redness At the higher temperature the cyanate is converted into cyanide, the carbon monoxide evolved escaping through the upper part of the tube along with the hydrogen formed from the ammonia, without taking any part in the reaction. The finished material is drawn off into air-tight receptacles where it is allowed to cool completely, after which it is systematically lixiviated with water. Potassium cyanide may be precipitated from the solution obtained (sp.gr about 1·4) by adding excess of potassium carbonate, but according to the later patents it is preferable to evaporate it almost to dryness and extract the unchanged potassium carbonate with small quantities of water at 66°. The residue of potassium cyanide and cyanate is then treated with water between −18° and +5°, which dissolves the cyanide and any residue of carbonate, leaving almost pure potassium cyanate. The product of this process was first put on the market in 1892 (G. Beilby, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 630), but as the substance was in the form of a damp deliquescent mass, it could not be exported for use at the mines by itself but had to be fused with the product of the ferrocyanide process.

In the Beilby process (Eng. Pat. 4820 of 1891), which began to produce in the same year, the quantity of charcoal used is very much smaller, very little more being employed than is necessary to convert the potassium carbonate into cyanide thus :

$$K_2CO_3 + 4C + 2NH_3 = 2KCN + 3CO + 3H_2$$
The charcoal is added gradually during the progress of the operation, so that the material is always in the form of a fused liquid through which the ammonia gas is forced under some pressure. This is continued until a sample shows the conversion to be sufficiently complete ; it is then only necessary to separate the small excess of charcoal by filtration in order to have a pure white saleable product. Since the melting-point of pure potassium carbonate (890°) is inconveniently high, previously made cyanide was mixed with it in starting the process, or the more readily fusible mixture of sodium and potassium carbonates was used, so that the cyanide made by the process was very similar in composition to that produced by the Erlenmeyer process from potassium ferrocyanide. In 1899 the Beilby process contributed fully one-half of the total European production of cyanide.

It is difficult to obtain a satisfactory yield on the ammonia in these processes, owing to the rapidity with which it decomposes into its

elements at temperatures above 500° and in contact with metals, especially iron (Ramsay and Young, Chem. Soc. Trans. 1884, 88; Beilby and Henderson, *ibid.* 1901, 1245). For this reason it is necessary to work at the lowest possible temperature. Siepermann, for example, obtained a yield of 86 p.c. on the ammonia when it was absorbed at a dark-red heat, but only 58 p.c. at a bright cherry-red heat. Readman (J. Soc. Chem. Ind. 8, 757, 1889) showed that almost theoretical efficiencies can be obtained at the low temperatures attainable in an ordinary organic combustion furnace; whilst Conroy (*ibid.* 15, 12, 1896), working at very high temperatures (1000°–1200°), could not get more than 30 to 33 p.c. of the ammonia in the form of cyanide. In practice the reaction velocity is also of great importance; in the Beilby process, where the advantage of the large surface exposed by Siepermann's dry mass of alkalised charcoal is sacrificed, the reaction is too slow at temperatures below 900°, the best results are obtained at 980°. In order to keep down the dissociation of the ammonia at this high temperature it is injected into the fused mixture through copper-lined tubes of such diameter that its time of contact with the hot metal is less than one-tenth of a second.

The chemistry of the reaction has been investigated by J. Pfleger (F. Roessler, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 638). Ammonia and potassium carbonate react, yielding potassium cyanate and hydroxide, a carbamate being most probably formed as an intermediate product:

$$CO(OK)_2 + NH_3 = CO{<}^{NH_2}_{OK} + KOH$$

$$CO{<}^{NH_2}_{OK} = KCNO + H_2O$$
When pure potassium cyanate is heated at 800°–900°, it decomposes, cyanide and carbonate being formed and nitrogen, carbon dioxide, and carbon monoxide evolved. The mechanism of this change is probably as follows: Drechsel (J. pr. Chem. 1877, [2] 16, 201.) has observed that the cyanates of the alkaline earth metals decompose, when heated, into carbon dioxide and the corresponding cyanamide salts. Assuming that the alkali cyanates behave similarly, the first change will be

$$2KCNO = K_2CN_2 + CO_2$$
Potassium cyanamide, however, decomposes completely at lower temperatures than 800° into cyanide, potassium, and nitrogen:

$$K_2CN_2 = KCN + K + N$$

The carbonate and carbon monoxide observed are thus due to the reaction between the metallic potassium and carbon dioxide which are formed simultaneously. In presence of charcoal in excess, the greater part of the cyanamide follows Drechsel's reaction (J. pr. Chem. 1880, [2] 21, 77), $K_2CN_2 + C = 2KCN$, instead of decomposing; so that the apparent reduction of cyanate by carbon probably takes place in the two stages:

$$2KCNO = K_2CN_2 + CO_2$$
$$\text{and } K_2CN_2 + C = 2KCN$$
$$CO_2 + C = 2CO$$
The reactions occurring in the Beilby process are the same, except that, the whole process

being carried on at the higher temperature, the formation of cyanate and its conversion into cyanide take place simultaneously instead of being more or less sharply separated as they are in Siepermann's process.

In the Siepermann process, it is easier to use the ammonia efficiently, owing to the lower temperature employed, but this is counterbalanced by the greater difficulty of working up the product into a marketable form.

The Castner Process.—In 1894 H. Y. Castner (Eng. Pat. 12219 of 1894) patented a process in which sodium was fed in at the upper end of a column of red-hot charcoal through which a current of dry ammonia gas was passed from below, the reaction being expressed by the simple equation:

$$2Na + 2C + 2NH_3 = 2NaCN + 3H_2$$
In a second patent (H. Y. Castner, Eng. Pat. 21732, 1894) it is shown that better results are obtained by first allowing the sodium and ammonia to react at a low temperature (300° to 400°), forming sodium amide $NaNH_2$, and then running the amide on to an excess of red-hot charcoal with which it reacts thus:

$$NaNH_2 + C = NaCN + H_2$$
Working in this way, it happened on one occasion that an excess of amide was accidentally run into the vessel containing the charcoal, and a product of unusual appearance was obtained, in which the writer found a large quantity of sodium cyanamide. The reaction, therefore, takes place in three stages, in which the nitrogen enters successively into more and more stable combinations. First sodium amide is produced, a compound which begins to decompose rapidly into its elements at 500° (Titherley, Chem. Soc. Trans. 1894, 504); this reacts either with carbon

$$2NaNH_2 + C = Na_2CN_2 + 2H_2$$
or, as Pfleger found, with sodium cyanide

$$NaNH_2 + NaCN = Na_2CN_2 + H_2$$
forming sodium cyanamide, a compound which only decomposes slowly at 600°, and finally this takes up carbon, forming sodium cyanide which is quite stable at any temperature attained in the process.

Like the Beilby process, this process yields a fused product containing very small quantities of solid impurities which are easily removed by filtration. After being cast in iron moulds, the cyanide is obtained in the form of pure white cakes with crystalline fracture, containing 97¼ to 98 p.c. of NaCN (equivalent to 129–130 p.c. of KCN).

The greater part of the world's cyanide requirements has been from its inception to the present date, 1920, supplied by this process in England. It was worked out, under Mr. Castner's direction, at the works of the Aluminium Co. at Oldbury; the first manufacturing plant was erected, by the writer, at Frankfurt-on-Main, just before Mr. Castner's death in 1899, and the second at Glasgow in 1900. The experienced assistance of the staffs of the Frankfurt and Glasgow companies led to rapid improvement of working details. A third installation started work near New York in 1901.

'*Schlempe*' *Process.*—The juice of the sugar beet contains both inorganic and organic substances other than sugar, and these substances accumulate in the molasses. In Germany, rather more than half of the molasses made are treated with strontia, which combines with the sugar to form an insoluble sucrate; the residue left after removing this, the concentrated essence of the impurities of the original juice, is known as 'schlempe.' After concentration to sp.gr. 1·4, it contains 75 p.c. of dry substances, 30 p.c. of which are inorganic (mainly potassium) salts and the remainder organic substances. The 'schlempe' contains about 4 p.c. of nitrogen in the form of betaïne

$$CH_2—CO$$
$$\underset{N(CH_3)_3}{|} >O$$

and decomposition products of the vegetable proteïns. Of the molasses not treated by the strontia process, a large part is consumed as cattle food and a small part fermented to alcohol. The residue of the alcoholic fermentation is known in France as '*vinasses.*'

The first attempt to utilise the nitrogen of 'vinasses' was made by Vincent in 1877–1880. He distilled the 'vinasses' in horizontal iron retorts at a red heat, ammonia, a mixture of the three methylamines, monoethyl-, mono-butyl, and monopropylamines, methyl alcohol, and combustible gases was evolved, and potassium carbonate mixed with some carbon remained behind (E. Duvillier and A. Busine, Ann. Chim. Phys. 1881, [5] 23, 289; H. Ost, Zeitsch. angew. Chem. 1906, 19, 609). In 1879 Ortlieb and Müller devised a process for converting Vincent's methylamines into hydrocyanic acid, which was worked by the Société Anonyme de Croix (Eng. Pat. 3844, of 1879). The vapour of the methylamines was passed through a red-hot retort, yielding ammonia, hydrocyanic acid, methane, and hydrogen. The ammonia was absorbed by sulphuric acid, and the hydrocyanic acid by a suspension of ferrous hydroxide in caustic potash. The manufacture of the methylamines was abandoned in 1881 for want of a market, and with it the production of cyanides.

The problem was again attacked by Bueb (Reichardt and Bueb, Eng. Pat. 7171 of 1895; Bueb, Eng. Pat. 26259 of 1898). Instead of separating the products of distillation of the 'schlempe,' he passed them directly, after condensing some tar, into a series of firebrick channels which were heated to bright redness. The ammonia and hydrocyanic acid were absorbed together in a solution of ferrous sulphate, and the product worked up in the same way as that made in the gas-works. The narrow flues were soon stopped up by deposits of carbon, so that they were replaced by chambers filled with fire-brick checker-work, which is heated up to 1000° by firing directly with producer gas; during this process, the deposit of carbon is burned. Two such chambers are used alternately, the one being heated up whilst the gases from the retorts are passing through the other. The gases leaving the decomposing chambers contain 7 p.c. HCN; 7 p.c. NH₃; 8 p.c. (mainly) CH₄; 12 p.c. H₂; 18 p.c. CO; 24 p.c. CO₂; and 24 p.c. N₂. In passing through the decomposing

chamber, the methylamines disappear and hydrocyanic acid is formed, the ammonia undergoing but little change. The ammonia is now removed from the gas by absorption in sulphuric acid, and the hydrocyanic acid absorbed in water in a suitable column. The solution of hydrocyanic acid is then distilled into a solution of caustic soda (A. Vasseur, Bull. Soc. Ind. Nord de la France, 1913, 41, 445). The solution of sodium cyanide is evaporated to crystallisation, the crystals dried, and briquetted by compressing them into blocks which are dried at 70° *in vacuô* (Eng. Pat. 18096, of 1907), and then contain sodium cyanide equivalent to 120 p.c. of KCN.

Of the nitrogen in the 'schlempe,' about one-half is converted into nitrogen gas and so lost; a quarter is obtained as sodium cyanide and the remainder as ammonium sulphate.

The decomposition of di- and tri-methyl-amine, when passed through a heated porcelain tube filled with fragments of porcelain, fire-brick, or charcoal, has been studied by Voerkelus (Dissertation, Hannover, 1909). At temperatures lying between 800° and 1000°, as much as 98 p.c. of the trimethylamine decomposes into hydrocyanic acid and methane $N(CH_3)_3 = HCN + 2CH_4$, the remaining 2 p.c. yielding ammonia $N(CH_3)_3 + 3H_2 = NH_3 + 3CH_4$. This result was obtained when the gaseous contents of the tube were changed once in 7½ seconds; with a slower current of gas and also with a contact material of large surface (fireclay or charcoal) or with iron, a part of the hydrocyanic acid is decomposed into its elements. The rate of decomposition at 1000°, however, is small. At 720° the yield of hydrocyanic acid was only 78 p.c., and at 600° none was produced.

The formation of hydrocyanic acid from dimethylamine also begins between 600° and 700°, from 800° to 1100° the change takes place quantitatively in accordance with the equation $NH(CH_3)_2 = HCN + CH_4 + H_2$. If hydrogen is present, however, a second change occurs $NH(CH_3)_2 + 2H_2 = NH_3 + 2CH_4$. Using equal volumes of hydrogen and dimethylamine, this reaction is of no importance, but as the hydrogen present increases more and more of the dimethylamine is converted into ammonia until, with a mixture of 97 parts of hydrogen to 3 parts of dimethylamine, ammonia is the sole product.

The behaviour of monomethylamine is probably analogous to that of dimethylamine. A. Wurtz (Ann. Chim. Phys. 1850, [3] 30, 443) found that, at a red heat, it decomposes in accordance with the equation :

$$3CH_3.NH_2 = 2HCN + NH_3 + CH_4 + 3H_2$$
In practice, therefore, the losses of hydrocyanic acid and ammonia by decomposition will depend on the rate of passage of the gases and on the nature of the contact material—the deposit of carbon on the porous bricks diminishing the decomposition of hydrocyanic acid.

The Deutsche Gold und Silber Scheide Anstalt (Fr. Pats. 447725 and 448722 of 1912) has made practical application of these observations by passing the gases at a high velocity through heated conduits made of fused quartz or Dinas brick without filling material. By this means, it is said that practically the whole

of the nitrogen is obtained as ammonia or hydrocyanic acid.

Manufacture of Sodium and Potassium Cyanides from Sulphocyanides.—The sulphocyanide is first converted into ferrocyanide by one of the methods already described, and the ferrocyanide then worked up into cyanide; this is the method actually in use. Other more direct processes have been used to some extent.

The earliest of these was D. J. Playfair's process (Eng. Pat. 7764 of 1890). Playfair found that certain metals, lead and zinc especially, when fused with potassium sulphocyanide, abstract the sulphur, leaving potassium cyanide, which may be separated from the metallic sulphide by extraction with water. The fusion is carried out at 400°, and 70–80 p.c. of the sulphocyanide is converted into cyanide (D. J. Playfair, J. Soc. Chem. Ind. 1892, 11, 14; Conroy, *ibid.* 1896, 15, 8). The reaction is slower with lead, owing to the small surface offered by the fused metal, whilst with zinc the product is apt to be contaminated by the double cyanide of zinc and potassium. The process was worked about 1894 by the British Cyanides Co. at Oldbury (Brussels Exhib. 1910, Catalogue of British Chem. Section, p. 63).

Raschen's process (Eng. Pats. 10476, 10956, and 21678 of 1895 ; 19767 of 1898 ; 12180 of 1900) is based on the oxidation of sulphocyanic acid to hydrocyanic and sulphuric acids which was first observed by E. A. Hadow (Annalen, 1858, 108, 380). Hadow found that permanganate, lead peroxide, manganese dioxide, and nitric acid bring about the same reaction. Raschen found that it takes place quantitatively in acid solutions only when an excess of the oxidising agent is present. If the oxidising agent is added to the sulphocyanate, solid yellow compounds are produced of variable composition, one of which, 'canarin' (*q.v.*), has been used as a yellow dye.

The Raschen process (J. T. Conroy, J. Soc. Chem. Ind. 1899, 18, 432) was carried out by allowing a solution containing about 15 p.c. of sodium sulphocyanate to flow into dilute nitric acid kept at the boiling-point by means of live steam. The reaction :

$$NaCNS + 2HNO_3 = HCN + NaHSO_4 + 2NO$$

took place. From 3 to 5 p.c. of the nitric acid was less completely reduced, N_2O_3 being formed, so that the gases leaving the decomposer were first scrubbed with a little water. The resulting solution of nitric, nitrous, and hydrocyanic acids was returned to the decomposer. The gas, which now contained about 1 volume of hydrocyanic acid to 2 volumes of nitric oxide, was passed through a solution of caustic soda (sp.gr. 1·37), which absorbed the hydrocyanic acid. It was found necessary to avoid saturating this solution completely with hydrocyanic acid because of the brown decomposition products which are formed from the free acid in presence of a cyanide. The nitric oxide was then mixed with air and passed upwards through towers packed with flints down which water trickled ; in this way it was reconverted into nitric acid (sp.gr. 1·12) which was returned to the decomposer. The solution of sodium cyanide was evaporated to dryness in vacuum pans without appreciable loss.

The reduction of sulphocyanides by hydrogen was studied by Playfair (J. Soc. Chem. Ind. 1892, 11, 14). He found that hydrogen acts on potassium sulphocyanide at a dull-red heat, forming potassium cyanide and sulphide and sulphuretted hydrogen.

Conroy, Heslop, and Shores (J. Soc. Chem. Ind. 1901, 20, 320) showed that the reaction takes place slowly at 500°, and fairly fast at 600°. Their results indicate that two reactions occur simultaneously :

$$KSCN + H_2 = KCN + H_2S$$

and

$$2KSCN + 2H_2 = K_2S + 2HCN + H_2S$$
A little ammonia is also evolved, probably owing to the difficulty of drying the sulphocyanide completely. About 70 p.c. of the nitrogen is obtained in the form of cyanide and 20 p.c. as hydrocyanic acid. With barium and cuprous sulphocyanides, the reaction is similar to that represented by the second of the above equations, the principal nitrogenous product being hydrocyanic acid. With the cuprous salt, the reaction begins below 300°.

Rossiter, Crowther, and Albright (Eng. Pats. 4403 and 6226 of 1901) have patented a process based on the behaviour of the cuprous salt. It is mixed with finely divided copper and heated at temperatures rising from 150° to 650° in a current of hydrogen. Hydrocyanic acid is evolved and cuprous sulphide remains behind.

Synthesis of Cyanides from Uncombined Nitrogen.

Up to the outbreak of the European War in 1914 the nitrogen of cyanides was almost exclusively derived either from organic matters of animal origin or from coal. The persistent attempts to synthesise cyanogen compounds from atmospheric nitrogen, which date back to the first half of the nineteenth century, have been renewed during recent years, and important progress has been made. The deficiency of cyanide caused by war conditions has, to a small extent, been supplied by the product of one of the processes using atmospheric nitrogen ; but it remains to be seen whether any one of them will be able to hold its own in competition with the older sources of supply under more normal conditions.

The attacks on the problem of fixing free nitrogen in the form of cyanide have been made by several paths which sometimes intersect. For convenience of description, they may be arranged according to the raw materials used ; the action has been studied of nitrogen on :—

1 *a.* Alkali metal carbonates and carbon.
   b. Alkali metals and carbon.
   c. Barium carbonate and carbon.
2 *a.* Carbides of metals.
   b. Acetylene.
3. Metals forming nitrides, subsequently converted into cyanides.

1 a. *Action of Nitrogen on Alkali Metal Carbonates and Carbon.*

Scheele may have been the first to fix atmospheric nitrogen in the form of a cyanide. Writing in 1783, he says (Chemical Essays, 1901, reprint, 288) : ' We know that charcoal powder, brought into fusion with fixed alkalis, yields likewise a kind of lixivium sanguinis, though weak.' The

source of the nitrogen is, however, doubtful, since charcoal contains a little combined nitrogen. Desfosses (Ann. Chim. Phys. 1828, 38, 158) mentions that notable quantities of cyanide are obtained by the action of nitrogen on a mixture of potash and carbon heated to redness, but the first thorough investigation of the reaction was made by Lewis Thompson, who was awarded the Gold Isis Medal of the Society of Arts, in 1838, for his improvements in the manufacture of Prussian blue. The chief improvement consisted in the substitution of atmospheric nitrogen for that contained in animal matters (Mechanics Magazine, 1839, 31, 92). Potash (2 parts), coke (2 parts), and iron turnings (1 part), were ground together to a coarse powder and heated in an open crucible, for half an hour, to a full red heat with occasional stirring; the end of the operation was indicated by the cessation of the jets of purple flame which arose from the surface of the mixture. After cooling, the material was lixiviated, and Prussian blue precipitated in the usual way. The yield was better with larger quantities of material than it was with smaller batches; thus 6 oz. of pearlash, containing 45 p.c. K₂O, yielded 0·62 oz. (295 grams) of Prussian blue, whilst 12 oz. (1 lb.) of the same material yielded 2·8 oz. (1355 grams) of blue; [1] that is, 0·23 and 0·54 part of Prussian blue for 1 part of K₂O used. Assuming that the Prussian blue was dried at 30°–40°, and contained 28 p.c. of water, the theoretical yield is 2·1 parts, so that Thompson cyanised from 11 to 26 p.c. of the potash used. This calculation may underestimate the yield, because it is stated that the Prussian blue spoken of is the 'pure perferrocyanate of iron.' Coke was used (because wood charcoal burns away too quickly), and the 'carbonaceous matter may be worked over again many times, and is even improved by each operation.' The importance of the addition of iron is insisted on; when it is not employed a much higher temperature is required.

The importance of Thompson's discovery of the catalytic action of iron was not fully appreciated for nearly three-quarters of a century, perhaps because the addition of iron for an entirely different purpose was a familiar feature of the current process of manufacture of ferrocyanide. Contemporary criticism was concerned mainly with the source of the nitrogen, although Thompson's statement that the carbonaceous matter improves on re-use would, if confirmed, have put the matter beyond doubt.

G. Fownes, in a paper read to the British Association (The Chemist, 1841, 2, 261), insisted on the possible error due to the presence of nitrogen in the coke used, and found, like Scheele, that charcoal or coke yields 'abundance of cyanide' when heated with potash in a closed crucible at a moderate red heat, which is not the case when pure carbon is used. When pure nitrogen was passed over a mixture of pure potassium carbonate and sugar charcoal heated, in a porcelain tube, he observed that carbon monoxide was evolved at first in much greater volume than that of the nitrogen passed in. When the evolution of carbon monoxide ceased he found in two experi-

[1] The bracketed figures are Thompson's; they are recalculated on the assumption that Troy weight was used.

ments at a 'full red heat' that 11¼ and 12⅔ p.c. of the potash had been converted into cyanide, whereas at 'whiteness, much above the melting-point of copper,' the production of cyanide appeared much greater.

The repetition of Fownes' experiment by several chemists added little to our knowledge, and may be dismissed in a few words. Erdmann and Marchand (J. pr. Chem. 1842, 26, 407) observed only a doubtful trace of cyanide; Liebig and Wöhler (Handwörterbuch der Chemie, 1842, ii. 384) could not confirm Fownes' result; and Delbruck (J. pr. Chem. 1847, 41, 161) also obtained a mere trace of cyanide. None of these authors gives details of their methods. Bunsen and Playfair (Brit. Ass. Rep. 1845, 142), on the other hand, by heating a mixture of pure potassium carbonate and sugar charcoal in a gun barrel in a current of nitrogen at a temperature high enough to form potassium (about 1200°), obtained 6·982 grams of silver cyanide from an unmentioned quantity of potash. It may be surmised that the different results noted were due to differences of temperature.

In addition to these laboratory experiments, a most remarkable attempt was made to develop this process on a manufacturing scale. Possoz and Boissière (Eng. Pat. 9985 of 1843, granted to their agent A. V. Newton) began their experiments at Grenelle, near Paris, in 1843, but transferred the plant in 1844 to the works of Messrs. Bramwell & Co. (one of the leading prussiate makers of that time) at Newcastle-on-Tyne. The experiments were carried on by Mr. Bramwell and Mr. F. R. Hughes until 1847, and a detailed account of them, furnished by Mr. Hughes, was published by Graham (Report of Juries, Exhib. of 1851, 1, 95).

Wood charcoal was soaked in a solution of ordinary potash and dried, yielding a mixture containing about 20 p.c. K₂O. This was, at first, heated in vertical fire-clay retorts of small diameter, which were fired externally. Owing to the low thermal conductivity of the retorts and of the charcoal, the heat penetrated the mass very slowly, and the output of a tube was small. It may be pointed out that this very serious difficulty is accentuated by the endothermic nature of the reaction, which was unknown at that time; it is not only necessary to heat the charge to the reaction temperature, but the large quantity of heat absorbed by the reaction

$$K_2CO_3 + 4C + N_2 = 2KCN + 3CO - 129 \text{ Cals.}$$

must also be supplied.

After a number of alterations, retorts were adopted, which were built of ordinary firebrick; they were 2 feet in internal diameter, and were heated for a length of 6 to 8 feet to a temperature sufficient to produce cyanide. In an upper prolongation, the wet charcoal was dried and preheated, and in a lower, unheated extension, made of cast iron, the product was cooled down, and then discharged, by means of an arrangement which permitted a periodical withdrawal of a part of the charge, into a solution of a ferrous salt, into which the lower end of the cast-iron tube dipped. A ring of small slots was left in the brick retort at every third or fourth course of bricks, through which the hot

mixture of nitrogen and carbon dioxide in the furnace was drawn into the retort by means of an aspirator attached to the upper end. In this way the difficulty of heating the charge to its centre was overcome. The highest temperature in the furnace was sufficient to soften a Stourbridge fireclay brick throughout its substance (1350°-1400° ?). The hot gases were aspirated upwards, drying and preheating the fresh charge in the upper part of the retort. As much as one-half of the alkali in the cyanised charcoal produced was found to be in the form of cyanide, and 7 or 8 retorts of the dimensions given yielded 36–40 cwts. of prussiate of potash per week, under favourable circumstances. About one-half of the charcoal used was consumed, and 3 parts of potash were used for 1 part of prussiate made. About one-third of the potash was accounted for by the prussiate; one-third remained in the refuse charcoal, which could not be profitably lixiviated; and the remainder combined with the bricks of the retort, or was volatilised up the chimney. The financial failure of the process was due to the losses of potash and to the short life of the retorts.

R. Hoffmann (Report of Juries, Exhib. of 1862, 59) also tried large-scale experiments at Oedenwald in the Black Forest, in 1858–1859, which may be referred to as a further illustration of the difficulties mentioned above. The alkalised coke was heated in wrought-iron tubes, not more than 1 foot in diameter, protected with fireclay. The furnace was heated to a bright, white heat, which fused the common brick work behind the firebrick lining, but only minute quantities of cyanide were formed; the failure is ascribed to too low temperature, for it was found that the middle portion of the coke in a tube was far from being white hot.

In 1878, C. A. Fawsitt (Eng. Pat. 4544 of 1878) described a method of making ammonia by this process. In his experiments, which were made at St. Rollox, Glasgow, he used sodium carbonate instead of potash (J. Soc. Chem. Ind. 1890, 9, 30). Using 3-inch or 4-inch wrought-iron tubes, he obtained as much as 50 p.c. of the theoretical yield of ammonia, but with 6-inch cast-iron tubes the yield was much smaller, because the cast iron would not withstand the temperature needed. These experiments, therefore, indicate that a temperature exceeding 1100° (the approximate melting-point of cast iron) is required; although, in this case, the differences may have been due, in part, to the facts that a tube of larger diameter would give worse results even with the same external temperature, and that the nitrogen used with the 6-inch tubes contained from 3 to 5 p.c. of oxygen.

The patents of Victor Alder of Vienna are of interest, because they contain a clear recognition of the catalytic rôle of iron, and of the necessity of obtaining intimate admixture of the reacting constituents, together with sufficient porosity to admit of free access of nitrogen. Alder proposed to heat an intimate mixture of alkaline material and carbon in a closed vessel, in an atmosphere of nitrogen, and said: 'The addition of finely divided iron greatly promotes the conversion into cyanide, but is not absolutely essential to the success of the operation' (Eng. Pat. 1004 of 1880). In Eng. Pat. 5617 of

1881 he states that the reaction only succeeds in presence of carbonising gases, such as hydrocarbons or carbon monoxide, and that metals 'capable of fixing and transmitting the carbon, such as iron, chromium, manganese, nickel, or cobalt, greatly promote the conversion.' The charge is prepared, for example, by mixing a solution of the alkali with charcoal and adding sawdust or other substance, which, when heated, will yield a porous mass; or a thin paste of the alkaline solution and finely ground charcoal containing some binding material is spread out on the surface of lumps of charcoal. The 'carbonising metal' is to be added as such, as oxide or in the form of a solution of a salt which, when heated in a current of steam, will decompose, leaving a deposit of the oxide, which, in the cyanising process, will be reduced to metal. Alder appears, however, to have been under the impression that the success of a technical process depends on the employment of the cheapest raw materials, however unsuitable they may be, and a great part of the specifications consists of descriptions of the preparation of alkali-carbon mixtures from such substances as alkali sulphates, limestone, and coal, as in the Le Blanc alkali process; the failure of the process is not, therefore, surprising.

The catalytic action of iron was re-discovered by E. Tauber in 1899 (Ber. 1899, 32, 3150; and more fully in Die Chem. Ind. 1903, 26, 26). Trials of different kinds of carbon and different alkalis showed that potash or soda and wood charcoal are the most active materials. An intimate mixture of alkali and charcoal was made by soaking sawdust in the alkaline solution and carbonising the mixture; iron (reduced by hydrogen) in fine powder was added to this, 3 parts of iron to 1 part of soda giving the best results. The mixtures were heated, in iron boats enclosed in glass tubes, for 1¼ hours at temperatures between 'dark and moderate' red heats, a current of purified nitrogen being passed. In some cases more than 25 p.c. of the soda used was cyanised, but usually a conversion of 10 p.c. was not exceeded. Magnesium, tungsten, chromium, and nickel were found to possess some catalytic activity, though much less than iron.

Between 1843 and 1912 some 30 patents were granted in Great Britain for modifications of the process described by Possoz and Boissière, in which the blast furnace type of apparatus recurs frequently; no details of the results obtained, or of the causes of failure, appear to have been published. Since 1912 the numerous patents of J. E. Bucher (especially Eng. Pats. 27713 of 1912; 23292 and 13332 of 1914; 2286 of 1915), which are being developed by the Nitrogen Products Co. of Providence, Rhode Island, at their works at Saltville and Niagara Falls, have directed renewed attention to the catalytic action of iron. Prof. Bucher's results (J. Ind. Eng. Chem. 1917, 9, 233) surpass any which have previously appeared in print; this appears to be due partly to the fact that he has clearly realised that the necessary conditions, already known separately, must be fulfilled simultaneously, and partly to the ingenuity and care devoted to the detailed adaptation of means to this end.

Carbon and iron oxide are separately ground

in a ball mill to pass 100-mesh sieve, and then re-ground together, after which dry sodium carbonate is added. The open-grained structure which is necessary to allow nitrogen to pass through the material is obtained by briquetting. This is done by kneading the powder, at about 100°, with a little more water than is required to form the monohydrate Na_2CO_3,H_2O, and squirting the paste into small rods about 1 inch long and $\frac{1}{4}$ inch diameter. These are dried at once, before cooling, because the expansion due to the formation of the decahydrate at temperatures below 35° causes them to fall to powder. When heated above the melting-point of sodium carbonate (852°) these little briquettes become plastic to some extent, but retain their shape sufficiently well to permit free circulation of gases through a column several feet thick. Mixtures of coke, iron, and sodium carbonate in proportions from 2 : 2 : 1 to 2 : 2 : 2 give satisfactory results, the smaller proportion of sodium carbonate giving the fastest reaction owing to the greater accessibility of the active carbon-iron surfaces to nitrogen. The reaction is said to begin about 700°, and the eutectic temperature of iron-carbon (about 1150°) should not be exceeded because fusion of the particles of iron into larger globules diminishes their active surface. The speed of the reaction, under suitable conditions, is considerable; for example, the 2 : 2 : 1 mixture heated, in 13 minutes, from 710 to 920 in a current of nitrogen, yielded a product containing 15·2 p.c. NaCN, 92 p.c. of the sodium being in the form of cyanide. Sodium cyanide volatilises somewhat freely at 900°–950°, so that in a stationary column of material in a vertical tube, the upper layers are much richer than the lower ones, and a considerable loss of alkali is observed ; it is anticipated that this will not occur in a continuous process, since the incoming fresh charge will condense the cyanide vapour.

In order to supply the necessary quantity of heat $(Na_2CO_3+4C+N_2=2NaCN+3CO-138·5$ Cals.) at a sufficient rate, Bucher proposes, for example, to use the hot charge itself as an electrical resistance (cf. Readman's apparatus, below), or to use electrically heated molten iron saturated with carbon and to pass a mixture of nitrogen and sodium vapour through it.

Producer gas may be used at high temperatures, but the cyanide disappears if the product is allowed to cool in an atmosphere containing carbon monoxide. This may be due to the formation of carbon dioxide, as Bucher suggests, by the reaction $2CO=CO_2+C$, which is accelerated by iron; it is also possible that the reaction $Na_2CO_3+4C+N_2=2NaCN+3CO$ is reversible, as has been proved in the analogous case of barium carbonate.

Since this was written the reversibility of the reaction has been proved by J. B. Ferguson and P. D. V. Manning (J. Ind. Eng. Chem. 1919, 11, 946). Mixtures of sodium cyanide or of sodium carbonate (3 parts), charcoal (1 part), and iron (1 part) were heated in presence of definite mixtures of carbon monoxide and nitrogen. The composition of the product was not affected by the nature of the initial materials, but varied with the temperature and the composition of the gas. With 5 p.c. CO, for example, 75 p.c. of the alkali was cyanised at

946° and 80 p.c. at 1000°; with 48 p.c. CO, 27·5 p.c. and 59 p.c. were cyanised at the same temperatures. Owing to volatilisation of cyanide it is probable that true equilibrium was not realised ; the error will be greatest for products rich in cyanide.

C. O. Brown (J. Ind. Eng. Chem. 1919, 11, 1010) has described the plant which was erected by the Government of the United States in 1917–18 to produce 10 tons of sodium cyanide daily by the Bucher process. Briquettes, made in the way described above, were heated at 1000° in vertical, gas-fired, steel, or nichrome tubes in a current of very pure nitrogen. The product, containing about 20 p.c. NaCN, was extracted with liquid, anhydrous ammonia ; by this means the formation of ferrocyanide is avoided, and any unchanged alkali is left undissolved in the residues which are reground with sufficient carbon and soda and reused. Evaporation of the ammonia solutions leaves sodium cyanide, containing 92 p.c. NaCN, as a white powder. The loss of ammonia was about 2 lbs. per 100 lbs. cyanide made. Each steel tube produced about 7½ lbs. of sodium cyanide hourly, and had a life of 11–14 days. The work was abandoned after the armistice in 1918.

It may be mentioned here that the Cassel Cyanide Co., of Glasgow, has used iron as a catalyst in the manufacture of cyanides from atmospheric nitrogen since the year 1909, when the writer first became fully aware of its great activity under suitable circumstances. The work in which sodium carbonate was employed as raw material was carried out entirely by Mr. J. H. Young. Setting out from finely divided, precipitated ferric oxide and charcoal (the purest and most active form of carbon available), the mixtures were made by grinding these substances separately and then together, finally adding the dry sodium carbonate and re-grinding. The necessary porosity of the material to be treated with nitrogen was secured by adding a quantity of the very bulky charcoal obtained by carbonising shavings ; the addition of 15 parts of this material to a ground mixture of 20 parts of sodium carbonate, 8 parts ferric oxide, and 15 parts charcoal, gave good results, 60–80 p.c. of the alkali being cyanised at 900°. The residual charcoal-iron mixture resulting from the lixiviation of the cyanised mass gave even better results than a fresh mixture. A larger scale, continuous plant was at work in 1913, in which the mixtures were heated in vertical steel tubes, of 6 inches bore and about 10 feet long, of which a length of about 5 feet was heated to the working temperature. The lower part of the tube served for cooling the product, which was withdrawn by means of a horizontal spiral conveyor, fresh material being fed in at the top of the tube. Pure nitrogen was employed, and very careful measurements of the temperature showed that under satisfactory working conditions the temperature in the axis of the tube was 900°, near the inside wall of the tube it was 950°, whilst a thermocouple in the furnace in contact with the outer wall of the tube indicated 1010°. These measurements indicate quite clearly the necessity of using tubes of small diameter when external heating is relied on. Temperatures higher than those mentioned were found to be undesirable

owing to their serious effect on the life of the steel tubes, and also on account of the danger of fusing part of the iron catalyst, and so diminishing its active surface. Each tube of the dimensions mentioned produced from 40 to 50 lbs. of sodium cyanide in 24 hours, the product containing from 21 to 26 p.c. NaCN.

The results described, together with the older experience of the reaction between alkalis and nitrogenous organic matter, make it easy to understand the occurrence of cyanides in kelp, barilla, Le Blanc alkali, and the residues from the preparation of potassium (which were known to Lewis Thompson in 1839), and especially in the blast furnace. Clark (Phil. Mag. 1837, 10, 729) described the occurrence of cyanide at the Clyde Iron Works, in a furnace using raw coal and hot blast, in quantities such that wheelbarrows full could be obtained. Zincken and Bromeis (J. pr. Chem. 1842, 25, 246) found a quantity of potassium cyanide in the charcoal remaining in the hearth of a furnace in the Harz which had been closed down. This furnace had been worked with charcoal and a hot blast. Redtenbacher (Annalen, 1843, 47, 150) described the formation of potassium cyanide in quantity (it was used for electroplating) in a charcoal iron furnace at Mariazell in Steiermark, which was also worked with blast heated as high as 350°. Bunsen and Playfair (Brit. Ass. Rep. 1845, 142) observed the production of more than 2 cwts. per day of potassium cyanide in the coal-fired furnace at Alfreton, which worked with blast at 330°; they also showed that the potassium was derived mainly from the iron ore used, the furnace charge containing sufficient potassium to produce 377 lbs. of KCN per day. The cyanide was found in the hottest part of the furnace, 2 feet 9 inches above the tuyeres, but some 7 feet higher there was very little. Sir Lowthian Bell (J. Soc. Chem. Ind. 1890, 9, 710) gives the following figures for the distribution of cyanogen in a more modern furnace at the Clarence Works, which was worked with coke and Cleveland iron ore and blast at about 700° :—

Height above hearth	8 ft.	24 ft.	52½ ft.	60 ft.	escape pipe
Grams CN per cb. m. gas	49·06	15·76	7·67	5·94	4·73

It is generally assumed, probably correctly, that the blast furnace cyanide is produced from free nitrogen, but it is interesting to note that Sir L. Bell's furnace consumed 50 tons of coke per day, which probably contained at least ⅓ ton of combined nitrogen.

The mechanism of the reaction which occurs between carbon, alkali carbonates, and nitrogen, and the rôle of iron, are still quite obscure. The old view, that carbon and nitrogen ('nascent' or otherwise) unite to form cyanogen which is then fixed by alkalis, is extremely improbable in view of the nature of the equilibrium

$$2C + N_2 \rightleftarrows C_2N_2$$
(v. Cyanogen), and of the fact that no one has succeeded in isolating a trace of cyanogen gas made by the direct union of the elements. The possibility that a carbide may be an intermediate product is discussed later. It is, at least, an ascertained fact that some metallic acetylides do combine with nitrogen, although the behaviour of

the alkali metal derivatives has hardly been investigated. The intermediate formation of free alkali metal has also been asserted to be necessary, but as the alkali metals (except lithium) do not combine directly with nitrogen, whereas they do combine with carbon, this seems to be identical with the assumption of the intermediacy of a carbide. No valid experimental evidence appears to have been advanced in support of the existence of any intermediate compound.

1b. Action of Nitrogen on Alkali Metals and Carbon.

This reaction appears to have been observed for the first time by R. F. Marchand (J. pr. Chem. 1850, 49, 351). A statement that cast iron and steel contain from 0·5 to 1·2 p.c. of nitrogen induced him to test some 30 samples of cast iron by Lassaigne's method, that is, by heating the sample to redness, in a test tube, with potassium, extracting the product with water, and applying the Prussian blue test to the solution. A copious precipitate was obtained in every case. He found, however, that, when the residue of iron was dried and again heated with potassium, there was a further production of Prussian blue, and that this continued so long that, with 8 grams of powdered iron, it was impossible to exhaust the reaction. This led Marchand to suspect that the nitrogen was derived from the air, and he proved that this was the case by carrying out the reaction in an atmosphere of hydrogen or of carbon dioxide, when no more than a doubtful trace of blue was obtained, and, further, by heating the mixture of cast iron and potassium (after drying it in a current of hydrogen) in an atmosphere of nitrogen in a closed tube, when he found that the nitrogen was completely absorbed. He also showed that steel behaves like cast iron, but soft iron does not. Marchand did not obtain the reaction with a mixture of carbon and iron obtained by heating ferric succinate or benzoate, and therefore concluded that success depends on the carbon being in chemical combination with the iron.

The success of Lassaigne's test, when applied to organic substances containing sulphur, had been questioned by O. Jacobsen, who recommended the addition of reduced iron in such cases. Making the test in this way, I. Remsen (Amer. Chem. J. 1881, 3, 134) obtained Prussian blue from substances, such as pure cane sugar and sodium potassium tartrate, which contain no nitrogen. After proving that the reduced iron employed was not the source of the nitrogen, Remsen heated a mixture of the tartrate, pure reduced iron and sodium, first in hydrogen to dry it, and then in nitrogen, obtaining a very large precipitate of Prussian blue. He also made the new observation that the iron powder loses its activity when it is superficially oxidised by exposure to air, which may perhaps explain Marchand's failure to obtain the reaction with his mixtures of iron and carbon.

The reaction was re-discovered by E. Täuber (Ber. 1899, 32, 3150), whose experience coincided almost exactly with that of Remsen.

H. Y. Castner, in 1894, patented a process in which sodium was allowed to flow downwards over a column of red-hot charcoal in

an iron vessel, a current of nitrogen passing upwards through it (Eng. Pat. 12218 of 1894). It is doubtful whether this process received more than a cursory trial. It was taken up again by the Roessler and Hasslacher company about 1910. They find that a mixture of sodium vapour and nitrogen reacts with charcoal in the absence of iron at 650°, and that the speed of reaction is sufficient for manufacturing purposes at temperatures above about 800°. (H. Philipp, Chem. and Met. Eng. 1920, 22, 313; U.S. Pats. 1249821, 1917; 1235887, 1917).

In 1912, J. E. Bucher applied for a patent for the manufacture of cyanide by the direct union of its elements in presence of iron (Eng. Pat. 11797 of 1913; U.S. Pats. 1082845 of 1913; and 1116559 of 1914). A temperature of from 500° to 800° is said to be suitable, and iron and carbon are to be intimately mixed. Like Marchand, Bucher also observed the removal of carbon from cast iron or steel by the action of sodium and nitrogen on them. He also follows Marchand in adopting the view that iron acts as a solvent of carbon, the dissolved carbon being supposed to be capable of entering into combination with sodium and nitrogen. When sodium carbonate is used, it is assumed that a little metallic sodium is formed by the action of carbon, even at the low temperature (700°) at which the reaction proceeds, the removal of this, by conversion into cyanide, disturbs the equilibrium and permits the decomposition of further quantities of sodium carbonate. This hypothesis appears to be open to the criticism that it makes the extremely rapid rate of formation of cyanide depend on the rate of solution of solid carbon in solid iron; it also fails to make clear why the usually inert nitrogen becomes so active.

The Cassel Cyanide Co.'s experiments with this process were begun, as already stated, in 1909; in 1911 engineering difficulties had been so far surmounted that a unit plant producing about 50 lbs. of cyanide hourly was at work. From the experience thus gained a larger industrial unit was designed and erected, which was producing cyanide for some time before war was declared in 1914.

1c. *Action of Nitrogen on Barium Carbonate and Carbon.*

In 1860 Margueritte and De Sourdeval (Eng. Pat. 1171, of 1860; Compt. rend. 1860, 50, 1100) discovered that a mixture of barium oxide and carbon absorbs nitrogen readily forming barium cyanide. Ludwig Mond (Eng. Pat. 433 of 1882; J. Soc. Chem. Ind. 1889, 8, 505) experimented with this process in 1882. He found that a temperature of 1200° was required for the formation of cyanide, and that the reaction goes best about 1400°. The barium compounds fuse readily at these temperatures and attack the fireclay retorts. To avoid this he briquetted them with an excess of carbon and pitch. The apparatus used was similar to that of Possoz and Boissière, and 40 p.c. of the barium used was readily cyanised. The object of Mond's experiments was the production of ammonia, and he abandoned this process in favour of the more promising method of acting on coal with air and steam in large excess (*see* AMMONIA).

As Mond pointed out, the reaction is endothermic

$$BaCO_3 + C = BaO + 2CO - 101.2 \text{ Cals.}$$
$$BaO + 3C + N_2 = Ba(CN)_2 + CO - 43.1 \text{ Cals.}$$
The introduction of internal electrical heating by Readman (Eng. Pat. 6621 of 1894) therefore marks a very considerable step in advance. His process was worked by the Scottish Cyanides Co. at Leven in Fifeshire, between the years 1899 and 1907. Considerable quantities of sodium cyanide of excellent quality were produced, but the financial results were unfavourable. The following account of the process in its final form is believed to be substantially accurate.

Barium carbonate, produced in a later stage of the process, was intimately mixed with ground coal to a thick paste, which was dried and coked in ordinary gas retorts. The granular mixture of barium oxide and coke so produced was then fed into an electric furnace, consisting of a vertical shaft of circular cross-section, lined with magnesia bricks. A ring of carbon blocks in the wall of the shaft near its lower end formed one electrode, a carbon cylinder suspended in the mouth of the shaft formed the other. The alternating current passed between these electrodes through the granular mass of coke and barium oxide, heating it to a high temperature. A current of producer gas with about 70 p.c. of nitrogen, passed upwards through the mass, which was constantly fed downwards into a cooling chamber by means of a plate and rotating arm which closed the lower end of the shaft, fresh material being fed in to the annular space round the upper electrode. The cooled product was lixiviated with water, and the resulting solution, containing barium cyanide, cyanamide, and hydroxide, treated with barium bicarbonate. After filtering off the barium carbonate, the solution of sodium cyanide was concentrated *in vacuo* and then passed over cooling coils depositing crystals of the hydrate NaCN,2H₂O. These were separated from the mother liquor in a centrifugal machine, and then dehydrated by heat and the powder briquetted. The mother liquor, from which no further crystals could be obtained, was distilled with sulphuric acid to recover the residue of hydrocyanic acid.

The chemistry of this process has been studied in some detail at temperatures up to 1150°, but little is known of it at higher temperatures. Undecomposed barium carbonate, as Finkelstein (Ber. 1906, 39, 1585) showed, does not melt at 1350°, but when heated alone or with carbon, it is partially converted into barium oxide, which yields readily fusible mixtures with the carbonate. Le Chatelier, for example, found that pure decomposed barium carbonate melts at 795°. The fusibility of the mixtures is increased by the formation of barium cyanide (which melts about 600°), so that the material under treatment in this process is a liquid phase of variable composition.

Kühling and Berkhold (Ber. 1908, 41, 28) found that when a mixture of barium carbonate and carbon is heated in a current of nitrogen under constant conditions, a little more than 40 p.c. of the barium combines with nitrogen at 1150°, and that at lower temperatures the quantity combined diminishes, reaching zero at about 925°.

Ewan and Napier (J. Soc. Chem. Ind. 1913, 32, 467) also found that the absorption of nitrogen begins at 925°. They showed, however, that it depends on the two reversible reactions $BaCO_3 + C \rightleftharpoons BaO + 2CO$ and

$$BaO + 3C + N_2 \rightleftarrows Ba(CN)_2 + CO$$
If carbon monoxide is allowed to accumulate, therefore, the change is brought to a standstill, if it is swept out with large quantities of pure nitrogen a considerable portion of the barium may be cyanised even at comparatively low temperatures. Using 29 molecules of nitrogen to each molecule of BaO, for example, over 40 p.c. of the barium combined with nitrogen in 2 hours at 960°.

The pressure of carbon monoxide in equilibrium with pure barium carbonate and carbon is relatively large, it falls, however, to very low values for the dilute solutions of the carbonate in barium oxide or cyanide. For this reason the greater part of the barium carbonate decomposes before any cyanide is formed, but the decomposition is never complete.

When a mixture of $BaCO_3 + BaO + C$ or of $Ba(CN)_2 + BaCN_2 + C$ is heated in a mixture of carbon monoxide and nitrogen of definite composition until no further change occurs, the percentage of the barium in the product, which is combined with nitrogen (as cyanide or cyanamide), is independent of the composition of the initial mixture, and depends only on the temperature and on the composition of the gas used. The maximum quantities of barium which can combine with nitrogen under different conditions, observed in this way, are given in the following table :—

P.c. of CO in the gas	P.c. of the barium combined with nitrogen		
	1000°	1100°	1150°
0	50	50	50
10	28	41	44
20	5	32	38
30	—	22	32
40	—	13	26
50	—	4	15
70	—	—	9

The curves drawn through the experimental points appear to be straight lines converging towards 50 p.c. conversion for pure nitrogen ; it is probable, however, that this is not their true form at very small concentrations of carbon monoxide, because a product in which 57·1 p.c. of the barium had combined with nitrogen was obtained by continuing the heating for 82 hours at 1100° with nitrogen containing only 0·1 p.c. of CO. For practical purposes, the rapid increase in the quantity of carbon monoxide required to reverse the reaction at higher temperatures is important.

In addition to the two equilibria just mentioned, the reaction $Ba(CN)_2 = BaCN_2 + C$ occurs. Pure barium cyanide decomposes even at 500°, the reaction is a slow one, which is accelerated by iron. The results appear to show that at temperatures between 600° and 1000°, and in absence of barium oxide, the decomposition ceases when about two-thirds of the

nitrogen is in the cyanamide form ; in presence of barium oxide the change does not go so far. The relative quantities of cyanide and cyanamide produced by the action of nitrogen on mixtures of barium oxide and carbon are very erratic, anything from 0 to 70 p.c. of the nitrogen fixed may be in the cyanamide form, the average of 36 experiments was 15 p.c.

The equilibrium pressure of carbon monoxide in the reaction $BaO + 3C \rightleftarrows BaC_2 + CO$ was found to be 1 mm. of mercury at 1200°. Cyanide formation therefore proceeds freely in presence of quantities of carbon monoxide, which are quite incompatible with the existence of barium carbide. The suggestion that barium carbide is an intermediary in this process is, therefore, incorrect.

The effect of pressure was studied by Hempel (Ber 1890, 23, 3388). The mixture of barium oxide and carbon was heated for 15 minutes by the same quantity of electrical energy in a closed bomb ; the quantity of hydrocyanic acid obtained increased 16 times when the nitrogen pressure was increased from 1 to 60 atmospheres. The improvement may have been due to greater reaction velocity of the more concentrated nitrogen or to a larger value of the ratio of nitrogen to carbon monoxide in the bomb. Stahler (Ber. 1916, 49, 2292), by a somewhat similar method, finds that with 60 atmospheres N pressure a product containing 74 p.c. of barium cyanide and no appreciable quantity of cyanamide is obtained.

The addition of barium chloride or of potassium carbonate to the mixture of barium oxide and carbon neither reduces the minimum temperature nor increases the speed of the reaction.

The effect of the addition of calcium and barium fluorides was studied by N. Caro (Zeitsch. angew. Chem. 1910, 3, 2405) at temperatures about 1100° and 1200°. Since the quantity of carbon monoxide in the nitrogen was not observed it is impossible to draw definite conclusions from the results ; it is, however, of interest that in the 15 experiments recorded the quantity of the barium which combined with nitrogen never exceeded one-half of that present.

Very little information exists about the course of the reaction at higher temperatures. From Eng. Pats. 2133 of 1907, and 22039 of 1906 (Badische Co.), it may be gathered that 80 p.c. of the barium can be combined with nitrogen at 1500° ; and, according to Kaiser (Fr. Pats. 454237–8 of 1913), 90–95 p.c. of the theoretical quantity of nitrogen is absorbed, when barium carbonate and carbon are heated at ' 900° to 1400° ' in nitrogen and cooled in it under pressure. It appears, therefore, that the inactivity of one-half of the barium, which has been shown to exist at temperatures below 1200°, may disappear at considerably higher temperatures ; possibly because a different mechanism comes into play. Ewan and Napier (l.c.), by applying Nernst's thermodynamic theorem to their measurement of the equilibrium pressure (p_{CO} in mm. of mercury) of the reaction $BaO + 3C \rightleftarrows BaC_2 + CO$, showed that, at absolute temperature T

$$\log_{10} p_{CO} = -\frac{16250}{T} + 1·75 \log_{10} T + 5·48$$

from which the value of $p_{00}=100$ mm. at 1500° and 1026 mm. at 1700°. M. Kahn (Compt. rend. 1907, 144, 913) found that barium carbide is formed from barium oxide and carbon heated in a well-closed crucible at the melting point of platinum (1760°); the equilibrium pressure at 1760° is, therefore, greater than 1 atmosphere, in approximate agreement with the calculated value. It is therefore possible that barium carbide is an intermediate product at high temperatures.

2a. Action of Nitrogen on the Carbides of Metals.

F. R. Hughes (Report of Juries, Exhib. of 1851, 1, 95) suggested that the first stage of the reaction between potassium carbonate and carbon might lead to the formation of potassium carbide, and that this might combine directly with nitrogen. Potassium carbide is actually formed in this way, E. Davy (Brit. Ass. Report, 1836, ii. 62), having discovered acetylene by treating with water, the black product of an unsuccessful attempt to prepare potassium. Berthelot (Compt. rend. 1868, 67, 1141) was led to suggest the same mechanism by the analogy with his synthesis of hydrocyanic acid from acetylene and nitrogen. He also showed that the products of the action of potassium on potassium carbonate or on carbon monoxide contain potassium acetylide. The action of nitrogen on the alkali metal carbides has not been investigated in detail. Frank and Caro (Eng. Pat. 15066 of 1895) mention that they combine at a 'dark red heat' forming cyanides.

The absorption of nitrogen by the carbides of calcium, strontium, and barium has been much more completely studied. Moissan (Compt. rend. 1894, 118, 503, and 684) found that pure, dry nitrogen did not react with the pure carbides even at 1200°, although the product obtained from barium carbide yielded a little ammonia when boiled with water. In 1895 Frank and Caro (Eng. Pat. 15066 of 1895), and T. L. Willson (Eng. Pat. 21997 of 1895), discovered independently that the impure carbides absorb nitrogen. According to Frank and Caro, moist nitrogen is necessary when the pure carbides are used, but not with impure substances; they also found that barium carbide yields the corresponding cyanide, but obtained an 'unsatisfactory result' with calcium carbide unless it was mixed with barium or sodium carbide. Willson proposed to treat the carbides with nitrogen either during their formation in the electric furnace, or subsequently in a separate operation. He also appears to have found difficulty with calcium carbide, and says that a cyanide or some more complicated nitrogen compound is formed. The fact that a large part of the combined nitrogen is in the form of a cyanamide salt was discovered by F. Rothe, working under Frank's direction, in 1898 (Zeitsch. angew. Chem. 1903, 658), and was published in Frank and Caro's Eng. Pat. 25476 of 1898.

Frank and Caro at first attempted to apply their discovery to the manufacture of cyanides.

Finely ground barium carbide, made in the electric furnace, was heated at about 700° in presence of pure nitrogen. The product contained about 11 p.c. of nitrogen, 30 p.c. of which was in the form of barium cyanide, the remainder being barium cyanamide. In order to convert the cyanamide into cyanide, the material was heated with dry sodium carbonate and carbon. The sodium carbonate may convert the barium cyanamide into the sodium salt, which then takes up carbon in the way discovered by Dreschel,

$$BaCN_2 + Na_2CO_3 = Na_2CN_2 + BaCO_3$$
$$\text{and } Na_2CN_2 + C = 2NaCN$$
By extracting the product with water, converting the sodium cyanide into ferrocyanide, and then fusing it with sodium, about 86 p.c. of the nitrogen fixed was obtained in the form of marketable sodium cyanide (G. Erlwein, V. Int. Kongress angew. Chem. Berlin, 1903, 1, 646). The process, however, even in this form, did not pay, and the cheaper calcium carbide was therefore tried. Commercial calcium carbide absorbs nitrogen at about 1100°, yielding a product containing from 20 to 23·5 p.c. of nitrogen, which is wholly in the form of calcium cyanamide $CaC_2 + N_2 = CaCN_2 + C$. Details of the manufacture of calcium cyanamide are given in the article on NITROGEN, ATMOSPHERIC, UTILISATION OF. By heating this product with sodium chloride, from 90 to 95 p.c. of the cyanamide is said to be converted into sodium cyanide. (G. Erlwein, loc. cit., G. Erlwein and Frank, U.S. Pat. 708333, 1902.)

It is not easy to obtain such a high yield in the laboratory; Kitawaki and Kusano, for example (J. Chem. Ind. Tokyo, 1917, 20, 234), state that when 10 parts of calcium cyanamide (18·6 p.c. N) are heated with 16 to 24 parts of salt, and 2 parts of charcoal for 10 minutes at 900°–950°, and the fused product cooled in absence of oxygen, it contains more than 70 p.c. of the theoretical quantity of cyanide.

Large-scale experiments were carried on in Germany with but little success; a description of these, up to 1914, has been published by W. S. Landis (Chem. Met. Eng. 1920, 22, 265). In the latest modification, from 2 to 3 parts of salt were fused separately, and 1 part of calcium cyanamide added gradually in order to control frothing. The highest temperature used was 960°, and from 40 to 75 p.c. of the nitrogen was obtained in the form of cyanide.

In 1916 the process was installed at Niagara. It was soon found that the troublesome evolution of gas was almost suppressed by the addition of a little calcium carbide, and that much better results were obtained by raising the temperature to 1200°–1400° (H. P. Eastman, U.S. Pat. 1282395, 1918), and also that the cyanide disappears when the fused product is allowed to cool slowly, the reversion apparently occurring between 400° and 700° (H. Freeman, U.S. Pat. 1282405, 1918). In 1919 the process was, therefore, carried out by feeding a mixture of calcium cyanamide (1 part), salt (about 0·8 part), and calcium carbide (0·05 to 0·1 part) into a single phase electric furnace of the arc-resistance type with conducting hearth and a single suspended electrode. The furnace treats about 30 tons daily. The mixture fuses, and is run off almost continuously into a pan in which a water-cooled drum rotates, taking up a thin layer of the fused material which solidifies and is scraped off in thin flakes which contain cyanide (possibly the calcium salt) equivalent to 36 p.c. NaCN. The

efficiency on the nitrogen is about 90 p.c. The equivalent of 975 tons of sodium cyanide was made in 1917, 1050 tons in 1918, and 1250 tons in 1919. The chemistry of this process is still incompletely known; Landis states that cyanide is formed even when little or no salt is used, which suggests that the principal change is represented by the reversible reaction

$$CaCN_2 + C \rightleftharpoons Ca(CN)_2$$
The initial frothing may be due to the decomposition of sodium cyanamide

$$2NaCN_2 = 2NaCN + N_2 + 2Na$$
the graphitic carbon present not being sufficiently active at lower temperatures to convert it quickly into cyanide; the addition of calcium carbide is supposed to supply the necessary active carbon.

2b. Action of nitrogen on acetylene.

In 1863 Berthelot had shown (Ann. Chim Phys 1863, [3] 67, 52) that acetylene is formed in the electric arc between carbon electrodes in an atmosphere of hydrogen, and also that hydrocarbons in general yield acetylene when induction spark pass through their vapours. The careful measurements of Bone and Jordan (Chem. Soc. Trans. 1901, 1042) indicate that, when equilibrium is established in the gas surrounding a carbon arc burning in hydrogen or hydrocarbon vapour, it contains 90–91 p c H_2, 7–8 p.c. C_2H_2, 1·25 p.c. CH_4 and 0·75 p.c. C_2H_6, no other hydrocarbons being present.

In 1868 Berthelot(Compt rend.1868,67,1141) discovered that acetylene and nitrogen combine, under the influence of strong induction sparks, to form hydrocyanic acid, and that the reaction $C_2H_2 + N_2 \rightleftharpoons 2HCN$ is reversible. Taken together with his earlier observations on the formation of acetylene, this led him to the generalisation that hydrocyanic acid must be formed in the carbon arc burning in mixtures of hydrogen and nitrogen or when sparks are passed through mixtures of nitrogen and hydrocarbons. The cyanogen compound observed when the arc burns between carbon electrodes in an atmosphere of nitrogen is hydrocyanic acid, the hydrogen of which is derived from the electrodes or from water vapour. A mixture of 10 vols. C_2H_2, 14·5 vols. N_2, and 75·5 vols. H_2 is suitable for the synthesis of hydrocyanic acid, since mixtures richer in acetylene deposit carbon. Dewar (Proc. Roy. Soc. 1879, 29, 188, and 1880, 30, 85) confirmed Berthelot's observations on the formation of hydrocyanic acid in the arc, and also showed that it is formed when a mixture of hydrogen and nitrogen is passed through a carbon tube heated externally by an electric arc. The minute traces of hydrocyanic acid found in the slightly luminous flame of a Bunsen burner (Lüdeking, Annalen, 1888, 247, 122) are doubtless due to this reaction.

Subsequent investigations add little to the information given by Berthelot; Hoyermann (Chem. Zeit. 1902, 26, 70) passed a mixture of nitrogen (2 vols.) and acetylene (1 vol.) into the arc through tubular carbon electrodes and found that 60 to 70 p.c. of the acetylene was converted into hydrocyanic acid. Gruszkiewicz (Zeitsch. Elektrochem. 1903, 9, 83) found that a mixture of carbon monoxide (2 vols.) hydrogen (1 vol.) and nitrogen (1 vol.) yielded small quantities of hydrocyanic acid when exposed to induction sparks between platinum points. Lipinsky (Zeitsch. Elektrochem. 1911, 17, 761) passed mixtures of methane, nitrogen and hydrogen through a 2200 volt alternating current arc between platinum electrodes. No carbon was deposited from a mixture containing CH (20 p.c.), H_2 (10 p.c.), and N_2 (70 p.c.). Under the best conditions about 1·75 gram of hydrocyanic acid was produced per kilowatt hour. It is instructive to compare this with the 50 grams of nitric acid per kilowatt hour which Raleigh obtained, in apparatus of comparable dimensions, from mixtures of oxygen and nitrogen.

E. Briner and A. Baerfuss (Helv. Chim. Acta. 1919, 2, 663) have obtained as much as 7·39 grams HCN per kilowatt hour by circulating 8–10 litres per hour of a mixture of 1 part methane and 5 parts nitrogen through an arc at 505 volts between platinum electrodes 12 mm. apart.

According to H. Philipp (Chem. Met. Eng. 1920, 22, 213), Lipinski's process was tried on a commercial scale in 1914 at Neuhausen, and a yield of 30 grams of HCN per kilowatt hour attained.

Hutton and Smith (Eng. Pat. 23835 of 1906, and Trans. Amer. Electrochem. Soc. 13, 359, 1908) showed that the temperature of the arc is not necessary, hydrocyanic acid being formed when a carbon rod is heated in a mixture of hydrogen and nitrogen to 1700°; and H. v. Wartenberg (Zeitsch. anorg. Chem. 52, 299, 1907) carried out quantitative measurements with the following results (using a mixture of equal volumes of hydrogen and nitrogen) :—

Temperature	P.c. HCN in the gas in equilibrium
1635°	1·95
1752°	3·10
1875°	4·70

Wallis (Annalen, 1906, 345, 353), by passing the same mixture through the electric arc at varying rates obtained a maximum of 33·5 p.c. of HCN in the gas. The estimated temperature of the arc is about 3250°.

Cyanides from nitrides. At high temperatures, nitrogen combines directly with several elements to form nitrides, and these, when fused with sodium carbonate and carbon, produce sodium cyanide. This has been shown to be the case with the nitrides of boron, calcium, magnesium, titanium, silicon, and aluminium, and with phospham PNH_2. Since none of these processes has emerged as yet from the experimental stage, it is sufficient to mention the possibility of producing cyanides in this way.

Hydrocyanic acid. Prussic acid (Ger. Blausäure). HCN.

This substance was discovered by Scheele in 1782 (Chemical Essays, London, 1786; reprinted 1901). He observed that Lixivium sanguinis loses its power of forming Prussian blue when it is exposed to the air, and traced this effect to the atmospheric carbon dioxide. Other acids also produced it, and the blue-forming principle was found in the vapour given off. By distilling

the *lixivium* with sulphuric acid, he obtained an aqueous solution of hydrocyanic acid. A more convenient method of preparation was to heat potassium ferrocyanide with dilute sulphuric acid. In doing this, he obtained a blue residue (oxidised Everitt's salt or Williamson's blue). Finally, he prepared mercuric cyanide by boiling Prussian blue with mercuric oxide; by heating this with iron and sulphuric acid, he decomposed it into mercury and hydrocyanic acid, which he distilled off. In 1783, Scheele found that hydrocyanic acid is inflammable, its combustion yielding carbon dioxide. He also proved that it contains nitrogen by synthesising it from ammonia. Equal parts of charcoal and potassium carbonate were heated to redness, but not sufficiently to melt the potash, in a crucible and then some ammonium chloride stirred in (for 2 minutes only); the mass was then thrown into water and a solution obtained which gave 'a great quantity of Prussian blue,' whereas a similar experiment without the sal-ammoniac yielded a very small quantity.

The exact quantitative composition of prussic acid was ascertained by Gay-Lussac (*Annales de Chimie*, 1815, 95, 156). He showed that it is similar in constitution to hydrochloric and hydriodic acids, the hydrogen being united with a compound radical, CN, which he called '*cyanogène*,' which plays the part of an element in so far as it passes through many transformations unchanged.

Compounds of hydrocyanic acid are widely distributed in nature in plants. The acid does not exist as such in the living plants, but is liberated after their death by the hydrolytic action of an enzyme on a glucoside, both of which are contained in the living cells; the glucoside may also be split up by boiling with dilute acids. Rarely a glucoside is found without an accompanying enzyme, as in the leaves of the common elder (*Sambucus niger*). The chemistry of the cyanogenetic glucosides is described under GLUCOSIDES. Very different quantities of hydrocyanic acid are obtained from different parts of the same plant, the quantity also depends on the age of the plant (it is usually greatest in the young plants) and on the conditions of growth such as climate and rainfall; the use of nitrogenous fertilisers has been found to increase the quantity of hydrocyanic acid present. Plants rarely yield as much as one or two tenths of 1 p.c. of their weight of hydrocyanic acid; for example: great millet (*Sorghum vulgare*) 0·013 to 0·044 p.c. in young plants, an exceptional North American sample gave 0·114 p.c.; wild cherry (*Prunus padus*) 0·03 p.c.; cherry laurel (*Prunus laurocerasus*) up to 0·2 p.c. in young leaves; cassava, sweet, 0·016 p.c. in the leaves, 0·043 p.c., in the peel of the stem, 0·005 p.c. in the edible part of the root, the corresponding parts of the bitter variety contained 0·041 p.c., 0·113 p.c., and 0·053 p.c. respectively; Rangoon beans (*Phaseolus lunatus*), 0·025 p.c.; linseed, 0·02 to 0·038 p.c.; *Nandina domestica*, 0·07 to 0·147 p.c.; bitter almonds 0·12 to 0·18 p.c. Cases of cattle poisoning are not infrequent in hot countries where sorghum is used as fodder, and linseed meal and white clover are also sometimes poisonous. The enzymes are de-stroyed and the cyanogenetic glucosides rendered harmless by thorough boiling with water.

Minute traces of hydrocyanic acid have been observed in the products of incomplete combustion, for example, in the luminous flame of a Bunsen burner, in boiler flue gases, and in tobacco smoke.
Preparation of Hydrocyanic Acid.—Hydrocyanic acid was formerly prepared by distilling potassium ferrocyanide with dilute sulphuric acid. A more convenient method, however, is to run a solution of sodium cyanide (97 to 98 p.c. NaCN) in from 2–2½ times its weight of water into hot sulphuric acid of 75 p.c. strength; about 1½ mols. of sulphuric acid to 2 mols sodium cyanide is sufficient and the cyanide solution is preferably allowed to enter the acid a little below its surface, so as to avoid contact of the alkaline cyanide solution with hydrocyanic acid vapour.

The vapour may be dried by calcium chloride, kept at a temperature of about 30° and then condensed in a vessel cooled by ice, although the greater part of it is quite readily liquefied in an ordinary Liebig's condenser cooled by cold water. It may be purified from traces of water and ammonia by distillation over phosphorus pentoxide (Nef, *Annalen*, 1895, 287, 265).

Hydrocyanic acid is formed in many different ways; the synthesis from free nitrogen and acetylene has already been mentioned. *The oxidation of organic compounds* by nitric acid often yields hydrocyanic acid in greater or smaller amount, and it has been proposed to manufacture hydrocyanic acid in this way. The interesting reaction described by Huntingdon (Eng. Pat. 14855, 1895) may be mentioned here. A mixture of acetylene and nitric oxide is readily exploded by a spark, yielding very considerable quantities of hydrocyanic acid in accordance with the equation

$$2NO + 2C_2H_2 = 2HCN + 2CO + H_2$$
When *ammonium formate* is distilled, water is first given off together with a little ammonia and formic acid; at 180° formamide begins to distil over, and, as the temperature gradually rises to 220°, this is accompanied by increasing quantities of carbon monoxide, but only traces of hydrocyanic acid are produced. In order to obtain a good yield of hydrocyanic acid, the vapour must be heated to much higher temperatures, and the result is greatly influenced by the nature of the substance with which it is in contact. According to unpublished experiments by the writer, the principal changes which occur are:—

$$H \cdot COONH_4 = HCO \cdot NH_2 + H_2O \quad (1)$$
$$H \cdot COONH_4 = NH_3 + HCOOH$$
$$\qquad\qquad = NH_3 + H_2O + CO \quad (2)$$
$$HCO \cdot NH_2 = HCN + H_2O$$
$$H_2O + CO = CO_2 + H_2$$

The ammonia and hydrocyanic acid in the product usually accounted for more than 95 p.c. of the nitrogen in the ammonium formate or formamide used. Under similar conditions, the yield of hydrocyanic acid obtained from formamide is much greater than that obtained from ammonium formate. For each contact substance there is a certain temperature at which the yield is a maximum. The following table

contains the best temperatures and correspond-
ing yields for several contact substances :—

| Contact substance | Ammonium formate | | Formamide | |
	Yield of HCN p.c. of theoretical	Temperature	Yield of HCN p.c. of theoretical	Temperature
Porcelain chips	41·5	700°	75	800°
Copper gauze	43·0	just below 500°	78	600°
Iron wire	39·0	just below 500°	—	—
Charcoal	21·0	420°	55	400°

With finely divided nickel, no hydrocyanic
acid was obtained in any circumstances; at
273°, 92½ p.c. of the nitrogen was recovered as
ammonia, but much less at higher temperatures.

Formaldoxime $CH_2 : N \cdot OH$, an isomeride of
formamide, obtained by the interaction of
formaldehyde and hydroxylamine, decomposes
very readily when heated alone or with phos-
phorus pentoxide into water and hydrocyanic
acid (Dunstan and Bossi, Chem. Soc. Trans.
1898, 353).

Ammonia and carbon monoxide were said to
yield hydrocyanic when passed over heated
spongy platinum (Kuhlmann, Annalen, 1841,
38, 62), $CO+NH_3=HCN+H_2O$, and this ap-
parently simple reaction has attracted several
inventors. A careful investigation by Jackson
and Laurie (Chem. Soc. Trans. 1905, 87, 433) has
shown that a dry mixture of the two gases,
when sparked, treated by the silent discharge
or heated in presence of platinum (an electrically
heated spiral of platinum wire gives the best
result) yields ammonium cyanate thus :

$$CO+2NH_3=NH_4CNO+H_2$$
and Kuhlmann's reaction does not take place.
The reverse change, $HCN+H_2O=CO+NH_3$,
however, does occur very readily, even at 200°,
when a mixture of steam and hydrocyanic acid
is passed over broken brick as contact material,
and at 600° it is practically quantitative. With
iron oxide as contact substance, the conversion
into ammonia is complete at 285°, and with
Weldon mud at 200° (Carpenter and Linder, J.
Soc. Chem. Ind. 1905, 63).

Cyanogen and hydrogen combine, forming
hydrocyanic acid when a mixture of them is
heated at 500°–550° (Berthelot, Ann. Chim.
Phys. 1879, [5] 18, 380).

Properties of Hydrocyanic Acid.—A colourless
liquid possessing a characteristic smell (or rather
taste), which produces a choking sensation in the
larynx. It is one of the most poisonous sub-
stances known, the fatal dose for a full-grown
man being about 0·06 gram of the acid or 0·15
gram of potassium cyanide. It may be absorbed
through all parts of the body, even through the
skin, and its action is very rapid, large doses
causing death almost instantaneously. Air in
which the smell of hydrocyanic acid is distinctly
perceptible may be breathed constantly with-
out ill effects. Experiments with cats showed
that 3 to 4 volumes of the acid per 100,000
volumes of air could be borne, but 5 volumes

produced symptoms of poisoning. In industrial
cases of hydrocyanic acid poisoning the persons
affected were usually working in confined spaces,
for example, cleaning or repairing apparatus
which had contained cyanides, removing
damaged cargo from the holds of ships, or work-
ing in insufficiently ventilated buildings where
cyanide solutions were used; in all these cases
hydrocyanic acid is generated from alkali cyanide
solutions partly by hydrolysis and partly by
the action of carbon dioxide.

The first symptoms of poisoning are giddi-
ness and darkness of the visual field (these
symptoms disappear after a few minutes ex-
posure to fresh air), they are followed by un-
consciousness accompanied by muscular cramps
and more or less complete cessation of respira-
tion; the heart still acting, however, artificial
respiration with oxygen may be successful at
this stage. When a cyanide has been swallowed,
hydrocyanic acid is liberated by the acids of the
stomach. The simplest and most effective
antidote is prepared by mixing solutions of
ferrous sulphate and sodium carbonate (suitable
quantities are 50 c.c. each of solutions containing
150 grams of $FeSO_4, 7H_2O$ and 57 grams of
Na_2CO_3 per litre). Stimulants, such as ammonia,
are also helpful. The writer has seen a dog,
which had swallowed some potassium cyanide,
and was already partially paralysed in its hind
quarters, recover in a few seconds when dosed
with the above mixture which had been made
up hastily from ferrous ammonium sulphate.
Subcutaneous injection of hydrogen peroxide,
which converts hydrocyanic acid into oxamide,
has also been recommended.

The action of hydrocyanic acid appears to
consist partly of a direct effect on the nerve
centres and partly of an inhibitory action on
the enzyme of the red blood corpuscles, which
brings about the transference of oxygen from
oxyhaemoglobin to the oxidisable substances
in the body; the venous blood therefore becomes
arterial, and death is due partly to a kind
of internal suffocation. Schönbein (J. pr.
Chem. 1868, 105, 202) showed that hydro-
cyanic acid inhibits the catalytic decomposition
of hydrogen peroxide by plant ferments, and
also by the red blood corpuscles, and suggested
that its poisonous properties might be due to
the inhibition of the oxidising power of the
blood. Bredig and von Berneck (Zeitsch. phys.
Chem. 1899, 31, 329) showed that hydrocyanic
acid has the same effect on the inorganic ferment,
colloidal platinum. The ferments recover their
activity when the hydrocyanic acid is removed.
This property has been applied in the preserva-
tion of fruit.

The sp.gr. of the liquid acid is 0·7058 at 7°
and 0·6969 at 18° (Gay Lussac). Freezing-point,
−10° to −12° (Nef.). The freezing-point is
raised by pressure; it is −2·88° under 500 kilos
per sq. cm. and +50·1° under 4000 kilos per sq.
cm. pressure (Tamman). The boiling-point at
atmospheric pressure is 25° (Nef.). The heat of
evaporation is exceptionally large, 210·7 Cals.
per gram. Heat of formation of the liquid acid
from the elements (amorphous carbon) −21·8
Cals. per mol. (Thomsen), diamond −24·8 Cals.
(Berthelot). Heat of solution, liquid acid in
water, 0·4 Cal. per mol. The dielectric constant
of hydrocyanic acid, 95, is the largest known,

with the exception of that of hydrogen peroxide (Schlundt). The acid is miscible in all proportions with water, alcohol, ether and many other substances; it is almost insoluble in light petroleum. It is an excellent solvent for many solid substances; among the inorganic salts the iodides are usually readily soluble. The solutions are good conductors of electricity, the conductivity of solutions of potassium iodide, for example, is about 3½ times greater than that of the corresponding aqueous solutions.

Hydrocyanic acid is one of the weakest acids; its dissociation constant in aqueous solution at 18°, 1 3 × 10⁻⁹, is 44 times smaller than that of sulphuretted hydrogen, and 230 times smaller than that of carbonic acid (Walker and Cormack, Chem. Soc. Trans. 77, 16, 1900). In a 0·1N-solution, only 0·011 p.c. of the acid is dissociated into its ions, consequently it does not behave as an acid to indicators, and its salts are more or less completely decomposed by water; thus for example,

$$KCN + H_2O \rightleftarrows KOH + HCN$$

In 0·1 N-solutions of the sodium or potassium salts, 1·1 p c. is dissociated in this way; in N-solutions, only 0·3 p.c. at 24·2° (Shields, Zeitsch. physikal. Chem. 12, 167, 1893). In solutions of pure sodium cyanide, containing no caustic soda, the hydrolysis is greater than that found by Shields. It may be calculated from the equilibrium constant K = [HaOH][HCN∥NaCN], the bracketed quantities representing concentrations of the substances in gram mols. per litre. The values of K × 10⁴ are: at 0°, 0 135; at 5°, 0 15; at 10°, 0·16; at 15°, 0·20; at 20°, 0·27; at 25°, 0·484; and at 30°, 0·72 (F. P. Worley and V. R. Browne, Chem. Soc Trans. 1917, 1057). This is of importance when it is required to concentrate an aqueous solution of a cyanide; the free hydrocyanic acid escapes until sufficient excess of the base has accumulated to reduce the hydrolysis to negligible proportions. In the case of weaker bases, the result is a considerable loss of hydrocyanic acid; with calcium cyanide, for example, the quantity of lime formed is greater than can be retained in solution, consequently equilibrium is never attained, and when such a solution is evaporated, the whole of the hydrocyanic acid escapes, leaving a residue of pure lime.

A large part (sometimes one-half) of the cyanide used in gold extracting is lost by the evaporation from the solutions of hydrocyanic acid set free by hydrolysis (H. A. White, J. Chem. Met. and Min. Soc. S. Africa, 1915, 16, 24).

Pure hydrocyanic acid, distilled over phosphorus pentoxide, can be preserved without change for considerable periods at the ordinary temperature; when heated to 100° or at the ordinary temperature in presence of alkaline impurities, such as ammonium or potassium cyanide, it changes into a solid, black mass from which a ter-molecular polymer, probably the nitrile of amino malonic acid, NH₂·CH(CN)₂, can be separated. Under imperfectly known conditions, the anhydrous acid sometimes explodes. G. Salomone (Gazz. chim. ital. 1912, 42, i. 617) isolated, from the products of an explosion, colourless crystals of a substance having the composition of cyanic acid and a

molecular weight, in benzene solution, corresponding with (HCNO)₅.

The aqueous acid also becomes brown rapidly in presence of alkali cyanides and deposits a dark brown amorphous substance, azulmin or azulmic acid, which contains carbon, oxygen, nitrogen, and hydrogen in variable proportions. The discolouration of solid alkali cyanide, when exposed to the air, is due to the hydrocyanic acid liberated at its surface undergoing this change.

The only useful *application of hydrocyanic acid*, as an insecticide, was developed at the Agricultural Experiment Station of the University of California, largely by the labours of D. W. Coquillett and H. D. Bishop (California Station Bull. 122). They found that foliage is much less liable to injury at night than in sunlight; the hydrocyanic acid vapour is applied by erecting a tent over the trees and generating the acid inside of it. The safe concentration of hydrocyanic acid depends on the kind of tree and on the time of year. In greenhouses less than 2 grams of hydrocyanic acid per 1000 cb. ft. of air space is said to kill green aphis, but as much as 30 grams may be needed for mealy bug or red spider. Most plants are unaffected even by the larger quantity. Since about 1918 98 p.c. hydrocyanic acid has been placed on the market for the fumigation of orange trees; formerly the acid was always generated on the spot, from sodium cyanide and sulphuric acid.

The constitution of hydrocyanic acid has been the subject of much discussion arising largely from the observation that the reaction of potassium cyanide with an ester yields a nitrile, R—C⦂N, as principal product, whereas silver cyanide yields a carbylamine, R—N⦂C. On the hypothesis that the salts are formed by the substitution of an atom of metal for an atom of hydrogen without change of position, and that the alkyl derivatives are formed similarly, it is of course necessary to suppose that the hydrogen in hydrocyanic acid may be united either with carbon or with nitrogen The cyanides are, however, in all probability more complex substances; silver cyanide, from its mode of formation, is probably silver dicyano argentaate, Ag[Ag(CN)₂], and the reaction with methyl iodide is similar to that of silver ferrocyanide (described above) leading to the well-crystallised

substance $\left[Ag{CN \atop CNCH_3}\right]$, which, like the corre-

sponding ferrocyanide, splits off methyl carbylamine when heated or when acted on by a solution of potassium cyanide (see, for example, H. Guillemard, Ann. Chim. Phys. 1908, [8] 14, 311).

The properties of hydrocyanic acid itself, however, leave little doubt that it is formonitrile; the isomeric substance H·N⦂C, has not been isolated. Like the nitriles, hydrocyanic acid is hardly affected by dilute mineral acids (it is frequently separated quantitatively by distilling acid solutions); the carbylamines are violently decomposed. Anhydrous hydrocyanic acid and the nitriles do not dissolve silver cyanide, whilst the carbylamines dissolve it very readily. In its high dielectric constant, solvent and dissociating powers and physiological action hydrocyanic acid also resembles the nitriles rather

than the carbylamines (Wade, Chem. Soc. Trans. 1902, 1613).

THE PRINCIPAL CYANIDES.

Potassium cyanide KCN crystallises in anhydrous, colourless octahedra from aqueous solutions, or in cubes when the fused salt solidifies; sp.gr. 1·52. It melts at a dull red heat, and volatilises without decomposition at high temperatures It is readily soluble in water; the saturated solution contains 122·2 grams of KCN to 100 grams of water at its boiling-point (103·3°). At 19·5°, 100 grams of absolute alcohol dissolve 0·88 gram, 100 gr. methylalcohol dissolve 4·91 grams (Landolt, Börnstein and Meyerhoffer, Tabellen, Berlin, 1905). It is moderately soluble in anhydrous ammonia at −38° (Franklin and Kraus, Amer. Chem. J 1898, 20, 820). It deliquesces in moist air.

Sodium cyanide NaCN crystallises from the fused liquid in apparently cubic crystals; from aqueous solutions below 35° large colourless plates of the hydrate $NaCN,2H_2O$ are deposited. Joannis (Ann. Chim. Phys. 1882, [5] 26, 484) obtained a hydrate $NaCN,\frac{1}{2}H_2O$ from cold 85 p.c. alcohol. F. Roessler (Eng. Pat. 279, 1899) showed that the hydrate $NaCN,2H_2O$ decomposes at 33° (34·7° according to the writer's measurements) into the anhydrous salt and a saturated solution, about 40 p.c. of the sodium cyanide separating in the anhydrous state. The solubility of the hydrate (in grams of NaCN to 100 grams of water) is, 35·4 at −20°; 43·4 at 0°; 58·3 at 20° and 82 at 34·7°. The solubility of the anhydrous salt is almost independent of the temperature (82 grams per 100 grams of water). Sodium cyanide appears to be more soluble in ethyl and methyl alcohol and anhydrous ammonia than the potassium salt. The sp.gr. of aqueous solutions of sodium cyanide at 25° is given by the expression $1+0·00534p$, where p is the percentage of NaCN. Sodium cyanide (96 p.c.) melts at 540°. The pure salt, when heated in a glass tube so as to be out of contact with metals, in a current of dry air free from carbon dioxide, remains entirely unchanged at temperatures up to 370°; if, however, it is in contact with iron or nickel, or if traces of the oxides of these metals are added to it, oxidation proceeds rapidly, cyanate and carbonate being formed and carbon dioxide evolved. The carbonate is formed by the oxidation of the cyanate, which is the primary product. Sodium cyanate behaves towards oxygen in exactly the same way as the cyanide; it is quite unaffected by dry air (free from CO_2) even at 400°, but when mixed with 1 p.c. of nickel oxide it oxidises rapidly; thus :

$$2NaCNO+3O=Na_2CO_2+CO_2+N_2$$
(writer's unpublished statement).

Sodium cyanide absorbs moisture with great avidity from ordinary moist air. The writer has found that it takes up water from purified air saturated with aqueous vapour at 20° at all temperatures below 44°, but not at higher temperatures. This is of importance in sampling and analysing the salt.

Dilute solutions of potassium or sodium cyanide decompose slowly in contact with the air, the loss being due to evaporation of the hydrocyanic acid formed by hydrolysis, which permits the decomposition to proceed further; absorption of carbon dioxide acts in the same direction by neutralising the caustic alkali.

Liebig's statement that metallic iron is dissolved by hot solutions of potassium or sodium cyanide with evolution of hydrogen is true of the finely divided metal, but iron vessels may be used for years for boiling concentrated solutions of cyanides without requiring repair, and iron tanks are regularly used in the treatment of gold ores with cyanide solutions.

With the exception of lead and platinum, all ordinary metals are dissolved by cyanide solutions in presence of oxygen.

Zinc is slowly dissolved without oxygen, but if a piece of zinc is half immersed in a cyanide solution, it is eaten through at the surface of the liquid before any appreciable action has taken place on the submerged portion.

Alkali cyanides yield ammonia and a formate when boiled with water or treated with strong sulphuric acid; in the latter case the formic acid produced is at once decomposed into carbon monoxide and water.

Mercuric cyanide $Hg(CN)_2$ was first prepared by Scheele, in 1782, by boiling Prussian blue with mercuric oxide, and, in 1783, by dissolving mercuric oxide in hydrocyanic acid and evaporating to crystallisation. He also found that mercurous salts, when treated with soluble cyanides, yield mercuric cyanide and metallic mercury. The decomposition of the ferrocyanides, as already mentioned, depends on the extremely small electrolytic dissociation of mercuric cyanide in aqueous solution. For the same reason, it is not decomposed by caustic alkalis, and hydrocyanic acid can only be expelled from it by boiling with a strong acid. The concentration of the mercury ions is, however, sufficient to permit of the precipitation of the extremely insoluble mercuric sulphide by sulphuretted hydrogen.

Mercuric cyanide crystallises in anhydrous, colourless crystals of sp.gr. 4·0. The saturated solution contains 93 grams per litre at 20°, 111 grams per litre at 25°; 100 grams of absolute alcohol dissolve 10·1 grams of it at 19·5°, and 100 grams of absolute methyl alcohol take up 44·2 grams at 19·5°.

Small quantities of mercuric cyanide are sometimes used in addition to alkali cyanide in the treatment of ores containing silver sulphide (Clennel, Cyanide Handbook, London, 1910, 297), the dissolution of which is accelerated, probably owing to the formation of mercuric sulphide :

$$Hg(CN)_2+Ag_2S+2KCN=HgS+2KAg(CN)_2$$

Calcium cyanide has never been prepared in the pure state. An aqueous solution of lime in hydrocyanic acid decomposes completely into its constituents when boiled (Scheele). By evaporating such a solution in vacuo, Joannis obtained a crystalline compound, $3CaO·Ca(CN)_2,15H_4O$, which decomposed completely in a vacuum, leaving nothing but lime. Dry reactions, at high temperatures, yield calcium cyanamide, but no cyanide.

Barium cyanide $Ba(CN)_2$. When a concentrated solution, made by adding hydrocyanic acid to baryta in theoretical quantities, is evaporated in vacuo, crystals of the hydrate

$Ba(CN)_2.2H_2O$ are deposited (A. Joannis, Ann. Chim. Phys. [5] 26, 484, 1882). This is a very deliquescent substance which, when dried *in vacuo* over sulphuric acid, yields an amorphous monohydrate which can be completely dehydrated by heating it very gradually to 100° in a good vacuum. The writer has failed to obtain a pure product in this way. Some 7 or 8 p.c. of the hydrocyanic acid escapes during evaporation, and the product contains a corresponding quantity of barium hydroxide. By drying pure $Ba(OH)_2,8H_2O$ in a good vacuum at 100°, a very finely divided powder of $Ba(OH)_2$ is obtained which is suspended in dry light petroleum and treated with a small excess of dry hydrocyanic acid also mixed with light petroleum. In this way, the solid hydrated barium cyanide is obtained without evaporation :

$$Ba(OH)_2 + 2HCN = Ba(CN)_2,2H_2O$$
When dehydrated *in vacuo*, it still contains a little hydroxide, but by shaking it with a little hydrocyanic acid and light petroleum and again drying, practically pure anhydrous barium cyanide is fairly easily obtained.

By saturating a solution of baryta in methyl alcohol with hydrocyanic acid, a compound $Ba(CN)(OCH_3) + CH_3OH$ is obtained, which, when heated, first loses methyl alcohol and then methyl ether, leaving $BaO + Ba(CN)_2$ (Drechsel, J. pr. Chem. [2] 21, 77, 1880).

Dry methods of preparation yield mixtures of cyanide and cyanamide. When barium ferrocyanide is heated it begins to decompose about 500°, yielding a mixture of barium cyanide and cyanamide (with carbon and iron) in which nearly 60 p.c. of the nitrogen is in the form of cyanamide, practically the same product as that obtained by the action of nitrogen on barium carbide. Even the action of cyanogen on barium amalgam yields a mixture (Drechsel), the reason being that barium cyanide decomposes into barium cyanamide and carbon, thus : $Ba(CN)_2 = BaCN_2 + C$. The change is very slow at 500° to 600°, but it is accelerated by iron (Ewan and Napier, J. Soc. Chem. Ind. 1913, 32, 467).

Barium cyanide is colourless ; 100 grams of cold water dissolve about 80 grams of it (Joannis). It melts about 600°. It is distinctly volatile, even at its melting-point, but when mixed with barium oxide it is much less so.

Silver cyanide AgCN. The precipitate obtained by adding excess of silver nitrate to a solution of a soluble cyanide is probably the silver salt of the complex acid $H[Ag(CN)_2]$. The solubility of silver cyanide in pure water lies between those of the chloride and sulphocyanide, as the following table shows :—

	Solubility at 25° in gram-mols. per litre
AgI	0.01×10^{-6}
AgBr	0.81×10^{-6}
AgSCN	1.08×10^{-6}
AgCN	4.40×10^{-6}
AgCl	14.10×10^{-6}

It is hardly attacked by cold dilute nitric acid, but is decomposed quantitatively on boiling (Plimmer, Chem. Soc. Proc. 1903, 285). When dry silver cyanide is heated about one-half of the CN is given off in the form of

cyanogen C_2N_2. Further heating in presence of oxygen yields a residue of metallic silver, which usually contains a little carbon. It is slightly soluble in a solution of hydrocyanic acid, forming the unstable acid $HAg(CN)_2$. It dissolves very readily in alkali cyanides to salts such as $KAg(CN)_2$, in which the silver is contained in the complex anion $Ag(CN)'_2$. Owing to the excessively small dissociation of this anion, all silver salts except the sulphide are dissolved by cyanide solutions, and in presence of oxygen, metallic silver and the sulphide are also dissolved.

Gold cyanides. Aurous cyanide and the soluble aurocyanides are of technical importance. The former, AuCN, a yellow crystalline powder, insoluble in water and acids, is formed by the action of hydrocyanic acid on auric hydroxide. It is readily soluble in solutions of alkali or alkaline-earth cyanides, yielding aurocyanides such as $KAu(CN)_2$. A solution of the potassium salt, which is used for electroplating with gold, is readily obtained by precipitating a solution of gold chloride with ammonia and dissolving the fulminating gold in a solution of potassium cyanide, or by precipitating gold chloride with magnesia, dissolving out the excess of magnesia in the precipitate with nitric acid, and then dissolving the auric hydroxide in potassium cyanide as before.

Potassium aurocyanide is also formed when gold is dissolved in a solution of potassium cyanide in presence of oxygen or other oxidising agent :

$$4KCN + 2Au + O + H_2O = 2KAu(CN)_2 + 2KOH$$
(Clennel, Cyanide Handbook, 1910, 10–32 gives a full account of the discovery of this reaction.)

The dissolution of metallic gold is primarily due to the great stability of the aurocyanogen ion $Au(CN)_2'$. Metals, like all other substances, have a tendency to dissolve in water. In contact with its aqueous solution, a salt will dissolve if the solution is unsaturated, or crystallise out if it is supersaturated. Metals behave similarly, with the important difference that they dissolve in the form of positively charged *ions*, so that when a metal is placed in contact with a solution containing fewer of its ions than correspond with equilibrium, it gives out positively charged atoms, becoming itself negatively charged, until the electrical attraction stops further change, and *vice versâ*. In this way, a definite potential difference always arises between a metal and a solution of it, the sign and magnitude of which depend on the nature of the metal and on the concentration of the positively charged ions of the metal in the solution.

In order for a metal to dissolve at all, therefore, it is necessary that the solution shall contain less than the saturation quantity of positive ions ; and for the dissolution to continue, the positive charges of the ions and the negative charge of the metal must be got rid of in some way.

These conditions are fulfilled in the case of the dissolution of gold in a cyanide solution containing oxygen, because the dissociation of the complex ion, $Au(CN)_2' \rightleftarrows Au^{.} + 2CN'$ is extremely small, and solutions of it therefore contain infinitesimal quantities of gold ion, and further the electrical charges produced by the

dissolution of the gold are removed by the reactions:

$$Au^{\cdot}+2(CN)'=Au(CN)'$$

and

$$O+H_4O+2(-)=2OH'$$
the result of which, written in the ionic form, is

$$4K^{\cdot}+4(CN)'+2Au^{\cdot}+O+H_2O+2(-)$$
$$=4K^{\cdot}+2Au(CN)_2'+2OH'$$

The potential difference between a metal like zinc (which has a greater tendency to dissolve than gold) and a cyanide solution is much greater than the natural potential difference between gold and the solution; hence gold ions are drawn out of the solutions to the zinc, where their positive charges are neutralised by the negative charge of the zinc. This disturbs the equilibrium between zinc and the solution and also between zinc and aurocyanogen ions and gold ions, causing fresh quantities of zinc to dissolve and of aurocyanogen ions to dissociate, processes which continue until the whole of the gold is precipitated.

As W. Skey (Trans. and Proc. New Zealand Inst. 8, 334, 1876) first showed, gold in cyanide solutions is electro-positive to silver and silver to mercury, so that gold will precipitate silver and mercury from their solutions in cyanides. This has been confirmed by Bodländer (Ber. 1903, 36, 3933). This reversal of the usual order is, as will be understood from the above explanation, due to the increasing stability of the mercury, silver, and gold complex cyanogen ions.

It is of interest to note that most of the minerals which accompany gold in its ores are electro-negative to gold in cyanide solutions, and therefore accelerate its dissolution in the way which is familiar in the solution of zinc in sulphuric acid in presence of copper or platinum.

Barium platinocyanide $BaPt(CN)_4.4H_2O$ is most readily made by electrolysing a solution of barium cyanide (270 grams per litre) with platinum electrodes and an alternating current (0·4 ampere per sq. cm.), about 0·6 gram platinum is dissolved per ampere hour. After removing the excess of barium by CO_2 the solution is concentrated to crystallisation (A. Brochet and J. Petit, Bull. Soc. chim. 1904, [3] 31, 630). The salt crystallises in monoclinic prisms, which are yellow by transmitted, violet-blue by reflected, light. It dissolves in 33 parts of water at 16°. By recrystallisation from a solution containing barium cyanide it is obtained in small crystals which are highly fluorescent when exposed to X-rays, and are suitable for making fluorescent screens for X-ray work.

Copper cyanides. When potassium cyanide is added to the solution of a cupric salt, a brownish precipitate of cupric cyanide $Cu(CN)_2$ is produced, which gradually evolves cyanogen, changing into green cupric cuprous cyanide. When heated, this loses a further quantity of cyanogen and yields white cuprous cyanide CuCN, the constitution and reactions of which appear to resemble those of silver cyanide.

Cuprous cyanide is soluble in solutions of potassium cyanide, about 2½ molecules of KCN being required to dissolve 1 molecule of CuCN; the solutions contain the complex anions $Cu(CN)_3''$ and $Cu(CN)_4'''$ (Kunschert, Zeitsch. anorg. Chem. 41, 359, 1904). These anions are so little dissociated into copper ions that sul-

phuretted hydrogen will not produce a precipitate in the solutions, and therefore copper itself (in presence of oxygen) and all its compounds dissolve readily in cyanide solutions. Solutions of the sodium or potassium cupro-cyanides are used in the electro-deposition of copper on iron.

Zinc cyanide $Zn(CN)_2$ is a white substance, insoluble in water, but soluble in acids and in cyanide solutions. It is not easily prepared in a perfectly pure condition, because water decomposes it partially. When dry it is very stable, decomposing only at a bright-red heat.

The complex salt potassium zinc cyanide $K_2Zn(CN)_4$ crystallises in large well-formed octahedra from aqueous solutions; 100 grams of water at 20° dissolve 11 grams of it. It is anhydrous, and may be fused at a red heat without decomposition. The sodium salt $NaZn(CN)_3.2\frac{1}{2}H_2O$ is very readily soluble in water. The complex zinc cyanogen ions are much less stable than those containing copper, gold, silver, and mercury; a small excess of an alkali sulphide precipitates the zinc completely.

Cyanogen (Ger. Cyan) C_2N_2 was discovered by Gay-Lussac. It is prepared by heating perfectly dry mercuric cyanide at a dull red heat, $Hg(CN)_2=Hg+C_2N_2$. A part of the cyanogen is always polymerised to dark-brown, non-volatile paracyanogen. Paracyanogen appears to be the stable form at ordinary temperatures, at high temperatures it is converted into cyanogen. The velocity of the change is very small at temperatures below 300°, so that cyanogen gas can exist in the cold without change.

Cyanogen itself is a gas which burns with a peach-blossom-coloured flame. Liquid cyanogen boils at −20·7° under atmospheric pressure and freezes at −34·4°. Its critical temperature and pressure are 128·3° and 59·6 atmos. respectively (Cardoso and Baume, Compt. rend 1910, 151, 141). Its heat of formation from graphite and nitrogen is 70,000 cals. per molecule. Water dissolves 4·95 times its volume of the gas at 0°. At 18° the dissolved cyanogen is hydrolysed to hydrocyanic and cyanic acids, the latter yielding ammonia and carbon doxide so that no definite solubility is observed (Naumann, Zeitsch. Elektrochem. 16, 772, 1910). After some time the solution deposits dark brown azulmic acid and contains also oxalic acid and urea. Cyanogen dissolves in caustic alkalis, yielding cyanide and cyanate: $2KOH+C_2N_2=KCNO+KCN+H_2O$. Silver nitrate solution has no action on it. By means of these two reactions, it may be separated from hydrocyanic acid and estimated quantitatively in mixtures of the two gases (Wallis, Annalen, 345, 353, 1906). Cyanogen is very poisonous.

A knowledge of the exact conditions under which cyanogen can be formed from its elements is of interest in the theory of several technical processes for the manufacture of cyanides.

Wallis loc. cit. has shown that the electric arc burning between electrodes of very pure carbon in an atmosphere of nitrogen produces no cyanogen at all. H. v. Wartenberg (Zeitsch. anorg. Chem. 52, 299, 1907) pointed out,- however, that a very intense cyanogen spectrum is seen, and that carbon is deposited at some distance from the arc. Nernst's theorem indicates that very considerable

quantities of cyanogen should exist in equilibrium with carbon and nitrogen at the temperature of the arc :

Temperature	Per cent. C_2N_2 in the gas calculated from Nernst's theorem
2000°	0·01
2500°	0·9
3000°	17·0
3250°	45·0

The probable explanation is that cyanogen is essentially unstable at low temperatures ; that it can exist at all is due to an excessively slow rate of decomposition. Berthelot (Force des Matières Explosives, Paris, 1883, 113) has shown that it can be detonated by mercury fulminate, and, when heated, its rate of decomposition becomes measurable at 1200°. v. Wartenberg supposes, therefore, that cyanogen is really formed at the high temperature, but that it decomposes again completely before it can cool to temperatures at which it can continue to exist. It is obvious from the figures given above that the direct union of carbon and nitrogen to cyanogen can play no part in the formation of cyanides in processes which are carried out at ordinary furnace temperatures.

Cyanogen chloride CNCl is formed by the action of chlorine on mercuric cyanide (Serullas, Ann. Chim. Phys. 1827, 35, 291), zinc cyanide (A. Held, Bull. Soc. chim. 1897, [3] 17, 287), or aqueous hydrocyanic acid (Berthollet, 1787 ; A. Wurtz, Annalen, 1847, 64, 367). Alkali cyanides are unsuitable, because, except in cold, very dilute solutions, they react violently with cyanogen chloride, yielding dark-brown, amorphous products. The preparation of cyanogen chloride in considerable quantities is described by T. S. Price and S. J. Green (J. Soc. Chem. Ind. 1920, 39). A 12 to 15 p.c. solution of pure hydrocyanic acid is treated with chlorine at about 40°, the slow absorption of chlorine is hastened by injecting it into the solution of a finely divided condition through porous earthenware. The cyanogen chloride distils off as it is formed, together with hydrocyanic acid, the product containing 10–20 p.c. of the latter. It is purified by retreatment with chlorine, or by shaking it with zinc oxide, which removes hydrocyanic acid almost completely. Hydrochloric acid is removed by distillation over sodium bicarbonate.

Cyanogen chloride is a colourless liquid, which boils at 12·66°, 760 mm., and solidifies at −8°. Its vapour pressure (mm.) is : 68·3 at −30° ; 148·2 at −20° ; 270·5 at −10° ; 441·1 at 0° ; 681·9 at 10° ; 1001·9 at 20° ; 1427·4 at 30° ; 1988·0 at 40° ; 2719·3 at 50° ; 3664·2 at 60° ; 4873·2 at 70° (Regnault). The vapour attacks the eyes violently. The cold, saturated aqueous solution contains about 6 p.c. CNCl. The heat of formation of liquid CNCl from its elements is −26·9 cals. per molecule. Dry cyanogen chloride may be preserved indefinitely when pure ; in presence of hydrochloric acid it polymerises to cyanuric chloride $C_3N_3Cl_3$. Aqueous hydrochloric acid (stronger than about 2N) hydrolyses it thus :

$$CNCl + 2H_2O = NH_4Cl + CO_2$$
Its behaviour towards alkalis is the same as that of cyanogen bromide described below. Hydriodic acid hardly attacks it in the cold, and it is without action on metals, such as iron and copper, at ordinary temperatures.

Cyanogen bromide CNBr. A solution containing cyanogen bromide in addition to a cyanide dissolves gold more rapidly than one containing cyanide alone (Sulman and Teed, Eng. Pat. 18592, of 1894 ; and J. Soc. Chem. Ind. 1897, 961). Cyanogen bromide is therefore used in the treatment of a few refractory ores, the West Australian tellurides especially. The final result of the reaction is expressed by the equation : $2Au + 3KCN + BrCN = 2KAu(CN)_2 + KBr.$

Cyanogen bromide is formed by the action of bromine on a cyanide or on hydrocyanic acid. Owing to the difficulty of transporting either bromine or cyanogen bromide, it is always prepared at the place where it is to be used by liberating bromine from a mixture of a bromide and a suitable oxidising agent by the addition of sulphuric acid, and then adding a concentrated solution of an alkali cyanide. By the use of a suitable quantity of the oxidising agent, the whole of the bromine is utilised ; with sodium bromate, for example, the reaction is (C. Göpner, Zeitsch. angew. Chem. 1901, 14, 355) :

$$2NaBr + NaBrO_3 + 3NaCN + 3H_2SO_4 = 3Na_2SO_4 + 3BrCN + 3H_2O$$
Cyanogen bromide is a colourless, crystalline substance, which melts at 52° and boils at 61° ; 100 grams of water dissolve from 5 to 6 grams of it at the ordinary temperature. It has an intensely irritating effect on the mucous membranes and eyes, and is said to be very poisonous. The perfectly pure substance can be kept without change, but traces of bromine (or hydrobromic acid) cause it to polymerise rapidly to cyanuric bromide, partial decomposition always occurring. It is very slowly decomposed by water : $CNBr + H_2O = HCNO + HBr$, the cyanic acid decomposing further to ammonia and carbon dioxide. Caustic alkalis bring about the same change instantaneously, alkali carbonates much more slowly, and bicarbonates have no action at all. Cyanogen bromide and potassium cyanide react in aqueous solution, yielding cyanogen ; thus :

$$CNBr + KCN = KBr + C_2N_2$$
(private communication from Mr. C. J. Ellis). In solutions containing 0·2 to 0·8 p.c. of potassium cyanide and 0·1 to 0·2 p.c. of cyanogen bromide, the latter is completely decomposed in from 3 to 6 hours at the ordinary temperature.

In aqueous solution cyanogen bromide reacts with hydriodic acid and with sulphuretted hydrogen according to the equations :

$$CNBr + 2HI = HCN + HBr + I_2$$
and
$$CNBr + H_2S = HCN + HBr + S$$
The first reaction provides a convenient method for the quantitative estimation of cyanogen bromide. Chattaway and Wadmore (Chem. Soc. Trans. 1902, 191) have shown that these reactions are characteristic of compounds in which the halogen atom is directly linked with nitrogen, and that cyanogen bromide therefore has the constitution C : N.Br.

Cyanamide NH₂·CN was first prepared by the action of ammonia on an ethereal solution of cyanogen chloride (Cloëz and Cannizzaro, Compt. rend. 1851, 32, 62) ; ammonium chloride crystallises out and cyanamide remains when the ether is evaporated. The same reaction

occurs in aqueous solution. The formation of the disodium salt, Na_2CN_2, by the action of sodamide on carbon or on sodium cyanide has already been described. The same substance is also produced when sodamide acts on sodium cyanate, sodium carbonate or carbon dioxide at a low red heat; it is also formed when either sodium cyanate or sodium cyanide is fused with sodium hydroxide.

The calcium and barium salts, $CaCN_2$ and $BaCN_2$, may be prepared from nitrogen and the carbides, by heating the corresponding ferrocyanide or by heating the carbamates or cyanates to redness (Drechsel, J. pr. Chem. 1877, [2] 16, 188; 1880, [2] 21, 77) thus:
$$Ca(OCONH_2)_2 = CaCN_2 + 2H_2O + CO_2$$
and
$$Ca(OCN)_2 = CaCN_2 + CO_2$$

Cyanamide is also obtained by the action of mercuric oxide on a solution of thiourea:

$$CS(NH_2)_2 + HgO = NH_2CN + HgS + H_2O$$
Several guanidine derivatives yield cyanamide when boiled with water or alkalis, for example, nitroso guanidine decomposes thus:

$$C\begin{matrix}\diagup NH_2 \\ : NH \\ \diagdown NH.NO\end{matrix} = C\begin{matrix}\diagup NH_2 \\ : N \\ \end{matrix} + N_2 + H_2O$$

(Thiele, Annalen, 1893, 273, 136).

Cyanamide is easily prepared from the di-sodium salt by neutralising its cold, aqueous solution with nitric acid, and evaporating to dryness on the water bath in a vacuum; the dry residue is extracted with ether. Werner (Chem. Soc. Trans. 1916, 1323) describes a convenient method of preparing it from the readily accessible calcium salt; 100 grams are mixed with 125 gr. of acetic acid and 120 gr. of water, the mixture well kneaded and left for 24 hours. The friable mass is then powdered and extracted with ether in a Soxhlet apparatus. Yield 94–96 p.c. of theory.

Cyanamide forms colourless, deliquescent crystals which melt at 43°–44° (E. Colson, Chem. Soc. Trans. 1917, 555), it is readily soluble in water, alcohol and ether, very sparingly soluble in carbon disulphide, benzene, and chloroform. When heated it polymerises very readily to dicyanodiamide, $NH_2.(C:NH).NH.CN$, it boils at 140° at 19 mm., much melamine being left behind; the neutral aqueous solution possesses considerable stability, but polymerisation occurs in presence of either acids or alkalis. The process has been studied carefully by Morrell and Burgen (Chem. Soc. Trans. 1914, 576) and by Grube and Krüger (Zeitsch. phys. Chem. 1914, 86, 65), who find that in alkaline solutions the reaction takes place between undissociated cyanamide molecules and cyanamide ions, $H_2CN_2 + HCN_2' = H_3C_2N_4'$. The rate of polymerisation is therefore a maximum when one-half of the cyanamide is in the ionised form, a condition which is practically attained when a quantity of a strong base (soda or lime) equivalent to one-half of the cyanamide is added, the salts of a weak base such as ammonia being largely hydrolysed, the necessary concentration of cyanamide ion is not readily attained, weak bases, therefore, have a much smaller polymerising action than strong ones.

The action of acids is more complicated, polymerisation and hydrolysis to urea occurring simultaneously. According to Carlson (Zeitsch. angew. Chem. 1914, 27, 724) cyanamide, treated with 10 to 20 p.c. sulphuric acid, is converted almost wholly into urea at the ordinary temperature, whereas near the boiling-point polymerisation predominates. In acid solutions the reaction is further complicated by the hydrolysis of the dicyanodiamide to dicyanodiamidine

$$NH_2.(C:NH)NH.CN + H_2O$$
$$= NH_2(C:NH).NH.CO.NH_2$$
a strong base which neutralises the acid.

Cyanamide is an extremely weak acid, its dissociation constant, for $H_2CN_2 = H^+ + HCN_2'$ is of the order 10^{-11} (Grube and Krüger). The sodium salt $NaHCN_2$ crystallises from a solution of cyanamide in absolute alcohol when sodium ethylate is added to it, but the salt Na_2CN_2 can only be prepared by one of the dry fusion methods mentioned above. The calcium salt $CaCN_2$ also decomposes when treated with water yielding a solution of $Ca(HCN_2)_2$. The silver salt Ag_2CN_2 is a canary-yellow precipitate obtained by adding a solution of silver nitrate to a dilute ammoniacal solution of cyanamide; it is readily soluble in cold dilute nitric acid. The lead salt $PbCN_2$ is an orange-yellow precipitate. Cyanamide, also combines with acids; a white crystalline substance $H_2CN_2.2HCl$ is formed when dry hydrochloric acid is passed into a solution of cyanamide in dry ether (Mulder and Smit, Ber. 1874, 7, 1634).

Cyanic acid HCNO is prepared by distilling cyanuric acid (Wöhler) or by warming urea with phosphorus pentoxide (Weltzien, Annalen, 1858, 107, 219) and condensing the vapour at −18°. It is a volatile liquid, the smell of which resembles that of strong acetic acid. It is extremely unstable, changing rapidly even at 0° into the white amorphous polymeric substance cyamelide. The solution in dry ether is comparatively stable. The interesting relationship of cyanic acid HCNO, cyanuric acid

Temperature.
(HCNO)$_3$, and cyamelide (HCNO)x, has been studied by Troost and Hautefeuille (Compt. rend. 1868, 67, 1340), van't Hoff and van Deventer (Studies in Chem. Dynamics, 1896). The diagram represents the approximate relative positions of the vapour pressure curves of cyanic acid (HCNO), cyanuric acid (HCNO)$_3$, and cyamelide (HCNO)x, all of which yield the same vapour.

(The few points determined experimentally are indicated by small circles.) At the triple

point A (150° and 50 mm.) the two solid phases cyamelide and cyanuric acid coexist together with the vapour phase. Above 150° cyanuric acid is the stable phase (vapour pressure curve AC), at lower temperatures cyamelide (curve FAB) is stable. The position of the vapour pressure curve of cyanic acid itself (very roughly indicated by DE) shows that cyanic acid is quite unstable relatively to cyamelide. If the curve DE cuts the curve AB and AC the points of intersection would represent the melting-points of cyamelide and cyanuric acid respectively. They obviously lie at temperatures at which these substances decompose.

In aqueous solution cyanic acid is hydrolysed, slowly in cold dilute solutions, rapidly when warmed, to ammonia and carbon dioxide, $HCNO + H_2O = NH_3 + CO_2$.

The formation of cyanates by the action of cyanogen on alkalis, by oxidation of cyanides by the action of alkalis on cyanogen bromide, and from carbon monoxide and ammonia, has already been described.

Ammonium cyanate $NH_4 \cdot CNO$ is prepared in the form of a white snow, by mixing the vapours of cyanic acid and ammonia well diluted with an indifferent gas. When warmed it is converted into urea $NH_4CNO = CO(NH_2)_2$. The same reaction occurs in aqueous solutions, in which, however, it is reversible, 3·2 p.c. of the cyanate remaining unchanged at 32° and 65 p.c. at 100' (Walker and Hambly, Chem. Soc. Trans. 1895, 746).

Potassium and Sodium cyanates KCNO and NaCNO are easily prepared by grinding together the dry cyanides and the theoretically necessary quantity of lead oxide, and heating the mixture gently until the lead is melted. The salt is then recrystallised from water or dilute alcohol. According to Paterno and Pannain (Gazz. chim. ital. 1904, 34, ii. 152) when a solution of 4 to 6 mols. KCN and 1 mol. KOH per litre is electrolysed with 4–6 volts and 1–4 amps. per sq. dcm. of anode surface and the solution at the anode agitated, the cyanide is oxidised almost quantitatively to cyanate. J. Milbauer (Zeitsch. anorg. Chem. 1904, 42, 433) observed that potassium sulphocyanide, when heated at 300° with lead oxide, gave cyanate thus : $KSCN + PbO = KCNO + PbS$.

The decomposition of the alkali cyanates at high temperatures and their reduction by carbon are described above.

Potassium cyanate crystallises in thin transparent plates of sp.gr. 2·05, readily soluble in water, and anhydrous ammonia, insoluble in absolute alcohol, and fusible without decomposition below a red heat.

Sodium cyanate. 100 grams of water at 16° dissolve 10·68 grams; it fuses without decomposition about 500°. *Lead cyanate* is a crystalline precipitate, which is formed when solutions of a soluble cyanate and of a lead salt are mixed. The dry salt is stable, but it decomposes when boiled with water, yielding urea and lead carbonate.

Silver cyanate is very slightly soluble in cold water, 100 c.c. at 12° dissolve 0·006 gram., but it is much more soluble in hot water. It is readily soluble in aqueous ammonia, and sparingly soluble in cold dilute nitric acid.

Sulphocyanides or **Thiocyanates.** (Ger. *Rhodanide* or *Schwefelcyanide*.)

At the present time sulphocyanides are obtained exclusively from the hydrocyanic acid of coal gas, but a modification of Gélis' synthetic process was working in 1907.

A. W. Hofmann (Reports by the Juries, Inter. Exhib. of 1862, 59–63), said that at that time ammonium sulphocyanide obtained by washing the spent oxide of gasworks was only treated to recover its ammonia, the sulphocyanide being thrown away. In 1863 P. Spence (Eng. Pat. 2364 of 1863 (provisional only)) proposed to separate the sulphocyanides in gas liquor (after distilling off the ammonia) in the form of cuprous sulphocyanide by adding copper and ferrous sulphates, and the idea has been revived in various forms since that time, but it does not appear to have become of any importance. Gas liquor is really a very dilute solution of sulphocyanide, as the following figures, calculated from Linder's analyses of various English gas liquors (Chief Inspector of Alkali Works, 42nd Rep. 1905, 35), show :—

	Grams per litre				
	1	2	3	4	5
HCN as ferrocyanide	0·068	0	0·576	0·460	0
HCN as sulphocyanide	1·688	4·457	1·238	1·029	1·042
HCN as hydrocyanic acid	0·680	0	0·030	0·050	0·355

These liquors had all been stored for some time : perfectly fresh gas liquor contains ammonium sulphide and cyanide. By the action of the air, the former is oxidised to ammonium polysulphide, which convert the cyanide into sulphocyanide ; thus :

$$(NH_4)_2S_2 + NH_4CN = NH_4SCN + (NH_4)_2S$$
The recovery of the whole of the hydrocyanic acid of coal gas in the form of a concentrated solution of ammonium sulphocyanide is possible by applying this reaction in a suitable way.

A very large part of the gas liquor produced is distilled and the gases evolved, consisting of ammonia, carbon dioxide, sulphuretted hydrogen, and a little hydrocyanic acid, passed into sulphuric acid for the production of ammonium sulphate. The unabsorbed gases, mixed with steam, are first cooled, which yields an aqueous solution of hydrocyanic acid and sulphuretted hydrogen, known as ' Devil liquor,' which is run to waste.

The cooled gases are passed usually into a heap of ferric hydroxide, in order to absorb the sulphuretted hydrogen, or occasionally they are burned in a Claus kiln, in which, as Carpenter has shown, the hydrocyanic acid is converted by steam into ammonia.

The waste liquors from the ammonia stills contain relatively considerable quantities of calcium sulphocyanide (about 0·15 p.c. SCN) and phenols, and are usually discharged into sewers. Frankland and Silvester (J. Soc. Chem. Ind. 1907, 231), and Fowler, Ardern and Lockett (*ibid.* 1911, 174), have published detailed accounts of the bacterial oxidation of these impurities in the septic tank system of sewage treatment. It appears that sulphocyanides are practically completely oxidised in the contact beds, if sufficient time is allowed. Fowler and Holton (J. Soc. Chem. Ind. 1911, 180) have shown that 92–98 p.c. of the impurities in the ammonia still effluent can be oxidised by allowing it,

after dilution to one-tenth of its original strength, to trickle through a column of clinker inoculated with bacterial material from a contact bed of a sewage work; one cubic yard of filter is required for 10 galls. per day of effluent.

Synthesis of sulphocyanides from ammonia and carbon disulphide.—In Gélis' original process (A. W. Hofmann, Reports by the Juries, Inter. Exhib. of 1862, 59–63; A. Gélis, Eng. Pat. 1816 of 1860), a concentrated solution of ammonia and ammonium sulphide was agitated with carbon disulphide, yielding a solution of ammonium sulphocarbonate

$$(NH_4)_2S + CS_2 = (NH_4)_2CS_3$$
which was then heated to 90°–100° with potassium sulphide

$$2(NH_4)_2CS_3 + K_2S = 2KCNS + _2NH_4HS + 3H_2S$$

A very large amount of sulphuretted hydrogen is produced in this way, the disposal of which would occasion much trouble and expense. Gunsburg and Tchernkiac (Eng. Pat. 1148 of 1878; 1359 of 1879; 1261 of 1881) heated a 20 p.c. solution of ammonia with carbon disulphide in autoclaves provided with stirrers at 100° until a pressure of 15 atmos. was reached, which indicated the end of the reaction. As Conroy (J. Soc. Chem. Ind. 1896, 15, 8) has shown, ammonium sulphocyanide is formed quantitatively under these conditions, the large pressure developed being due to the formation of the volatile ammonium sulphide $4NH_3 + CS_2 = NH_4SCN + (NH_4)_2S$.

Subsequent improvements were all in the direction of diminishing the quantity of ammonia required and reducing the pressure in the autoclaves. The simplest and most effective way of doing this is to add lime to the charge (Crowther and Rossiter, Eng. Pat. 17846 of 1893; Brock, Hetherington, Hurter, and Raschen, Eng. Pat. 21451 of 1893), the reaction then taking place in accordance with the equation:

$$2NH_3 + 2CS_2 + 2Ca(OH)_2 = Ca(SCN)_2 + Ca(SH)_2 + 4H_2O$$
A certain excess of ammonia over the quantity required by the equation must be used to prevent the formation of calcium sulphocarbonate. The excess of ammonia is distilled off, the residual mixture treated with carbon dioxide to remove sulphuretted hydrogen (in this way used in the treatment of Leblanc alkali waste), and the calcium carbonate filtered off. The clear solution of calcium sulphocyanide is easily converted into other salts.

THE PRINCIPAL SULPHOCYANIDES.

Potassium sulphocyanide KSCN crystallises in anhydrous, striated prisms or needles of sp.gr. 1·9, which melt at 172·3°. It resembles salt-petre in appearance and taste. It is deliquescent and very soluble in water, 100 grams of which dissolve 177·2 grams at 0°, 217 grams at 20°, and 239 grams at 25°. It is also soluble in anhydrous ammonia and in many organic liquids. The solubilities (in grams per 100 grams of solvent) are :

Acetone, 20·8 at 22°; 20·4 at 58°.

Ethyl acetate, 0·44 at 0°; 0·4 at 14°; 0·2 at 79°.

Amyl alcohol, 0·18 at 13°; 2·14 at 100°.

Pyridine, 6·75 at 0°; 4·97 at 58°, and 3·21 at 115°.

The fused salt becomes deep blue at 430°; the colour is said to be due to the liberation of sulphur. The sulphocyanides are plant poisons. Frankland and Silvester found that gold-fish were not affected in 24 hours by quantities of potassium sulphocyanide up to 260 parts SCN per 100,000 of water, but even as little as 10 parts of SCN per 100,000 is sufficient to stop the multiplication of, and eventually to kill, *Bacillus coli communis*.

Ammonium sulphocyanide NH₄SCN crystallises in anhydrous, colourless leaflets of sp.gr. 1·3, which melt at 159°; 100 grams of water dissolve 122 grams at 0° and 162 grams at 20°; it is readily soluble in alcohol. When heated a little above its melting-point, it is partly converted into the isomeric thiourea. At 220° decomposition takes place, ammonia, sulphuretted hydrogen, and carbon disulphide being evolved, and guanidine sulphocyanide remaining behind.

Thiocyanogen is obtained by the action of, a solution of a halogen in an anhydrous solvent on a suitable thiocyanate; a dry ethereal solution of bromine cooled to 0° and lead thiocyanate give good results. By cooling an approximately N/2-solution in carbon disulphide to −70° thiocyanogen is obtained in almost colourless crystals, melting at −3° to −2°, and decomposing at the ordinary temperature. In its chemical behaviour thiocyanogen resembles the halogens; it is at least as strongly electro-negative as iodine. The molecular weight has not yet been determined, but the constitution of thiocyanogen is probably CN—S—S—CN (E. Söderbäck, Annalen, 1919, 419, 217).

ANALYSIS OF CYANIDES.

The methods of analysis described here are those commonly employed in technical laboratories.

Detection of hydrocyanic acid.—The material is distilled with an acid and the distillate examined. The Prussian blue test may be applied by evaporating the solution (after the addition of a little sodium hydroxide) *in vacuo* at temperature below 70°, to 1 c.c.; 0·2 c.c. of 3 p.c. FeSO₄ and 0·05 gram KF are added, and, after 10 minutes, a small excess of 30 p.c. HNO₃. The blue colour is compared with that produced by a known quantity of KCN under similar conditions (A. Viehoever and C. O. Johns, J. Amer. Chem. Soc. 1915, 37, 601). The sulphocyanate test is also characteristic; the distillate containing 0·1–8 milligrams HCN is made alkaline with KOH, treated with 1 c.c. ammonium polysulphide solution and evaporated to dryness. The residue is extracted with acetone, which dissolves KSCN only. After removing the acetone by evaporation the residue is treated with 2 c.c. of 0·5 p.c. FeCl₃, and the colour matched by means of a standard sulphocyanide solution (M. O. Johnson, J. Amer. Chem. Soc. 1916, 38, 1230). Ferric sulphocyanate may be extracted from the aqueous solution by ether; meconic acid gives a similar colouration in ether, which, however, is not destroyed by 10 p.c. AuCl₃ (P. Lavialle and L. Varenne, J. Pharm. Chim. 1915, 12, 74).

Other sensitive colour tests have the disadvantage that they may be produced by

substances other than HCN. An alkaline solution of picric acid yields a reddish-violet colouration with NaCN, which is due to sodium isopurpurate $C_8H_2(NO_2)_2\cdot N(CN)_2\cdot ONa$, when excess of cyanide is used, but to amino-nitro-phenols when picric acid is in excess, as is usually the case (A. C. Chapman, Analyst, 1910, 35, 469). The liquid to be tested is mixed with an equal volume of a solution containing 0·05 p.c. picric acid and 0·5 p.c. Na_2CO_3, and digested at 40° for 1 hour. The colour is then compared with that produced by a standard HCN solution; 1 part of HCN in 500,000 parts water can be detected (A. D. Waller, Proc. Roy. Soc. 1910, B. 82, 574).

The cyanogen liberated by the action of HCN or a cupric salt oxidises many substances to coloured products, the tests are highly sensitive, but uncertain owing to the difficulty of excluding other oxidising agents. For details, see Thiéry (phenolphthalin), J. Pharm. Chim. 1907, 25, 51; C. Pertusi and E. Gastaldi (benzidine), Chem. Zeit. 1913, 37, 609; G. W. Anderson (guaiacum), J. Soc. Chem. Ind. 1917, 36, 195; J. Moir. and J. Gray, J. Chem. Met. and Min. Soc. S. Africa, 1910, 11, 152; and J. Moir, Chem. Soc. Proc. 1910, 26, 115 (hydrocœrulignone, tolidine, dianisidine).

Alkali cyanides. Owing to the hygroscopic nature of sodium and potassium cyanides when cold, samples, taken from different parts of a cake, should be transferred at once and without touching them with the hands to a hot iron mortar, broken up coarsely, and transferred to a hot perfectly dry bottle. If the sample has to be kept for any length of time before it is analysed, it is preferable to use glass-stoppered bottles and to grease the stopper with a little vaseline. Errors due to absorption of moisture in sampling are more common and more serious than those due to inaccuracies in testing.

Estimation of cyanogen.—5 grams of the sample are weighed out and made up to 500 c.c.; 25 c.c. of the solution are diluted to 200–300 c.c. and titrated with a solution of pure silver nitrate until the faintest visible turbidity results. The silver nitrate must be neutral and free from lead and zinc especially. A convenient strength of solution is obtained by dissolving 13·1 grams of silver nitrate in 1 litre of distilled water: 1 c.c. of this solution is equivalent to 0·01 gram of KCN. The solution is standardised by means of a solution of pure sodium chloride (dried by heating to redness before weighing) containing 4·487 grams per litre; 1 c.c. of the silver solution should exactly precipitate 1 c.c. of the sodium chloride solution using pure potassium chromate as indicator. In impure solutions of cyanides, the end point is often more easily observed if a little caustic soda (or a few drops of ammonia) and a crystal of potassium iodide are added before running in the silver nitrate solution. Sulphides interfere with the test, but they are easily removed by shaking the solution with a little lead carbonate and filtering it.

Estimation of sulphide.—10 grams of the finely powdered sample are dissolved in 15 c.c. of ordinary water and a solution of lead nitrate (2·4 grams per litre) run in gradually. The mixture is stirred until the colloidal lead sulphide at first formed has coagulated into brown flocks;

a drop of the solution is then placed on blotting paper beside a drop of the lead nitrate solution, and the two allowed to run together. When no difference can be detected between the colour of the paper where the drops have mixed and where they have not, the titration is considered to be at an end; 1 c.c. of the lead solution=0·001 gram of K_2S (T. Ewan, J. Soc. Chem. Ind. 28, 10, 1909; Rossiter, *ibid.* 30, 583, 1911).

Water is estimated by weighing out about 1 gram of the coarsely powdered sample into a small distilling flask (10–20 c.c.) which is then evacuated by a good water pump or preferably by a mercury pump. The sample is then warmed, gently at first, and finally to 200°–300°. The whole of the moisture is expelled in a few minutes without appreciable decomposition of the cyanide.

Carbonate is conveniently estimated by precipitating a suitable portion of the solution with barium chloride in the cold (to avoid decomposition of cyanate). The precipitate is washed and titrated, together with the paper, with normal hydrochloric acid and methyl orange.

Chloride. The solution is neutralised with dilute nitric acid, and methyl orange and boiled for about 1 hour (in a draught cupboard, of course) to drive off the hydrocyanic acid and decompose cyanate. The chloride remaining (Richards and Singer, Amer. Chem. J. 27, 205, 1902) is then precipitated by a known excess of standard silver nitrate solution, the silver chloride filtered off and the excess of silver titrated with ammonium sulphocyanide and iron alum in the usual way.

If ferrocyanide is present, it may be precipitated with excess of silver nitrate in ammoniacal solution; by acidifying the filtrate with nitric acid, silver chloride is precipitated and may be weighed.

Cyanamide in presence of alkali cyanides is easily estimated by exactly neutralising the solution of 1 gram of the substance in 100 to 150 c.c. of water with *nitric acid*, and then boiling for 20 minutes to expel hydrocyanic acid. After cooling, 2 or 3 drops of ammonia are added, and then excess of silver nitrate. The canary-yellow precipitate of silver cyanamide Ag_2CN_2 is filtered off and dissolved in cold dilute nitric acid (which usually leaves a small residue of undissolved silver cyanide). The silver in the solution is then titrated by means of ammonium sulphocyanide, using ferric alum as indicator. The method is applicable to most substances containing cyanamide, the boiling with acid being, of course, omitted when little or no cyanide is present.

When cyanamide is the principal constituent this method is insufficiently accurate, because the composition of the precipitate is not exactly that required by the formula Ag_2CN_2, the silver content depending to a small extent on the excess of silver nitrate used in precipitation. Caro (Zeitsch. angew. Chem. 1910, 23, 2405) has shown, however, that it contains the whole of the cyanamide nitrogen, which is very readily estimated by Kjeldahl's method.

Cyanate. The solution is acidified with nitric acid and boiled for 20 minutes at least to expel hydrocyanic acid, and convert the cyanate into ammonium nitrate and carbon dioxide.

The ammonia is then distilled off, after adding excess of caustic soda, and estimated by titration with N-hydrochloric acid as usual. In presence of cyanamide, the method is not available, because some ammonia is formed from the cyanamide when it is boiled with caustic soda. In this (rather uncommon) case, the cyanate must be estimated by collecting the carbon dioxide evolved when the sample is boiled with acid (Ewan, J. Soc. Chem. Ind. 1904, 23, 244).

Ferrocyanide is most conveniently estimated, either alone or in presence of cyanides, by titration with a standard solution of zinc sulphate until a drop of the solution no longer gives a blue colour when brought in contact with a drop of ferric solution on paper. A zinc alkali ferrocyanide of somewhat variable composition is precipitated, and H. G. Colman (Analyst, 33, 261, 1908 ; and J. Soc. Chem. Ind. 27, 806, 1908) has shown that the quantity of zinc solution required to precipitate a given quantity of ferrocyanide depends, to some extent, on the nature of the metal in the ferrocyanide used. This effect can be eliminated almost entirely by adding an excess of potassium sulphate. The method is carried out as follows : a solution containing 10.2 grams of $ZnSO_4, 7H_2O$ and 10 c.c. of concentrated sulphuric acid per litre is standardised against pure potassium ferrocyanide ; 25 c.c. of a solution containing 10 grams of $K_4Fe(CN)_6 \cdot 3H_2O$ per litre, mixed with 25 c.c. of a saturated solution of potassium sulphate, 25 c.c. of water, and 10 c.c. of 1 : 10 sulphuric acid, are convenient quantities. Equal volumes of the standard zinc and ferrocyanide solutions are required, the precipitate formed having the composition $Zn_3K_2(FeCy_6)_2$ (R. Meurice, Ann Chim. anal. 1913, 18, 342). Subsequent titrations should be made as nearly as possible under the same conditions.

A more accurate method is that of W. Feld (Journ. für Gasbeleuchtung, 47, 565, 1903). Ferrocyanide, equivalent to 0.3 to 0.5 gram of yellow prussiate is boiled for 5 minutes with 10 c.c. of N-NaOH and 15 c.c. of 3 (molecular) N-HgCl$_2$. If cyanide is present, the boiling is continued for 10 minutes and the hydrocyanic acid distilled into caustic soda and titrated with silver nitrate with potassium iodide as indicator. 100 c.c. of boiling $0.1N$-HgCl$_2$ are now run in, and the boiling continued for 10 minutes to convert ferrocyanide into mercuric cyanide This is then distilled with 30 c.c. of $3N$-sulphuric acid for 20–30 minutes, and the hydrocyanic acid collected in caustic soda and titrated as before. The conversion of the ferrocyanide into mercuric cyanide is avoided by H. E. Williams' procedure (J. Soc. Chem. Ind. 1912, 31, 468). After distilling off hydrocyanic acid in the way just described (lead nitrate may be used instead of magnesium chloride), 0.05–0.1 gram of pure cuprous chloride dissolved in HCl is added, and the hydrocyanic acid distilled off by $\frac{1}{2}$ hour gentle boiling. Even insoluble ferrocyanides are completely decomposed.

The estimation of the valuable constituents of gasworks products (cyanide and ferrocyanide) is performed by triturating 30 to 40 grams of the material in a mortar with excess of a cold solution of caustic soda for several hours. A little ferrous sulphate may be added to convert cyanide into ferrocyanide. The filtrate is treated with 4 to 5 times its volume of methylated spirit. Carbonyl ferrocyanide (from 2 to 5 p.c. of the cyanogen is usually present in this form, but exceptionally as much as 20 p.c. may be present), sulphocyanide, sulphide, and excess of caustic soda remain in solution, whilst the whole of the sodium ferrocyanide is precipitated. The precipitate is then treated by one of the methods described above (H. G. Colman, Analyst, 33, 261, 1908 ; and J. Soc. Chem. Ind. 27, 806, 1908 ; F. W. Skirrow, *ibid.* 29, 319, 1910).

Sulphocyanide. Ferrocyanide, if present, is first removed from the solution by adding iron alum after acidifying slightly. The filtrate is treated with acid sodium sulphite in excess and then with copper sulphate and boiled for 1 or 2 minutes. The precipitate of cuprous sulphocyanide, which may be mixed with copper sulphide, is filtered off and washed with boiling water. It is then digested with excess of caustic soda which gives cuprous hydroxide and a solution of sodium sulphocyanide. This is separated by filtration, acidified with nitric acid, and titrated with silver nitrate, using a ferric salt as indicator (Linder, 43rd Alkali Report, 1906, 39).

The small quantities of cyanogen compounds in concentrated ammonia liquor may be estimated by converting them into ferric sulphocyanide-and measuring the depth of colour by means of the tintometer (P. E. Spielmann and H. Wood, J. Soc. Chem. Ind. 1919, 38, 43T, and 369T). Sulphocyanide is first estimated by acidifying the diluted sample, in the cold, with sulphuric acid, and removing ferrocyanide by means of a small excess of iron alum ; a large excess of iron alum is added to the filtrate and the depth of colour measured. Cyanide is converted into sulphocyanide by digestion at 30°–35° with ammonium polysulphide, and a second estimation made as above described. Thiocarbonate is converted into sulphocyanide by digestion at 70°–75° for 45 minutes, cyanide and ferrocyanide remaining unaffected.

Alkali metals in commercial cyanides. 1 gram of the substance is evaporated to dryness with excess of hydrochloric acid. Traces of iron and calcium are removed by re-dissolving, adding a drop of ammonium carbonate, and filtering. The solution is again evaporated to dryness, and the residue is gently fused and weighed. The mixture of alkaline chlorides is dissolved in water and an aliquot portion titrated with silver nitrate, using chromate as indicator. If n gram of cyanide has yielded a gram of the pure mixed chlorides containing b gram of chlorine, the percentage of potassium in the cyanide is given by the formula

$$\left(\frac{2.431a - 4.012b}{n}\right)100$$

This method is sufficiently accurate for most purposes, but the gravimetric estimation of the potassium as potassium platinichloride must be resorted to if a greater degree of accuracy is required.　　　　　　　　　　　　　　T. E.

CYANIDIN, CYANIN v. ANTHOCYANINS.

CYANINE and **CYANINE DYESTUFFS** v. QUINOLINE COLOURING MATTERS.

CYANITE v. KYANITE. ●

**CYANOMACLURIN.** $C_{13}H_{12}O_6$, a colourless

compound existing in Jakwood is closely allied to the catechins, and may possibly belong to the same group. In its general reactions, indeed, it is very similar to these compounds, but differs from them in that by alkali fusion it yields β-resorcylic acid and not protocatechuic acid.

A full description of the properties of this compound is given in the article on JAKWOOD.

CYANOSINE v. TRIPHENYLMETHANE COLOUR-ING MATTERS.

Iso-CYANURIC ACID v. FULMINURIC ACID.

CYCLOFORM. The trade name of *iso*butyl ester of *p*-amino benzoic acid

$$NH_2 \cdot C_6H_4 \cdot COOC_4H_9$$
used as a local anæsthetic. A white crystalline powder, m.p. 65°. Sparingly soluble in water (0·022 p.c.), readily soluble in alcohol and ether.

CYLINDRITE. (*Kylindrit*, Ger.) A complex sulphide ore of tin, $Pb_3FeSn_4Sb_2S_{14}$, containing, according to this formula, Sn 25·85 p.c. It forms very peculiar cylindrical rolls of thin folia, the concentric shells parallel to the axis of the cylinder readily separating under pressure. The smooth, bright surfaces of separation no doubt represent the cleavages of cylindrically curved crystals. The colour is blackish lead-grey, with a brilliant metallic lustre. The mineral marks paper, and is difficult to pulverise, in these respects resembling graphite. The ore consists of numbers of these rolls, which measure up to 3 cm. in length and 1 cm. in diameter, confusedly aggregated together, or sometimes with a sub-parallel grouping, the interspaces being filled with massive material. It has been found in some quantity in the Santa Cruz mine, at Poopó, Bolivia. The above formula, written in the form
$$3PbSnS_2 + SnFeSb_2S_8$$

brings out a relation between cylindrite and the allied Bolivian minerals, teallite ($PbSnS_2$) and franckeite ($3PbSnS_2 + Pb_2FeSb_2S_8$). Analyses I and II by G. T. Prior (1904), III. by A. Frenzel (1893):

L. J. S.

CYMARIN. The physiologically active constituent of the root of *Apocynum cannabinum* and *A. androsœmifolium*, is a glucoside, $C_{30}H_{46}O_{10}$, colourless glistening prisms, m.p. 135°-140°, which, when boiled with alcohol containing hydrochloric acid, is resolved into *cymarose* $C_7H_{14}O_4$, colourless prisms, m.p. 88°, a substance resembling digitoxose, of which it is probably a methyl ether, and *cymarigenin* $C_{23}H_{30}O_5$, a lactone which appears to be identical with apocynamarin (Moore, Chem. Soc. Trans. 1909, 95, 734); it crystallises from aqueous methyl alcohol in rhombic tablets, m.p. 171° (decomp.). With a solution of a diazonium salt, cymarigenin forms dyes; it reduces ammoniacal silver nitrate, forms a

benzoyl derivative $C_{36}H_{36}O_7$,$\frac{1}{2}H_2O$, pearly leaflets, m.p. 230°, and when treated with hydrogen chloride in chloroform solution, is converted into *anhydro cymarigenin* $C_{23}H_{28}O_4$, rosettes of crystals, m.p. 246° (decomp.). (Windaus and Hermanns, Ber. 1915, 48, 979).

According to Impens (Pflüger's Archiv. 1913, 153, 239), cymarin is not a glucoside. It corresponds in activity with digitalis, being slightly more potent as a diuretic and slightly less so as a cardiac stimulant. The 'cynotoxin' of Finnemore and 'apocynamarin' are probably decomposition products of cymarine. V. DIGITALIS and STROPHANTHUS.

CYMENES. *Cymols.* The name *cymene* was first applied to the hydrocarbon isolated by Gerhardt and Cahours (Ann. Chim. Phys. [3] 1, 102 and 372) from Roman oil of cumin, which is the ethereal oil of *Cuminum cyminum*. Until 1891 this hydrocarbon was wrongly called *p*-methylpropylbenzene, but in that year Widman (Ber. 1891, 439, 970, 1632) proved it to be the *iso*propyl- compound (*see also* Fileti, J. pr. Chem. [2] 44, 150). Frequently, however, the various benzene hydrocarbons of the formula $C_{10}H_{14}$ are grouped together under the collective name of *cymenes*. No fewer than 22 of these are theoretically possible, of which 18 have been prepared; but only the most important, namely, cymene proper (*p*-methyl*iso*propyl-benzene) and the tetramethylbenzenes are described here.

p-**Methyl*iso*propylbenzene** (*Cymene*)

$$`CH_3)_2CH \cdot C_6H_4 \cdot CH_3 \ (1, 4)$$
occurs in Roman oil of cumin (Gerhardt and Cahours, *l.c.*; Brühl, Ber. 1892, 149; Wolpian, Chem. Soc. Abstr. 1897, i. 357); in the volatile oil from the seeds of the water-hemlock (*Cicuta virosa*) (Trapp, Annalen, 108, 386); in the oil from *Ptychotis ajowan* (H. Müller, Ber. 2, 130); in oil of thyme (Lallemand, Annalen, 102, 119; Labbé, Bull. Soc. chim. 1898, [iii.] 1009) along with thymol $C_{10}H_{14}O$ and thymene $C_{10}H_{16}$; in eucalyptus oil (from *Eucalyptus Globulus*) (Faust and Homeyer, Ber. 7, 1429); in oil of caraway (Wolpian, Chem. Soc. Abstr. 1897, i. 17); in bitter fennel oil (Tardy, J. Pharm. Chim. 1897, 98); in oil of lemon grass (Barbier and Bouveault, Compt. rend, 121, 1159; Stiehl, J. pr. Chem. 1898, 51); in oil of origanum (Gildermeister, Arch. Pharm. 1895, 174); in geraniol (Semmler, Ber. 1891, 205); and in American petroleum (Mabery, Amer. Chem. J. 19, 419). Considerable quantities of crude cymene, known as sulphide turpentine, collect on the surface of the liquid in the separator used in recovering sulphur dioxide in the manufacture of wood pulp. May be obtained from camphor by abstracting from it the elements of water

$$C_{10}H_{16}O = C_{10}H_{14} + H_2O$$
by heating it either with phosphorus pentoxide (Dumas, Ann. Chim. Phys. 50, 226; Delalande, *ibid.* [3] 1, 368) or with phosphorus pentasulphide (Pott, Ber. 2, 121), or with phosphorus pentachloride (Lippmann and Louguinine, Bull. Soc. chim. [2] 7, 374; *see also* Brühl, *l.c.*; Tiemann, Ber. 1895, 1089). Various isomerides of camphor yield cymene by the same treatment. The terpenes $C_{10}H_{16}$ may be converted into cymene by withdrawing two atoms of hydrogen; this

may be effected in the case of oil of turpentine, for example, by distilling it with bromine (Oppenheim, Ber. 5, 94 and 628), or better, with iodine (Kekulé, *ibid.* 6, 437). Old turpentine generally contains cymene (Wallach, Chem. Zentr. 1898, i. 572; Kondakow and Schindelmeier, Chem. Zeit. 30, 722). It has been obtained synthetically from *p*-brom*iso*propylbenzene by means of methyl iodide and sodium (Widman, *l.c.*). To prepare cymene, camphor is warmed with an equal weight of phosphorus pentoxide, the cymene is poured off, treated again twice with a little phosphorus pentoxide, and finally rectified from sodium. The yield varies from 50 to 80 p.c. (Fittica, Annalen, 172, 307). It can also be prepared from *iso*propyliodide, and *p*-bromotoluene (Reuter, Chem. Zentr. 1892, i. 625; Brühl, *l.c.*) or from *iso*propylchloride, toluene and aluminium chloride (Silva, Bull. Soc. chim. [n.] 43, 321).— Liquid boiling at 177°-177·5° (corr.); sp.gr. 0·8670 at 7·9°/4° (Perkin, Chem. Soc. Trans. 1896, 1125; 1900, 267). With chromic acid it yields paratoluic acid ((CH₃·C₆H₄·CO₂H) and terephthalic acid C₆H₄(CO₂H)₂ (1, 4); with potassium permanganate, hydroxy*iso*propylbenzoic acid (CH₃)₂(OH)C₆H₄·CO₂H (1, 4). Taken internally, it appears in the urine as cumic (*p-iso*propylbenzoic) acid

$$(CH_3)_2CH·C_6H_4·CO_2H \ (1, 4)$$
The preparation of cumene (*q.v.*) from propyl-bromide, benzene, and aluminium chloride, and that of cymene from *p*-bromotoluene, normal propylbromide, and sodium (Fittig, Schafer, and König, Annalen, 149, 331) was for a long time the cause of great confusion in ascertaining the constitution of members of the cumene and cymene groups, as it was not realised that in each case the propyl- group changed into the *iso*propyl- group owing to the temperature of the reaction not being regulated.

Tetramethylbenzenes :

1. *Consecutive tetramethylbenzene* (*Prehnitene*) C₆H₂(CH₃)₄ (1, 2, 3, 4). When sodium durene-sulphonate

$$C_6H(CH_3)_4SO_3Na(CH_3\text{- groups } 1, 2, 4, 5 \ v. \ infra)$$

is dissolved in concentrated sulphuric acid and allowed to stand for 12 hours, prehnitene-sulphonic acid is formed. The mixture is diluted with water, saturated with barium carbonate, the barium salts converted into sodium salts, and these, by treatment with phosphorus pentachloride and ammonia, transformed first into sulphonic chlorides and then into sulphonamides. Prehnitenesulphonamide is separated by means of its sparing solubility in alcohol, and is then hydrolysed by heating with concentrated hydrochloric acid to 170°, when it yields prehnitene (Jacobsen, Ber. 19, 1213; *see also* V. Meyer and Molz, Ber. 1897, 30, 1278). Also obtained by heating bromocumene

$$C_6H_2Br(CH_3)(CH_3,Br,CH_3,CH_3 : 1, 2, 3, 4)$$
with methyl iodide, benzene, and sodium, in a sealed tube at 150° for 12 hours.—Liquid boiling at 204° (corr.); solidifies in a freezing mixture, and melts at −4°. Dilute nitric acid oxidises it to prehnitylic acid C₆H₂(CH₃)₃CO₂H.

2. *Unsymmetrical tetramethylbenzene* (*Isodurene*) C₆H₂(CH₃)₄ (1, 2, 3, 5). From bromomesitylene (*v* CUMENES), methyl iodide and

sodium in presence of benzene (Jannasch, Ber. 8, 356). Best by passing methyl chloride into a mixture of mesitylene and aluminium chloride :

$$C_6H_3(CH_3)_3 + CH_3Cl = C_6H_2(CH_3)_4 + HCl$$
$$(1, 3 \ 5) \qquad\qquad\qquad (1, 2, 3, 5)$$
(Jacobsen, Ber. 14, 2629).—Liquid boiling at 195°-197°; solidifies in a freezing mixture. With dilute nitric acid it yields α-*iso*durylic acid, β-*iso*durylic acid, and mesitylenecarboxylic acid, isomeric acids of the formula

$$C_6H_2(CH_3)_3CO_2H$$
and dimethyl*iso*phthalic and dimethyltere-phthalic acids, isomeric acids of the formula C₆H₂(CH₃)₂(CO₂H)₂ (Jannasch and Weiler, Ber. 1894, 3441; 1895, 531); potassium permanganate ultimately converts it into mellophanic acid C₆H₂(CO₂H)₄ (1, 2, 3, 5).

Symmetrical tetramethylbenzene (*Durene*) C₆H₂(CH₃)₄ (1, 2, 4, 5). Occurs in coal tar (Schulze, Ber. 18, 3032). By the action of sodium on a mixture of bromopseudocumene- C₆H₂(CH₃)₃Br (1, 2, 4, 5), methyl iodide and sodium (Jannasch and Fittig, Zeitsch. Chem. 1870, 161) From toluene and methyl chloride in presence of aluminium chloride (Friedel and Crafts, Ann. Chim. Phys. [6] 1, 461). From o- or p-xylene, methyl chloride and aluminium chloride (Jacobsen, Ber. 14, 2629). From pseudocumene, methyl iodide, and aluminium chloride (Rugheimer and Hankel, *ibid.* 1896, 2173) —Crystalline mass, smelling like camphor? melts at 79°-80°, and boils at 189°-191° (Jacobsen). Yields by oxidation with potassium permanganate, finally pyromellitic acid

$$C_6H_2(CO_2H)_4 \ (1, 2, 4, 5)$$
CYMOLS *v.* CYMENES.

CYMOPHENOL *v.* CAMPHORS.

CYPRIAN VITRIOL. *Copper sulphate (v.* COPPER).

CYPRIDOL. Trade name for a suspension of mercuric iodide in sterilised oil.

CYRTOLITE *v.* ZIRCON.

CYSTAMINE, CYSTOGEN. Syns. for hexamethylenetetramine.

CYSTAZOL. An additive compound of hexamethylenetetramine and sodium benzoate. Used as a urinary antiseptic.

CYSTINE, β-*disulphido-α-aminopropionic acid*

$$HO_2C·CH(NH_2)·CH_2·S·S·CH_2·CH(NH_2)·CO_2H$$

first discovered by Wollaston in a urinary calculus (Phil. Trans. 1810, 223); is a product of protein metabolism under certain pathological conditions (Blum, Beitr. chem. Physiol. Path. 1903, 5, 1; Wolf and Shaffer, Amer. J. Physiol. 19; Loebisch, Annalen, 182, 231; Niemann, *ibid.* 187, 101; Thiele, Trans. Path. Soc. 1907, 58, 255), which, according to Abderhalden (Zeitsch. physiol. Chem. 1903, 38, 557), are hereditary. Dreschel found cystine as a normal product of metabolism in the liver of horse (Arch. Anat. Physiol. 1891, 243) and porpoise (Zeit. Biol. 1896, 33, 85). It was found by Külz (*ibid.* 1890, 27, 415) among the soluble products of an artificial pancreatic digestion of fibrin; and is a constant product of hydrolysis of keratin (Mörner, Zeitsch. physiol. Chem. 1899, 28, 595): Buchtala (*ibid.* 1907, 52, 474) obtained the following percentages of cystine from the materials mentioned : human hair, 13-14·5; human nails, 5·15; horsehair, 7·98;

horse's hoofs, 3·20 ; ox hair, 7·27 ; hoofs of oxen, 5·37 ; pigs' bristles, 7·22 ; pigs' hoofs, 2·17.

According to Folin (J. Biol. Chem. 1910, 8, 9), cystine is most readily prepared from wool by boiling it in a reflux apparatus for 5–6 hours with twice its weight of strong hydrochloric acid, or until it ceases to give the biuret reaction ; on removing the free hydrochloric acid by the addition of solid sodium acetate, a dark heavy precipitate of cystine is obtained ; this is purified by decolourising a solution in 3–5 p.c. hydrochloric acid with bone-black, and precipitating the cystine in the hot filtrate by hot concentrated sodium acetate solution (*see also* Denis, J. Biol. Chem. 1911, 9, 365).

The cystine of urinary calculus is identical with that obtained from protein hydrolysis (Rothera, J. Physiol 1905, 32, 175 ; Alsberg and Folin, Amer. J. Physiol. 1905, 14, 54 ; Fischer and Suzuki, Zeitsch. physiol. Chem. 1905, 45, 405), and was proved to be β-*disulphido-α-amino-propionic acid* by Friedmann (Beitr. Chem. Physiol. Path. 1902, 2, 433). This view of its constitution was confirmed by the synthesis of racemic cystine from ethyl monobenzoylserine, obtained by reducing ethyl formylhippurate, the product of the condensation of ethyl formate and ethyl hippurate. On heating ethyl mono-benzoylserine with phosphorus pentasulphide, and hydrolysing the product, cystein is obtained, and this is readily converted into cystine by oxidation with air in an ammoniacal solution :

H·CO₂Et + NHBz·CH₂·CO₂Et
  →CHO·CH(NHBz)·CO₂Et
  →OH·CH₂·CH(NHBz)CO₂Et
  →SH·CH₂·CH(NHBz)·CO₂Et
  →SH·CH₂·CH(NH₂)·CO₂H
  →CO₂H·CH(NH₂)·CH₂·S·S·CH₂·CH(NH₂)·CO₂H
(Erlenmeyer, Ber. 1903, 36, 2720). Fischer and Raske (*ibid.* 1908, 41, 893) also obtained *r*-cystine from *dl*-α-amino-β-chloropropionic acid hydrochloride by heating it with barium hydrosulphide at 100° in sealed tubes, and oxidising the product by atmospheric oxygen in the presence of ammonia. From the natural *l*-serine the authors obtained, by a similar process, an optically active cystine which is identical with the *l*-cystine obtained from natural sources. Removal of sulphur by ammonium copper solution gives *dl*-α-*aminopropionic acid*, and removal of sulphur by zinc *dl-alanine* (Mauthner, Zeitsch. physiol. Chem. 1912, 78, 30–32).

For the importance of cystine in nitrogen metabolism, *see* Abderhalden (Zeitsch. physiol. Chem. 96, 1–147 ; Ber. 1916, 49, 2449–2473), and in humin formation, Roxas (J. Biol. Chem. 1916, 27, 71–93).

Cystine crystallises in thin colourless hexagonal plates ; it has no melting-point, but decomposes slowly at 258°–261° (Neuberg and Mayer, Zeitsch. physiol. Chem. 1905, 44, 472). It is sparingly soluble in water, insoluble in alcohol or acetic acid, soluble in acids or alkalis. The heat of combustion at constant pressure is 4·137 calories (Emery and Benedict. Amer. J. Physiol. 28, 301–307). The cystine molecule contains two asymmetric carbon atoms, and *lævo*-cystine, the naturally occurring variety, has [α]_D −97·5° in ammonia, −223° in hydrochloric acid solution (Gaskell, J. Physiol. 1907, 36, 142), or −205·28°

in a hydrochloric acid solution containing 11·2 grams hydrochloric acid in 100-cm. (Mauthner, *ibid.* 29). *l*-Cystine is converted to the extent of 50 p.c. into *r*-cystine by heating with excess of hydrochloric acid of sp.gr. 1·124, at 165° for 12–15 hours ; this decomposes at the same temperature as the active isomeride, is three times as soluble in water and can be resolved into the active components by the action of *Aspergillus niger*, the *l*- compound being consumed.

Cystine is readily reduced to *cystein* (a *amino-β-thiolpropionic acid*) HS·CH₂·CH(NH₂)·CO₂H (Baumann, Zeitsch. physiol. Chem. 1882, 8, 300 ; Mauthner, Zeit. Biol. 1901, 42, 176), which can be converted by the action of bromine-water into *cysteic acid* (α-amino-β-*sulphopropionic acid*) HO₃S·CH₂·CH(NH₂)·CO₂H, and from this, by loss of carbon dioxide, *taurine* NH₂·CH₂·CH₂·SO₃H is obtained (Friedmann, Beitr. Chem. Physiol. Path. 1902, 2, 433). According to Von Bergmann (*ibid.* 1903, 4, 92), the normal taurine in the bile originates from the cystin groups contained in the ingested protein. Cystein yields cystine on oxidation, the change occurring spontaneously in alkaline solution, although the rate is increased by the addition of a mixture of ferric chloride and potassium cyanide (Mathews and Walker, J. Biol. Chem 1909, 6, 289). For the behaviour of cystine on oxidation, *see* Denis (J. Biol. Chem. 1911, 9, 373), and for its breakdown under the action of certain bacteria, *see* Bürger (Arch. Hyg. 1914, 82, 201–211, from the abstr. Amer. Chem. Soc. 1916, 10, 2911).

Slyke's reaction (Ber 1910, 43, 3170) for α-amino acids does not give absolutely quantitative results in the case of cystine.

Cystine and tyrosine can be quantitatively separated by means of absolute alcohol saturated with hydrogen chloride (Plimmer, Bio-Chem J. 1913, 7, 311–317).

When cystine is given with food, it is completely oxidised to sulphate and excreted as such (Rothera, J. Physiol. 1905, 32, 175). Baumann and Preusse (Zeitsch. physiol. Chem. 1881, 5, 309 ; Ber. 18, 258) found that when bromobenzene was administered to animals, it was excreted as *bromophenylcystein*

CO₂H·CH(NH₂)·CH₂·S·C₆H₄Br
a compound crystallising in glittering needles or plates ; m.p. 180°–182°, and yielding a blue crystalline *copper salt* (C₉H₉BrSNO₂)₂Cu.

Derivatives.—Cystine forms sparingly soluble salts with *copper*, C₆H₁₀O₄N₂S₂Cu ; or *mercury*

C₆H₈O₄N₂S₂Hg₂·HgCl₂ ;
2C₆H₁₀O₄N₂S₂Hg,HgCl₂,7H₂O ;
2C₆H₈O₄N₂S₂Hg₂,Hg(NO₃)₂
With 30 p.c. nitric or hydrochloric acid (at room temperature) it yields compounds

C₆H₁₂O₄N₂S₂·2HNO₃ and
C₆H₁₂O₄N₂S₂·2HCl
(Mörner, Zeitsch. physiol. Chem. 1914, 93, 203–208). *Benzoylcystine* C₆H₁₀O₄N₂S₂Bz₂, m.p. 156°–158°, crystallises in needles and forms a sparingly soluble sodium salt (Goldmann and Baumann, Zeitsch. physiol. Chem. 1888, 12, 254). *Cystinephenylhydantoin* is a well-defined

crystalline compound, and is used for identifying cystine. *Cystine ethyl ester hydrochloride*

$$S_2[CH_2 \cdot CH(NH_2) \cdot CO_2Et]_2, 3HCl$$
forms colourless needles, m.p. 185°, with decomposition (Friedmann, Beitr. Chem. Physiol. Path. 1902, 3, 1). Numerous *acyl*- derivatives of cystine have been described by Fischer and Suzuki (Zeitsch. physiol. Chem. 1905, 45, 405; Fischer and Gerngross, Ber. 1909, 42, 1485; Abderhalden and Wybert, Ber. 1916, 49, 2449–2473). Of these *di-l-leucyl-l-cystine* $S_2[CH_2 \cdot CH(CO_2H)NH \cdot CO \cdot CH(NH_2)C_4H_9]_2$ is a granular powder, turns yellow at 200°, and decomposes at a higher temperature, has $[\alpha]_D^{20} -136 \cdot 6°$, or, when obtained in a crystalline form, has $[\alpha]_D^{20} -141 \cdot 4°$; it gives a reddish-violet colour with copper sulphate; is precipitated by ammonium sulphate, and may be termed an *albumose*.   M. A. W.

CYSTOGEN. Syn. for hexamethylenetetramine.

CYSTOPURIN. A compound of sodium acetate and hexamethylenetetramine.

CYTISINE $C_{11}H_{14}ON_2$, prisms, m.p. 153°, b.p. 218°/2 mm., $[\alpha]_D^{17} -120°$, readily soluble in water, alcohol, or chloroform, insoluble in ether and petroleum; is a diacid base forming well-crystalline salts. It is found in the seeds of *Cytisus laburnum*, *Ulex europaeus*, *Baptisia spp.*, *Sophora spp.*, *Genista spp.*, and *Anagyris fœtida* in amounts varying from 1 to 2 p.c.

Cytisine is a secondary-tertiary base. Electrolytic reductions gives a base, tetrahydro deoxycytisine $C_{11}H_{18}N_2$. Hydriodic acid and phosphorus at 230° yields cytisoline $C_{11}H_{14}ON$, β-cytisolidine $C_{11}H_{11}N$ (this on reduction giving α cytisolidine $C_{11}H_{15}N$), hydrocarbons, and ammonia. The constitutions of α- and β-cytisolidines have been established by synthesis (Ewins, Chem. Soc. Trans. 1913, 103, 97). β-Cytisolidine is 6 : 8-dimethyl quinoline, α-cytisolidine the corresponding tetrahydro quinoline. Cytisoline, which on distillation with zinc-dust gives β-cytisolidine, is 2-hydroxy-6 : 8-dimethyl quinoline and has been synthesised

by Späth. On these grounds it has been suggested that cytisine is constituted by the fusion of three rings.

The following constitution is considered the most probable of the fourteen possibilities :—
Cytisine is a violent poison. Cases of infantile poisoning from eating laburnum seeds are by no means infrequent. Dale and Lajdlaw (J. Pharm. Expt. Therap. 1912, 3, 502) have shown that the physiological action of this alkaloid is qualitatively and almost quantitatively indistinguishable from that of nicotine. *See* Späth, Monatsh. 1919, 40, 15, 93; Partheil, Ber. 1890, 23, 3201; 1891, 24, 634; Freund and Friedmann, A. 1901, ı 288; Freund, A. 1904, ı. 263; Freund and Horkheimer, A. 1906, i. 302; Freund and Gauff, Arch. Pharm. 1918, 256, 33.

Methylcytisine $C_{12}H_{16}ON_2$, prismatic needles, m.p. 137°, $[\alpha]_D -221 \cdot 6°$, readily soluble in water and organic solvents, occurs in *Caulophyllum thalictroides* (Linn.) (Power and Salway, Chem. Soc. Trans. 1913, 103, 191); it may also be obtained by methylating cytisine. The salts are crystalline.

The physiological action of the base is similar to that of cytisine (*q.v.*), but the alkaloid is less potent.

Caulophylline (Lloyd, Proc. Amer. Pharm. Assoc. 1893, 41, 115) is methyl cytisine.

Anagyrine $C_{15}H_{22}ON_2$ (?), amorphous, occurring along with cytisine in the seeds of *Anagyris fœtida*, is possibly butyl cytisine (Klostermann, Diss. Marburg, 1898; Chem. Zentr. 1899, i. 1130; Partheil and Spasski, Apoth. Zeit. 1895, 10, 903; Goessmann, Arch. Pharm. 1906, 244, 20).   A. J. E.

D.

DAGUERREOTYPE *v.* PHOTOGRAPHY.

DAHL'S ACIDS. 1-Naphthylamine-4-7- and 4.6.-disulphonic acids. *v.* NAPHTHALENE.

DAHLIA. Syn. *Hofmann's violet, Primula* (*v.* TRIPHENYLMETHANE COLOURING MATTERS).

DAHMENITE *v.* EXPLOSIVES.

DAMASCENINE $C_{10}H_{13}O_3N$, crystalline, m.p. 25°-26°, b.p. 154°/15 mm., 270°/750 mm., occurs in the seeds of *Nigella damascena* (Linn.) (Schneider, Pharm. Centrb. 1890, 31, 173) and *N. aristata* (Keller, Arch. Pharm. 1908, 246, 1). Its constitution was established by synthesis (Ewins, Chem. Soc. Trans. 1912, 101, 544), and

shown to be methyl-2-methylamino-3-methoxy benzoate :
Keller's 'methyl damascenine' is identical with damascenine and 'damasceninic acid' $C_9H_{11}O_3N$, said by Pommerehne (Arch. Pharm. 1900, 238, 531) to be isomeric with damascenine, is obtained on hydrolysis of the alkaloid. Damascenine is mildly narcotic.   A. J. E.

DAMMAR RESIN, DAMMARYL, DAMMARYLIC ACID *v.* RESINS.

DANAITE *v.* **MISPICKEL.**

DANALITE. A rare sulpho-silicate mineral, with the formula $3R_3SiO_4 \cdot RS$, where R represents Fe, Zn, Be, Mn, containing BeO about 14 p.c. The flesh-red or grey cubic crystals are octahedral or tetrahedral in habit; sp.gr. 3·35–3·43; H.=5½–6. It occurs in granite at Rockport and Gloucester, in Massachusetts, and large crystals have been found in Cornwall. Closely allied is the tetrahedral-cubic mineral *helvite*, which contains about the same amount of beryllium, but with a preponderance of manganese and no zinc. L. J. S.

DANDELION ROOT. *Taraxaci radix*, B.P.; *Taraxacum*, U.S.P. (*Pissenlit*, Fr.; *Löwenzahnwurzel*, Ger.) The root of the common dandelion, *Taraxacum officinale* (Weber) (Bentl. a. Trim. 159), is used in medicine for its mild laxative and tonic properties. It is administered either in the form of expressed juice or weak spirituous extract. The roots employed should be collected in the autumn.

The latex contains two crystalline bitter principles, *taraxacin* and *taraxacerin* (Polex, Arch. Pharm. 19, 50; Kromayer, *ibid.* 105, 6) The root further contains *inulin*, 24 p.c. in October, according to Dragendorff (Sachsse's Farbstoffe, 125), but only 1·7 p.c. in March, when, however, 17 p.c. of uncrystallisable sugar and 19 p.c. of *levulin* is present. The latter carbohydrate is soluble in cold water to a sweet solution, without any action on polarised light.

The leaves and stalks, but not the root of the dandelion, contain *inosite* (Marmé, Annalen, 129, 222). G. B.

DAPHNETIN. Daphnetin is present in the form of its glucoside *daphnin* in the bark of the *Daphne alpina* (Linn.) and *D. mezereum* (Linn). The concentrated alcoholic extract is digested with boiling water, filtered, and treated with lead acetate solution. The precipitate is removed, basic lead acetate added to the filtrate, the lead compound of the glucoside decomposed with sulphuretted hydrogen, and the solution evaporated (Zwenger, Annalen, 115, 8).

Daphnin $C_{15}H_{16}O_9, 2H_2O$ crystallises in prisms, melting at 200°, and dissolves in alkaline solutions with a yellow colour. It is hydrolysed by boiling dilute acids with formation of daphnetin and glucose :

$$C_{15}H_{16}O_9 + H_2O = C_9H_6O_4 + C_6H_{12}O_6$$
Daphnetin $C_9H_6O_4$ forms pale yellow needles, is soluble in alkalis with a yellow colour, and gives a yellow precipitate with lead acetate solution. On acetylation, a *diacetyl-* derivative $C_9H_4O_4(C_2H_3O)_2$ is obtained, and by means of ethyl iodide a *diethyl ether* $C_9H_4O_2(OEt)_2$ is produced. When daphnetin diethyl ether is boiled with caustic soda solution, the diethyl ether of *daphnetinic acid*

$$(OEt)_2C_6H_2 {\Large\langle} {{-OH}\atop{-CH=CH \cdot COOH}}$$
is produced in the form of its sodium salt, which when ethylated gives the *triethyl* derivative :

$$(OEt)_2C_6H_3 {\Large\langle} {{-OEt}\atop{-CH=CH \cdot COOH}}$$

By oxidising daphnetic acid triethyl ether *triethoxybenzaldehyde* is formed, which is readily converted into *triethoxybenzoic* acid. The

silver salt of this acid, when destructively distilled, gives pyrogallol triethyl ether. Daphnetin is accordingly a *dihydroxycoumarin*, and has the following constitution :—
(Will and Yung, Ber. 1884, 17, 1081).

It has been synthetically prepared by heating pyrogallol with malic acid in the presence of sulphuric acid (Pechmann, Ber. 17, 933) :

$$C_4H_6O_5 + C_6H_3(OH)_3 = C_9H_6O_4 + CO_2 + 2H_2O + H_2$$
and by the condensation of pyrogallic aldehyde with sodium acetate (Gattermann and Koebner, Ber. 1899, 32, 287) :

$$C_6H_2(OH)_3 \cdot CHO + CH_3 \cdot COOH = C_9H_6O_4 + 2H_2O$$
Daphnetin is a yellow colouring matter, and gives with mordanted woollen cloth the following shades :—

Chromium	*Aluminum*
Olive-yellow	Pale olive-yellow
Tin	*Iron*
Very pale yellow	Olive-black

(Perkin and Wilson, Chem. Soc Trans. 1903, 83, 134). A. G. P.

DAPICHO or **ZASPIS.** The South American name for the caoutchouc which exudes from the roots of *Hevea guianensis* (Aubl.).

DARWINITE *v.* **DOMEYKITE.**

DATE. The fruit of the date palm, *Phœnix dactylifera*. A palm of the tropics of Africa and the East Indies. It furnishes food to a large population in Egypt and Arabia.

The fruit grows in bunches of from 15 to 20 lbs. weight, and a tree usually produces about 20 bunches annually. The date palm also yields a sweet sap, which flows, when incisions are made in the trunk, almost continuously from November to March; the sap is clarified and boiled down, when a brown sugar, known as jaggery, is obtained (Bied. Zentr. 1884, 284).

Analyses of the flesh of dates give :

Water	Protein	Fat	Sol carbo-hydrates	Fibre	Ash
28·8	1·9	trace	63·1	2·7	1·6

Dried dates, according to König, have the mean composition :

Water	Protein	Fat	Sugar	Free carbo-acid hydrates	Other carbo-hydrates	Fibre	Ash
18·5	1·9	0·6	67·2	1·3	4·3	3·8	1·8

Among the 'soluble carbohydrates' is included about 3 p.c. of pentosans, while the date stone contains about 2·7 p.c. of the same substances (Wittmann, Zeitsch. landw. Versuchs. Oesterreich. 1901, 4, 131).

König gives, as the composition of the date stone :

Water	Protein	Fat	free extract	Nitrogen carbo-hydrates	Fibre	Ash
7·7	5·2	9·0	53·0		24·0	1·1

Dates are sometimes used as coffee substitutes, the whole fruit being occasionally employed, but more usually the stones only.

König gives as the composition of 'date-coffee' :

Water	Protein	Fat	Sugar	Other carbo-hydrates	Fibre	Ash
6 6	5·5	7·9	2·2	48·7	27·8	1·3

yielding about 14 p.c. of its weight to water. H I.

DATHOLITE v. DATOLITE.

DATISCA CANNABINA (Linn.). This is a tall, erect herb, resembling hemp, belonging to the *Datisceœ*, and met with in the temperate and sub-tropical Western Himalayas from Kashmir to Nepal. The root, known as *Akalbir*, has been extensively used in Kashmir and throughout the Himalayas as a yellow dyestuff chiefly on alum-mordanted silk ; but the colouring matter appears to be present in the whole plant, for the leaves and twigs can also be employed for the same purpose.

The leaves of the *Datisca cannabina* were first examined by Braconnot (Ann. Chim. Phys. [2] iii. 277), who isolated from them a crystalline substance which he named datiscin. Somewhat later it was shown by Stenhouse (Annalen, 1856, 98, 167) that this compound is a glucoside, and when hydrolysed is converted into a sugar, together with a yellow colouring matter, *datiscetin* $C_{15}H_{10}O_5$.

Schunck and Marchlewski (Annalen, 278, 261), however, considered that ·the formula $C_{15}H_{12}O_6$ was preferable, and showed that, on fusion with alkali, datiscetin gives *salicylic acid*. By the action of dilute nitric acid, a *nitrosalicylic acid* was produced, whereas with strong nitric acid, picric acid, as already indicated by Stenhouse, was formed. Datiscetin appeared to contain methoxyl groups, and was at that time considered by the authors to be most probably a xanthone derivative.

Korczynski and Marchlewski (Ann. d. Akad. Krakau, 1906, 95) have shown that pure datiscetin $C_{15}H_{10}O_6$, however, does not contain methoxy-groups. It consists of yellow needles, m.p. 268°–269°, soluble in alkaline solutions, with a yellow colour, and gives, with sulphuric acid, a yellow liquid possessing a green fluorescence. When boiled with strong alkaline solutions, phenol and salicylic acid are produced.

Tetraacetyldatiscetin $C_{15}H_6O_6(C_2H_3O)_4$ forms colourless needles, and melts at 138° : and *tetrabenzoyldatiscetin* $C_{15}H_6O_6(C_7H_5O)_4$ gives colourless needles, m.p. 190°–191°.

Leskiewicz and Marchlewski (Ber. 1914. 47, 1599) by the action of bromine on datiscetin in boiling acetic acid solution obtained *tribromphloroglucinol*, and as a result suggest that this colouring matter is the 1 . 3 : 1'-trihydroxyflavonol :—
A substance indeed of this constitution in the form of its trimethyl ether has been synthesised by Bargellini and Peratoner (Gazetta, 1919, 49, 64) by the usual methods of flavonol synthesis. Thus 2 hydroxy 4 : 6-dimethoxy phenyl methyl ketone (phloracetophenone dimethyl ether) condensed with salicylic aldehyde methyl ether yields 2 hydroxy 4 : 6 : 2' trimethoxy phenyl styryl ketone I. :—

I. MeO⟨⟩—CO—CH : CH—⟨⟩
   MeO   OMe
which by means of dilute alcoholic hydrochloric acid gives 5 : 7 : 2' trimethoxy flavanone II. :—

II. MeO⟨⟩ O CH—⟨⟩
    MeO   CO—CH₂   OMe
The iso-nitroso derivative of this latter when heated with hydrochloric acid in acetic acid solution gives the trimethoxy flavanone :—

MeO⟨⟩ O C——
MeO   CO—C·OH   MeO
crystallising in pale yellow needles, m.p. 158°–160°, and giving with sulphuric acid an intensely green fluorescent solution. This is probably a trimethyl ether of datiscetin.

Datiscin $C_{21}H_{24}O_{11}$ (S. and M.), the glucoside crystallises in silky needles, which melt at about 190°, and dissolve in alkaline solutions with a yellow colour. Hydrolysis with dilute sulphuric acid yields datiscetin and *rhamnose*, not datiscetin and glucose, as stated by Stenhouse (*l.c.*).

The dyeing properties of datisca root on wool are very similar to those of old fustic. It is, however, slightly inferior in dyeing power. On cotton it dyes more like quercitron bark, in so far that the olives obtained on iron mordant are bluer in shade, as though some tannin matter were present. It appears to have about the same colouring power as quercitron bark, but gives a brighter yellow with aluminium mordant. Applied to wool, it differs from quercitron bark by giving with chromium mordant an olive-yellow which is not of such a reddish tinge, and with tin mordant a bright yellow instead of an orange. It is an excellent dyestuff, and worthy to rank with the natural yellow mordant colouring matters at present in use (Hummel and Perkin, J. Soc. Chem. Ind. 1895, 14, 458).

A. G. P.

DATISCIN v. DATISCA CANNABINA.

DATISCETIN v. DATISCA CANNABINA.

DATOLITE. A native boro-silicate of calcium $HCaBSiO_5$, containing B_2O_3 21·8 p.c. Monoclinic crystals, with a profusion of small brilliant faces, many with five-sided outlines, are of common occurrence ; these are usually transparent and colourless, or with a faint greenish tinge ; sp.gr. 3·0. The mineral most often occurs associated with zeolites in the amygdaloidal cavities of basaltic rocks, *e.g.* in the neighbourhood of Edinburgh and Glasgow, and at Bergen Hill and West Paterson in New Jersey. It, however, presents several other modes of occurrence, viz. in granite at Baveno in Piedmont ; in diorite at Rosskopf in Baden ; in gabbro with copper ores at Monte Catini in Tuscany ; in ' limurite ' (an axinite-pyroxenite) at Dundas in Tasmania ; in serpentine in the Lizard district in Cornwall ; in calcite veins in sandstone at Sonthofen in Bavaria ; in veins of silver ore at Andreasberg in the Harz Mountains ; in the Lake Superior copper mines (here in a compact, opaque, white form resembling unglazed porcelain) ; in beds of magnetite in gneiss at Arendal in Norway.

L. J. S.

DATURA STRAMONIUM v. TROPEINES.

DAUCINE C$_?$H$_{18}$N$_2$, colourless, oily base, b.p. 240°–250°, occurring in carrot leaves (Pictet and Court, ... 1907, 40, 3771), together with pyrrolidine.

DEAD DIPPING. The process of producing a pale-yellow dead surface on ornamental brass-work. The brasswork, after the final stamping, with its adhering black scale from the annealing oven, is placed in dilute nitric acid until the scale is detached, when it is removed and washed with water. It is next plunged into stronger nitric acid, and when its surface is covered with minute gas bubbles, it is washed in a solution of argol and dried in hot saw-dust.

DEAD OIL. The higher boiling fractions of shale oil, from which the greater portion of the solid paraffin has been crystallised out.

DECACYCLENE C$_{36}$H$_{18}$. A hydrocarbon obtained together with fluorocyclene C$_{48}$H$_{28}$ and chlorene C$_{48}$H$_{26}$ by heating acenaphthene with lead oxide at 370°–380° (Dziewonski and Suknarowski, Ber. 1918, 51, 457).

n-DECAHEXANEDICARBOXYLIC ACID CO$_2$H[CH$_2$]$_{16}$CO$_2$H. Prepared by the electro-lysis of an aqueous solution of the potassium salt of the monoethyl ester of suberic acid, and hydrolysing the diethyl ester thus formed (Brown and Walker, Annalen, 261, 125); m.p. 118°.

DECAMETHYLENEDICARBOXYLIC ACID CO$_2$H·[CH$_2$]$_{10}$·CO$_2$H. Prepared by heating the methyl ester of bromundecylic acid with alcohol and potassium cyanide, and hydrolysing the product with alcoholic potassium hydroxide (Nördlinger, Ber. 1890, 2357); m.p 124·5°–125·5°.

DECATOIC ACIDS C$_{10}$H$_{20}$O$_2$.

1. *Capric acid* CH$_3$(CH$_2$)$_8$COOH is found as a glyceride in the butter of the cow and goat, and in cocoa-nut oil, in association with caproic and caprylic acids. Many fusel oils also contain it (Fischer, Annalen, 118, 307; Grimm, *ibid* 157, 264; Rowney, *ibid.* 79, 236), and it is found as *iso*amyl caprate in certain Hungarian wines, and is formed by the oxidation or distillation of oleic acid (Redtenbacher, *ibid.* 59, 45), and by heating octylacetoacetic ester with alcoholic potash (Guthzeit, *ibid* 264, 5). A white crystal-line substance of m.p. 31·3°; b p. 268·4° (corr.); sp gr. 0·8858 at 40°/4°; possessing a goat-like smell; insoluble in cold water, but slightly soluble in boiling water.

2. *Di-iso-butylacetic acid*

$$[CH(CH_3)_2CH_2]_2CH·COOH$$

Obtained by heating di*iso*butylmalonic acid (Bentley and Perkin, Chem. Soc. Trans. 1898, 62); b.p. 225°–230° (730 mm.).

DECHENITE v. VANADIUM.

DECOIC ACID, CAPRIC ACID v. DECATOIC ACID.

DECOLOURISING CARBONS. This term has been applied to nearly pure forms of carbon, possessing remarkable decolourising powers, and manufactured only within the last ten years. In this article it will be convenient to group these special carbons separately from those which have been employed as decolorants for over a century.

(a) *Vegetable Charcoals.*

The decolourising property of wood charcoal was first observed by Löwitz in 1791, and was used for treating beet-syrup. An improved charcoal, produced by washing and grinding, was patented by Louis Constant in 1812, and employed in the refining of sugar. Wood char-coal is manufactured by burning wood in special ovens, or in heaps, air being excluded. Oven charcoal has the composition : carbon, 81 p.c. ; hydrogen, 4 p.c. ; oxygen and mineral matters, 15 p c. Charcoal burnt in heaps has the com-position : carbon, 90 p.c. ; hydrogen, 2·5 p.c. ; oxygen and mineral matters, 7·5 p.c. Klasen and Bergh (Chem. Zeit. 1910) state that the oven-charcoal absorbs 15 p.c. by weight of oxygen at 100° C. The decolourising power of most vegetable charcoals is very slight, but superior qualities are obtained from cherry stones, cocoanut, and certain grasses. But if wood be treated with certain chemicals before being carbonised, the resulting charcoal is a very efficient decolorant (*see* group (c) below).

(b) *Animal Charcoals.*

In 1811, Figuier proved that bone charcoal was a far more effective decolorant than wood charcoal. In 1815, Messrs. P. and J. Martineau patented the use of bone charcoal for refining and clarifying sugar solutions. In 1817, De Cavaillon patented the calcining of bone charcoal after it has been used as a decolorant, rendering it 'superior to new charcoal, and the operation may be repeated any number of times with equal effect' Up to the year 1828, bone charcoal was used in the form of fine powder, mixed with the liquid to be decolourised, and, finally, separated therefrom by filtration. Payen, in 1828, introduced an important im-provement, the 'bone-char' being produced in a granular form, permitting the syrup (or other liquid) to be filtered through the bone-char in 'char cisterns' or 'char filters,' first designed by Dumont. The granular charcoal acted as efficiently as the powder, and avoided the troublesome filtration to separate the powder from the liquid. The granular form was also more suitable for burning in order to restore its activity after it becomes charged with organic impurities absorbed from the liquid under treatment. Dumont's 'char filter' was of the open type, operating by gravity. The modern vessels are closed, and operate under pressure, and the same liquid may pass through two or even three filters, if necessary.

Formerly, bone-char was employed for decolourising both beet and cane juices, in order to produce white sugar direct from the plant. Less costly methods of purifying these juices have led to the abandonment of bone-char in the raw sugar factory, and its application in the refinery only.

Manufacture of Animal Charcoal. The bones employed should be carefully selected, hard, and free from extraneous matter. Whale and fish bones are not of a suitable character, as they yield a soft char. Bones which have been exposed to atmospheric action for a long time, or which have been buried in the ground, cannot be successfully employed, as, owing to the alteration in their composition, they produce a char deficient in carbon.

Before proceeding to carbonise the bones, the fat is removed by boiling, or by means of a suitable solvent such as benzene. By the first-named treatment from 4 to 5 p.c. of fat is extracted, and by the second from 8 to 12 p.c.

The crushed bones are carbonised in apparatus similar to that used in a gasworks, in vertical or horizontal iron retorts of a round, oval, or D section, the latter by preference. The length of the horizontal retort is usually from 8 to 10 feet, the long diameter being 18 inches and the short diameter of the oval retort 12 inches. There are usually five or seven retorts in each bed. The retorts are connected in the same way as gas retorts, with a hydraulic main, and this again with condensers or scrubbers filled with coke, in which the bone oil separates, and from which the gases are exhausted. The gases are then forced through a series of washers containing water to remove the ammonia, the residual gases, which are employed for heating and lighting purposes, finally passing into a gas-holder. Charges of about 2½ cwt of bones are carbonised in vertical, and 5 cwt. in horizontal retorts, the operation taking about 6 to 8 hours with the former, and 8 to 10 hours with the latter. The bone oil, collected in the condenser, amounts to from 3 to 5 p.c. on the bones carbonised, and the ammonia in the ammoniacal liquor is equal to about 8 p.c. of ammonium sulphate, into which it is converted in the usual way. When the bones are completely carbonised, the charcoal is removed from the retorts and cooled in strong sheet-iron canisters, which are at once covered with closely fitting lids and luted round the edges, either with charcoal paste, or a water lute. The char, when quite cold, is crushed in a suitable mill (any iron it may contain being removed by passing over the poles of an electro-magnet), and then sifted into various sizes to suit the requirements of the sugar-refiner. It is usually moistened before grinding, to keep down the dust. Good bones yield about 65 p.c. of char, but from 20 to 30 p.c. of this is dust, which fetches a lower price than the larger grist.

The following is the approximate composition of a good sample of new bone charcoal :—

Carbon . . • . . .	10·51
Calcium and magnesium phosphates, calcium fluoride, &c.	81·21
Calcium carbonate . . .	7·30
Calcium sulphate . . .	0·17
Ferric oxide . . .	0·12
Silica	0·34
Alkaline salts . . .	0·35
	100·00

Moisture originally present . 8·00

Space occupied by one ton, 48 cubic feet.
Weight of char left on sieves of various degrees of fineness :—

Above 10 holes to linear inch	.	0
10 to 20	,,	,,	,,	. 28
20 to 30	,,	,,	,	. 32
30 to 40	,,	,,	,,	. 27
40 to 50	,,	,,	,,	. 11
Through 50	,,	,,	or dust	2
				100

New charcoal of good quality should, in the dry state, contain not less than 9 and not more than 11·5 p.c. of carbon. The silica should not exceed 0·5 p.c., the oxide of iron 0·15 p.c., the calcium sulphate 0·2 p.c., and the moisture 8 p.c. Its weight should not exceed 52 lbs. per cubic foot. It should be of a dull black colour, and, when incinerated, leave an ash of a uniform white or cream colour ; the presence of grey or reddish particles indicates that the sample has been mixed with old charcoal. When brought in contact with the tongue, it should adhere to it somewhat strongly. The size of grain depends upon the use to which it is to be applied. Large-grain charcoal is preferable for strong liquors, such as that used for washing loaf sugar. Refiners, as a rule, prefer small grain ; if, however, it be very small, it impedes the passage of liquor and also gives considerable trouble in washing. Char may be used over and over again, and sometimes lasts several years, being revivified from time to time by reburning in special kilns (see SUGAR). When, by continued use, it has lost its power of removing colour, it is known as spent char, and is then used as a manure, generally after treatment with sulphuric acid, so as to form superphosphate of lime.

The carbon always contains a certain proportion of nitrogen, amounting to about one-tenth of its weight ; also a minute proportion of hydrogen The nitrogen present decreases whilst the bone charcoal is being used for sugar-refining.

When char is repeatedly reburned, it becomes less porous and shrinks in volume, so that a ton, which measures 48 to 54 cubic feet when new, may be reduced to 28 cubic feet after being reburned many times ; in other words, its apparent density may be nearly doubled.

Wallace has, however, shown that the real sp.gr. varies but little ; thus, a new char, occupying 50·6 cubic feet per ton, or having an apparent sp.gr. of 0·71, has a real sp.gr. of 2·822, whilst a moderately old sample, occupying 35 cubic feet per ton, or having an apparent sp.gr. of 1·03, has a real sp.gr. of 2·857, or only a trifle over that of the new.

Another proof that char loses its porosity by long-continued use and reburning, is afforded by the fact, pointed out by Wallace, that dry new char will absorb from 80 to 100 p.c. of its weight of water, whereas old char will only retain from 30 to 45 p.c.

Properties.—Although the decolourising property is the most important, bone-char absorbs other organic and mineral substances from their solutions. Tilbot was the first to prove that the absorption of organic matter increases with the temperature, and Kohlrausch first demonstrated that the absorbed colouring matters remain chemically unchanged, and can be extracted from the charcoal by washing it with ammonia, in which the colouring matters dissolve. It was proved by Graham that various mineral substances are removed from solution by animal charcoal ; thus the lime is taken up from lime water, and metallic salts are absorbed from their solutions in water. According to Chevallier, lead nitrate and acetate are completely removed by animal charcoal. Weppen has shown that this action extends to a great variety of metallic salts, including cupric, zinc,

chromic and ferrous sulphates, nickel, cobalt, silver, mercurous and mercuric nitrates, tartar emetic, stannous chloride, and ferric acetate.

As the result of a number of experiments on the absorption of different salts by animal charcoal, Bodenbender arrived at the following conclusions :—

1. The power of absorbing salts is a physical property.

2. A given weight absorbs a larger proportion of salts from a concentrated than from a diluted solution ; on the other hand, the proportion absorbed from a constant quantity of salts is more considerable when this quantity is in a dilute, than when it is in a concentrated, solution.

3. The presence of sugar has only a slight influence on the absorption of salts.

4. The salts of potassium are absorbed in smaller proportion than those of sodium.

5. Among the salts experimented with, the amount taken up is in the following order, beginning with that least absorbed : potassium chloride, sodium chloride, potassium nitrate, sodium nitrate, potassium acetate, sodium acetate, potassium sulphate, sodium sulphate, magnesium sulphate, potassium carbonate, sodium carbonate, sodium phosphate.

6. A chemical action of charcoal has been observed with respect to some carbonates, oxalates, and other salts, being brought about by the presence of calcium sulphate and phosphate in the charcoal.

7. Charcoal, saturated with one salt, is capable, within certain limits, of withdrawing another salt from solution.

8. There is less absorption of a salt when the contact is brief than when the contact is prolonged. The difference due to time of contact ceases when the contact has lasted some hours.

Investigations by W. B. Clark (J. Soc. Chem. Ind. 1912, 262) indicate that the decolourising power of bone-char depends very largely on the quantity of mineral matter and reducing sugar in the liquor treated in the sugar refinery. The first portion of syrup leaving the char filter contains only about 60 p.c. of the reducing sugar, and 30 p.c. of the mineral matters originally in solution. After these have been absorbed by the char, they are subsequently set free, so that the final portions of syrup contain even more reducing sugar and mineral matters than were originally in solution. At this stage there is a gradual decrease in the decolourising power of the char. After the syrup inlet has been closed, hot water is passed through the char to displace the syrup. In this wash-water, the reducing sugars and mineral matters are present in considerable quantities. This washing treatment restores the normal activity of the char, although the washed char still contains much organic matter, which can be extracted by means of caustic soda solution. Clark remarks that the behaviour of char closely resembles diffusion, the char itself acting as a dialyser, permitting the crystallisable sugar to diffuse through it more rapidly than the other substances present. Bone-char attains its maximum efficiency after being used, washed, and burnt several times. The porosity is thereby reduced, as also is the percentage of organic matter other than carbon, and the percentage of calcium carbonate is reduced from about 9 to 3 p.c. The residual calcium

exists as a basic phosphate, which is partially decomposed by heating the char with dilute acids, causing an increase in decolourising power.

New char exerts a slight oxidising action on colouring matters which are not absorbed by it. Degener and Lack state that freshly ignited bone-char, moistened with water, and exposed to light and air, produces a perceptible quantity of hydrogen peroxide, and is thus rendered more active than the untreated char. If milk of lime be sprinkled over the char, calcium peroxide is produced. ·

The high decolourising power of bone-char relative to wood charcoal was formerly supposed to be due to the presence of 5–7 p.c. of nitrogen in the former, and only traces in the latter ; but this view has now been abandoned in favour of a physical, or purely mechanical, action.

Charcoal prepared from flesh has about the same decolourising efficiency as that made from bone. Blood charcoal is less efficient. Fish charcoal is the subject of a patent by Adler, 1913. The finely minced fish is boiled with water, carbonised, and the resulting charcoal washed with hydrochloric acid.

(c) *' Decolourising Carbons.'*

As stated under (a), very active carbons can be obtained from various woods when these are chemically treated before being carbonised. The earliest patent appears to be that of R. von Ostrejko, in August, 1900, for treating wood powder with calcium chloride or magnesium chloride before carbonising, and subsequently treating the carbon with acid to extract the lime. In a later patent, October, 1900, he employs calcium acetate or chloride, and starch mucilage. Subsequent patentees employ sulphuric acid at 200° C. (Halse, 1902) ; earthy lignites treated with kaolin (Goldstein, 1907) ; carbonaceous matter of animal or vegetable origin is ignited in the presence of chlorine gas (Molenda and Wunsch, 1912) ; peat treated with hydroxides or carbonates of potassium, sodium, calcium, or barium (Kruszewski, 1912) ; wood treated with zinc chloride (Wunsch, 1913) ; wood treated with calcium oxide or carbonate (Bonnard, 1914).'

Two very successful carbons are the Dutch ' Norit ' and the German ' Eponit.'

' *Norit* ' is a fine black powder, containing 94–96 p.c. carbon, and 4–6 p.c. mineral matter. It possesses about 30 times the decolourising power of bone-char, and about 100 times that of wood charcoal. The activity increases in the presence of acids, but diminishes in the presence of alkalis.

' *Eponit* ' is also a fine powder, containing carbon, 86·5 p.c. ; mineral matters, 4·1 p.c. ; and moisture, 9·4 p.c. Experiments by Ströhmer indicate that it possesses 10 times the decolourising power of bone-char, and is not influenced by the acidity or alkalinity of the liquid treated. From his chemical and microscopical examination he concludes that ' Eponit ' is a carbonised vegetable substance, probably wood.

More recently, a Committee of the Royal Society of London has investigated this carbon, and attempted to reproduce it by carbonising various kinds of wood. The conclusion arrived at was that ' Eponit ' is made from a mixture

of coniferous wood, such as pine or cedar, and angiospermous wood, such as poplar or willow.

Following Ostrejko's patent (*see* above), the Committee carried out the following experiments :—

(*a*) A mixture of pine and willow woods was treated with calcium acetate and starch, carbonised at a white heat, and the resulting carbon boiled with hydrochloric acid, washed with water, and heated to a red heat in a retort.

(*b*) Cedar wood was treated with calcium acetate alone, before carbonising, and the same subsequent treatment.

Both (*a*) and (*b*) proved superior to ' Eponit.' Further experiments with cedar and willow were conducted as follows : (*a*) untreated ; (*b*) treated with milk of lime ; and (*c*) with calcium acetate before carbonising at a white heat, subsequent treatment as before. The following results were obtained : (*a*) both charcoals were useless for decolourising purposes ; (*b*) and (*c*) both woods gave very active charcoals, equal to ' Eponit,' (*c*) being slightly superior to (*b*). The Committee concluded that the type of wood has little or no influence on the result, and that probably any porous wood, after similar chemical treatment, would yield an active charcoal. Further, that the treatment with milk of lime is less costly than that with calcium acetate, and the resulting carbon is practically equal in decolourising power.

Pellet (Bull. Assoc. Chim. Sucr. 1916, **33**, 220–227) has studied the relative decolourising powers of numerous carbons and charcoals relative to ' Eponit ' taken as standard. He employed a dilute solution of molasses, previously clarified with basic lead acetate and the clear solution acidified with (*a*) hydrochloric ; and (*b*) sulphurous acids. As some of the carbons gave slightly different values in the presence of these different acids, the two following series were obtained, in which ' Eponit ' is the most efficient :—

(*a*) With hydrochloric acid : Eponit, 1 ; Littoral, 2 ; Flandrac, 3 ; Flaming, 4 ; special carbon for wines, 5 ; bone-char, 6 ; special carbon, 7 ; bone-char washed with acid, 8 ; cherry stone carbon, 9.

(*b*) With sulphurous acid : Eponit, 1; Flandrac, 1 ; Littoral, 2 ; special carbon, 3 ; special carbon for wines, 5 ; bone-char washed with acid, 6 ; Flaming, 7 ; bone-char, 8 ; cherry-stone carbon, 9.

' Norit ' and ' Eponit ' resemble bone-char in absorbing organic and mineral matters from the solutions treated by them, and thus gradually losing their activity. This can be restored by two methods : (*a*) carbonising, so as to destroy the organic matter ; and (*b*) by boiling with dilute caustic soda, which dissolves the organic matters, after which the carbon is separated in a filter-press, and washed with hot water until free from alkali.

In the former method, a special type of kiln must be employed (Wijnberg's Patent, 1916). The second method was patented by Wijnberg and Sauer in 1911 and 1912, and requires no special plant, but appears to have been applied to bone-char many years previously. In another patent by Wijnberg, in 1915 Norit is employed to facilitate filtration of sugar juices through cloth-filters, owing to its power of absorbing gums and pectins.

(*d*) *Mineral Carbons.*

Coal, or other bituminous substance, is impregnated with an alkali, or alkali carbonate, and some time later with an acid ; or first with acid, and later with alkali, before ignition in retorts (Lotz, D. R. P. 1911). ' Culm,' a bituminous mineral present in the alum slate of Sweden, is dry distilled, the residue leached with acid, and washed with water. It can be regenerated by washing and re-heating (Hellsing, Eng. Pat. 1913). Coal is heated with excess of anhydrous zinc chloride in an open vessel until the chloride begins to volatilise. The mass is cooled, crushed, washed in a filter press with dilute hydrochloric acid, and finally with water (Wunsch, Eng. Pat. 1914). The residue from shale-oil distillation is carbonised (Catlin, U.S. Pat. 1917).

(*e*) *Carbons produced from Industrial By Products.*

Clacher claims that an active carbon can be prepared from ' bagasse, 'or crushed sugar cane, after the extraction of the juice (Int. Sugar Journ. 1914, **64** 66). The Pan Chemical Co., U.S.A , manufacture an active carbon from the by-product obtained in the manufacture of salts of tartaric acid from argol. This residue contains 50 p.c. moisture, and 50 p.c. crude fibre with lime and sand. It is dried and heated in retorts (U.S. Pat. 1912). Mathéus (Papierfabrikant, 1911, 9, 1435) evaporates sulphite waste lyes with milk of lime to a thick syrup, and finally in flat vessels, until it solidifies, forming a brittle mass. This is powdered and heated in a closed vessel.

' Black ash residue,' obtained by evaporating the alkali separated from wood pulp, consists mainly of carbon with 1-5 p.c. of ash. The percentage of ash can be reduced to about 0·8 p.c. by washing the residue with hydrochloric acid. The washed carbon has ten times the decolourising power of bone-char (McKee, U.S. Pat. 1914). T. H. P. H.

DÉGRAS, or **SOD OIL,** is the waste fat obtained in the chamoising process, and is used for currying purposes, *i.e.* dressing bark-tanned or chrome-tanned leather. The skins which are to be converted into chamois leather, are first ' limed,' the hair is then removed and the unhaired hides are ' drenched,' *i.e.* placed in a ' sour bath,' in which the free lime is neutralised through the development of an acid fermentation, caused by *Bacillus furfuris.* The skins are then stretched and well rubbed with whale oil, or cod (liver) oil, in the United States with menhaden oil, and worked in ' stocks,' so as to become thoroughly saturated with the oil. The skins are then exposed to the air, and the process of rubbing with oil and stamping in the stocks is repeated until enough oil has been absorbed. By exposure to the atmosphere, a portion of the oil becomes changed, and is most likely converted into the glycerides of ' oxidised ' acids. In order to promote the oxidation of the oil, the skins are heaped together in a warm room, and covered carefully with canvas, so as to keep the generated heat in the heap whereby a large proportion of the oil is converted into ' oxidised ' oil. The bulk of the oil is expressed from the skins by pressure, the remainder of the

oil retained by the skins being removed by one of the two following methods, known respectively as the English and German method, or the French method. In the English and German method, the skins are washed with alkaline lyes; the emulsion thus obtained is acidified with sulphuric acid, when the fatty matter separates and is skimmed off. This fatty substance forms, the 'sod oil' of commerce. In the French method, the skins are 'stocked,' aired, and 'fermented' for a shorter period than in the English or German method, so that a large proportion of the oil can be obtained from the skins by steeping them in warm water, and wringing or pressing in hydraulic presses. The oil thus obtained is termed 'première torse moëllon.' The oil still retained by the skins is recovered by washing with alkaline lyes, as is done in the English and German method, and the fatty matter so recovered is usually added to the moellon An addition of other oils is also made to moellon, and for this reason the commercial product contains less fibre and mineral matter than sod oil.

The most characteristic constituents of dégras are the oxidised fatty acids.

According to Jean, the characteristic oxidation product is a resin-like body melting at 65°–67°. This substance is insoluble in petroleum spirit, but dissolves in alkaline solutions, from which it is again precipitated on the addition of acid. It has been termed *dégras former* by Simand, and has been shown by Fahrion to be composed of a mixture of hydroxy acids and anhydrides.

Dégras is largely admixed with fish oils, blubber oils, tallow of low quality, &c. According to trade custom, such products are considered as a genuine product. On the other hand, the numerous substitutes of dégras, or *artificial dégras,* which occur in commerce, consist of highly adulterated dégras, the adulterants being mineral oils, wool fat, or blown blubber oil, and rosin. Analyses of dégras and sod oils of different kinds are given in J. Soc. Chem. Ind. 1891, 10, 557; 1892, 11, 639; and J. Amer. Chem. Soc. 1899, 21, 291.

<div align="right">J. L.</div>

DEHYDROTHIO-*p*-TOLUIDINE, DEHYDRO-THIO-*p*-TOLUIDINE SULPHONIC ACID, *v.* PRIMULINE AND ITS DERIVATIVES.

DEHYDROTHIO-*m*-XYLIDINE
is prepared by heating *m*-xylidino with sulphur until hydrogen sulphide ceases to be evolved (*cf.* Dehydrothio-*p*-toluidine; Art. PRIMULINE). The excess of *m*-xylidine is removed by distillation and the residue treated with hydrochloric acid, in which the *iso*dehydrothio-*m*-xylidine (m.p. 121°), formed simultaneously, is insoluble; m.p. 107°; b.p. 283°/14 mm. Insoluble in water, readily soluble in hot alcohol (Anschütz and Schultz, Ber. 1889, 22, 582; Paul, Zeitsch. angew. Chem. 1896, 9, 679).

DELPHINE BLUE, *v.* OXAZINE COLOURING MATTERS.

DELPHINIDIN, DELPHININ, *v.* ANTHO-CYANINS.

DELPHININE $C_{31}H_{49}O_7N$ is one of a series of ill-defined poisonous alkaloids, including *delphisine, delphinoidine, staphisagroine,* and *staphisagroidine,* found in stavesacre seeds (*Delphinium Staphisagria* (Linn.). Official in the B. P. and U.S. P. (Kora-Stojanoff, Chem. Zentr. 1890, [ii.] 628, and Ahrens, Ber. 1899, 32, 1581, 1669.) *Delphinium consolida* and *D. ajacis,* according to Keller (Arch. Pharm. 1910, 248, 468; 1913, 251, 207), also contain alkaloids. From various *Delphinium* spp Heyl has obtained 'delphocurarine,' an amorphous mixture of bases, including a crystalline substance, m.p. 184°–185° (Chem. Soc. Abstr. 1903, i. 650) 'Delphocurarine' resembles curarine in physiological action (Lohmann, Pflug. Arch. 1902, 92, 398).

DELPHINIUM CONSOLIDA. *Delphinium consolida* is a common European plant belonging to the Larkspur family; its name refers to its powers, real or imaginary, of healing or consolidating wounds. The blue flowers were examined by Perkin and Wilkinson (Chem. Soc. Trans. 1902, 81, 585) to determine if these yield the same colouring matters as those previously isolated from the flowers of the *D. zalil* (*ibid.* 1898, 73, 267). The presence of kaempferol only could, however, be detected. For its isolation an aqueous extract of the flowers was digested at the boiling-point with addition of sulphuric acid, and the brown resinous product which separated on keeping, extracted with alcohol and the extract evaporated to a small bulk. Addition of ether to this solution caused the precipitation of resinous impurity, and on evaporating the ethereal liquid a semicrystalline residue of the crude colouring matter was obtained. The product was crystallised from dilute alcohol, converted into acetyl derivative, and this after purification retransformed into colouring matter in the usual manner The yield was approximately 1 p.c.

Kaempferol $C_{15}H_{10}O_6$ consists of yellow needles, m.p 276°–277°, soluble in alkaline solutions with a yellow colour. These liquids on exposure to air are slowly oxidised with development of a brown tint.

Tetra-acetylkaempferol $C_{15}H_6O_6(C_2H_3O)_4$, when crystallised from methyl alcohol forms colourless needles, and when heated commences to melt at 116° and becomes completely fluid at 120°. On further heating, however, gradual solidification ensues and the product subsequently melts at 181°–182°. This peculiarity of acetylkaempferol, which is not apparent when the substance is crystallised from ordinary alcohol, affords a convenient method for its detection.

Tribromkaempferol $C_{15}H_7Br_3O_6$ forms yellow needles, m.p. 275°–277°; *kaempferol sulphate* $C_{15}H_{10}O_6$SO_4, orange-red needles; *kaempferol hydriodide* $C_{15}H_{10}O_6$HI, needles, and *monopotassium kaempferol* $C_{15}H_9O_6K$, orange-yellow prismatic needles.

Kaempferide, a monomethyl ether of kaempferol, exists in Galanga root, and a monomethyl ether, apparently distinct from this latter, has been isolated from the berries of the *Rhamnus catharticus.* The glucosides at present known of kaempferol are *robinin,* which occurs

in the flowers of the *Robinia pseudacacia*; *kaemp-feritrin*, found in the leaves of the *Indigofera arrecta*; and *kaempferin*, which has been isolated from senna.

Fused with alkali, kaempferol gives *phloro-glucinol* and p-*hydroxybenzoic acid*.

To kaempferol v. Kostanecki assigned the constitution of a *trihydroxyflavonol* (Ber. 1901, 34, 3723) :—
and its synthesis was subsequently effected by v. Kostanecki and Tambor (Ber. 1904, 37, 792).

2-*Hydroxy*-4 : 6 : 4'-*trimethoxychalkone* (1) when digested with boiling dilute alcoholic sulphuric acid gives 1 : 3 : 4'-trimethoxy flavanone (2) :—
and the latter by means of amyl nitrite and hydrochloric acid is converted into *iso-nitroso*-1 : 3 : 4'-*trimethoxyflavanone* (3).

When a solution of this substance in acetic acid is boiled with 10 p c sulphuric acid 1 : 3 : 4'-*trimethoxyflavonol* (4) is produced, from which by the action of hydriodic acid *kaempferol* (5) is readily prepared :—
Kaempferol possesses well-defined dyeing properties, and gives with mordanted woollen cloth the following shades which closely resemble those given by morin :—

Chromium.	Aluminium.
Brownish-yellow.	Yellow.
Tin.	Iron.
Lemon-yellow.	Deep olive-brown.

It is also present in the *Impatiens balsamina* (Chantili Pass), the *Erythrina stricta* (vernacular name 'Kon kathet') (Perkin and Shulman, Chem. Soc. Proc. 1914, 30, 177), the berries of the *Rhamnus catharticus* and together with quercetin, both apparently as glucosides, in the flowers of the *Prunus spinosa* (Perkin and Phipps, Chem. Soc. Trans. 1904, 85, 56). For the separation of the two colouring matters a fractional crystallisation from acetic acid was

employed, kaempferol in these circumstances being the more sparingly soluble. A. G. P.

DELPHLEGMATOR. An apparatus used in fractional distillation. The term is also employed in distilleries for an apparatus for freeing alcohol from water (*phlegma*).

DELTA ACID. Disulpho acid S. 1-Naph-thylamine-4 : 8-disulphonic acid.

DELTAPURPURIN *v.* Azo- COLOURING MATTERS.

DENATURANTS. This term is applied to substances which are added to articles usually subject to revenue imposts, and primarily intended for human consumption (as spirits, tobacco, &c.) in order to render such articles unfit for human consumption, but without impairing their efficacy as raw material for use in various arts and manufactures. Articles thus 'denatured' may safely (from a revenue point of view) be released from revenue control without payment of duty.

The principles underlying the choice of suitable denaturants are mainly as follows :—

(*a*) They should be inexpensive, so as not to add materially to the cost of the denatured article;

(*b*) Their use should cause the minimum amount of inconvenience to the manufacturer, both in regard to his processes and the necessary revenue supervision involved ;

(*c*) The denaturant should not be incompatible with the process of manufacture or the subsequent use of the denatured article ;

(*d*) It should be of such a nauseous and repugnant character as to remove any temptation to would-be consumers of the denatured article ; and

(*e*) The denaturant should have such a relation to the original article both in quantity and character as to preclude its removal from the mixture by any process which could be profitably carried out on a commercial scale, and it should be capable of being readily detected even if present in very small quantity.

In the United Kingdom the dutiable articles allowed to be denatured are *tea*, *tobacco*, *wine*, and *spirit*, the last being by far the most important, both by reason of the large amount of revenue derived from it, and the great variety and extent of its applications in the arts and manufactures.

Tea, before being admitted for consumption in the United Kingdom, is examined by the Customs under sect. 30 of the Sale of Food and Drugs Act, 1875, and, if found satisfactory, is passed on payment of duty : but if otherwise, it is refused admission as 'tea.' Since, however, it still possesses a certain commercial value as a raw product for the extraction of theine or caffeine, the Commissioners of Customs and Excise usually permit it to be admitted for this purpose duty free, after it has been effectively denatured in such a way as to make it unsuitable for use as a beverage, but without interfering with its efficacy as a source of caffeine. The same applies to those teas which have been accidentally damaged and are voluntarily withdrawn by the importers from sale as ' tea.'

In the case of tea, the denaturing process consists in grinding and mixing the tea with lime and asafœtida in the proportions of 1 part of asa-fœtida and 100 parts of lime to 1000 parts of tea.

Tobacco is dutied on the whole leaf, of which certain portions, as the midribs or so-called 'stalks,' are by manufacturers treated as waste or 'offal,' and the same applies to the unused portions of manufactured tobacco, known as 'shorts' or 'smalls.' On these the duty which has been paid is returned as 'drawback' to the manufacturer on condition, either that the tobacco offal is surrendered to the Government for destruction, or (if intended for such purposes as the manufacture of nicotine, insecticides, sheep dips, &c.), that it is denatured according to certain prescribed formulæ, and under the supervision of revenue officers. Denaturing is equally necessary in the case of offal from tobacco manufactured in bond (although no duty has been paid nor drawback given), in order to prevent its fraudulent use as a substitute for duty-paid tobacco.

The following formulæ have been officially approved in the United Kingdom for denaturing certain preparations having tobacco as a basis :—

" (*a*) *Sheep wash.* To every 100 lbs. of tobacco are added 10 lbs. of blue vitriol, 15 lbs. of common salt, 2 lbs. of oil of turpentine.

(*b*) *Tobacco extract* manufactured in bond may be denatured by adding 30 parts of soft soap to 70 parts of extract.

(*c*) *Hop powder.* To every 75 lbs. of snuff or tobacco are added 28 lbs. of sulphur, 5 lbs. of asafœtida, and 3 lbs. of sago flour.

(*d*) *Fumigant* for horticultural purposes. To every 100 lbs. of tobacco or snuff are added 10 lbs. of ground hellebore, 18 lbs. of saltpetre, 6 lbs. of asafœtida, 4 lbs. of cayenne, 2 lbs. of lampblack, 10 lbs. of sago flour.

Wine which has become unsound and sour (owing to the formation of acetic acid) so as to be no longer suitable for use as a beverage, is released from revenue custody after being denatured with a view to its conversion into wine vinegar. The denaturant used in this case is 20 p.c of commercial vinegar, or an equivalent quantity of acetic acid.

(For methods of denaturing alcohol, *v.* *Methylated spirits* and *Industrial alcohol,* art. ALCOHOL.) J C.

DENITRIFICATION *v.* FERMENTATION AND SOILS.

DENSIMETER *v.* SPECIFIC GRAVITY.

DENTALONE. A solution of chloretone in essential oils.

DERMATOL. Bismuth subgallate (*v.* BISMUTH, ORGANIC COMPOUNDS OF ; *also* SYNTHETIC DRUGS).

DERMOGEN. A trade name for zinc peroxide.

DERMOL. Bismuth chrysophanate. A yellowish - brown powder, said to have the composition $Bi(C_{15}H_9O_4)_3Bi_2O_3$. According to Merck, it is a mixture of impure chrysarobin and bismuth hydroxide (*v.* BISMUTH ORGANIC COMPOUNDS OF ; CHRYSAROBIN and SYNTHETIC DRUGS).

DERRIS ULIGINOSA (Benth.). The stem of this species of derris, used in the Far East as a fish poison, contains a poisonous resin (Proc. Amer. Pharm. Assoc. 1902, 50, 296).

DESAEGIN ('Colloidal chloroform'). An albuminous substance containing chloroform.

DESCLOIZITE. A basic lead and zinc vanadate, $(Pb,Zn)_2(OH)VO_4$, crystallising in the orthorhombic system, and isomorphous with olivenite (basic copper arsenate). A small amount of copper is sometimes present. The small crystals are deep reddish-brown in colour, and the streak is a paler yellowish-brown. It occurs in veins of lead ore in association with vanadinite, &c., and has been mined to a limited extent in New Mexico and Arizona, as a source of vanadium. It also occurs in considerable quantities in the Sierra de Cordoba in Argentina, and at Broken Hill in North-Western Rhodesia. L. J. S.

DESICCATION AND DRYING. The removal of mechanically admixed water from substances. The removal of chemically combined water is usually termed *dehydration,* but it is not always possible to draw a sharp distinction between the two processes.

A substance may be termed 'dry,' even though it still contains mechanically admixed water, provided that this water is not apparent to the touch ; the term 'desiccation' refers, strictly speaking, to the complete removal of admixed water.

The importance of drying and desiccating will be appreciated by a consideration of the numerous reasons for which these processes have to be employed, among which the following may be mentioned :—

1. To preserve material from undergoing physical and chemical alterations, *e.g.* leather, tobacco, fruit.

2. To remove water needed in preceding operations, *e.g.* drying coal after washing, woollen and cotton goods after dyeing, &c.

3. To facilitate accurate sampling, since substances are much more readily and uniformly mixed in the dry state than in the moist condition.

4. To diminish the weight of an unnecessary ingredient and thereby diminish cost of packing, carriage, and freight ; *e.g.* timber, peat, &c.

5. To retain desirable moisture in a substance by drying its surface, thereby rendering the outer layer impervious to moisture, *e.g.* the drying of soaps and chocolates:

6. To prevent injury to health or goods, as in the case of the moisture-laden air of textile factories, evaporating rooms, &c.

7. To prevent waste of heat in vapourising water when combustibles are burnt.

A slight consideration of the various purposes served by drying processes is sufficient to bring out the wide range of degrees of dryness, and the various conditions to which the term 'dry' is applied. This vagueness arises partly from the difficulty of stating quantitatively the amount of water present in a given instance, and partly owing to the varying capacity that substances possess for absorbing moisture. Thus it is that in ordinary conversation substances are variously described as 'soaked,' 'wet,' 'moist,' 'damp,' 'dry,' 'dried,' 'desiccated' or 'dehydrated,' in order to indicate qualitatively their degrees of dryness.

The drying processes in use may be classified under the following headings, corresponding with the degrees of drying to which they lead :—

A. Gravitational drying, by draining, filtering, absorbing, and condensing.

B. Mechanical drying, by pressure and centrifugal force.

C. Drying by evaporation.

A. Gravitational drying. The processes included under this heading are usually only preliminary to the employment of method C above.

Drainage is a natural process occasionally used for the purpose of removing surface water, e.g. from washed coal. The procedure requires no special description.

Decantation is a process by which solid substances mixed with a large amount of water are separated from the greater portion of that liquid by allowing them to settle, and running off the liquid from above the sediment. In practice it is often the custom to arrange 'settling tanks' in series, stepwise, and gradually feed the mixture of liquid *plus* suspended solid into the upper vessel by means of a pipe leading to the bottom. The overflow runs into the second vessel, and so on throughout the series. Arrangements are provided for emptying each tank as required. China clay, chalk, and barytes are separated in this manner.

Filtration is a process of accelerated drainage. Thus wet pigments prepared by precipitation are drained on calico sheets stretched loosely over a skeleton framework. Filtration is greatly accelerated by partially exhausting the air from the chamber into which the liquid drains. A vacuum filter has been designed to work continuously, and consists of a hollow drum, mounted with its axis horizontal, and partly submerged in a tank containing the suspension to be filtered. The periphery is covered with filter cloth, and the water is drawn by suction, applied to the interior of the drum, through this cloth, leaving the solid matter as an outside coating. By slowly revolving the drum, a continuous coating of solid is thus formed, and, after it reaches a certain thickness, an adjustable skimmer removes the surplus. This arrangement can be adapted to many drying operations, and consumes very little power.

Absorption is a drying process in which the material is dried by causing it to yield its moisture to other substances which are capable of annexing it. This process is not often applied on a large scale, although it is commonly employed in the laboratory. Instances are furnished, however, in the preliminary drying of large clay ware in dried plaster of Paris moulds, and in the drying of the highly water-laden atmospheres of evaporating rooms, dye houses, &c., by pumping warm, fresh air into them. Warm air having a much higher capacity for holding water vapour than cold air, the result is naturally to effect a drying of the atmosphere, besides warming up the room and fittings.

In the laboratory, substances are frequently dried by placing them in a *desiccator*. This is simply a closed glass vessel containing in a suitable receptacle some chemical compound, such as anhydrous calcium chloride, concentrated sulphuric acid, or phosphoric anhydride, which has a remarkable affinity for water, so that it will, by absorption, remove water vapour from the interior even when the tension of the aqueous vapour therein is exceedingly small. The substance to be dried being placed in the desiccator, in the interior of which the tension of aqueous vapour is almost *nil*, it gives off its moisture, and this is continuously absorbed by the desiccating agent employed. The latter must expose a large surface for rapid absorption

to occur. The velocity of drying in a desiccator may be greatly increased by exhausting the air from the interior (vacuum desiccator), since the rate at which moisture can diffuse from the material to the absorbing agent is thereby largely augmented. The degree of drying attained cannot, however, be increased, since that is limited merely by the pressure of the aqueous vapour when it has reached equilibrium with the absorbing agent. The rapidity of drying is also increased by placing the material to be dried at the bottom and suitably arranging the desiccating material above it. This arises from the fact that moist air has a smaller density than dry air at the same temperature and pressure; consequently, the natural process inside the desiccator is for the moist air to rise. The error in design exhibited in most laboratory desiccators, in which the above arrangement is reversed, was pointed out by Hempel (Ber. 1890, 23, 3566), to whom the desiccator shown in Fig. 1 is due. In this desiccator, the drying agent is placed in the trough of the lid.

It is usual to evacuate laboratory desiccators by means of the water-pump, but it may be easily accomplished by simple chemical means (J. Amer. Chem. Soc.

FIG. 1.

1906, 28, 834 ; Amer. Chem. J. 1902, 27, 340).

A desiccator for drying by means of a current of air has been described by Pratt (J. Amer. Chem. Soc. 1917, 39, 271). It consists of a Buchner funnel connected below, through
FIG. 2.

cock S', to a safety flask, which in turn is connected with a pump. Resting on the funnel is

a heavy brass disc, B, on the lower surface of which is cemented a ring or sheet of rubber, R, to make a tight joint. Pressure is brought to bear on the disc by means of three screws acting between the disc and a metal collar, C. Heavy rubber tubing, R', prevents the collar from exerting unequal pressure on the funnel. In the centre of the disc is set a brass tube, to which is attached, by means of heavy rubber tubing, R'', the cock S'. This cock is further attached to a system of drying-bottles or towers. The material to be desiccated is either filtered into or placed in the funnel (Analyst, 1917, 156).

Condensation.—This is employed as a means of drying materials which must be handled at low temperatures, and is a method adopted in cold storages. The principle of the process is, briefly, that the moist air of the rooms is drawn out and passed into chambers maintained at a very low temperature, where it is made to deposit the greater part of its moisture as a liquid. The dry air is then returned to the drying rooms, either cold, when it warms itself at the expense of the materials drying, or after being previously heated. This circulation of air goes on continuously. The method adopted in order to maintain a low temperature in the cooling rooms is to allow liquid ammonia, carbon dioxide, or ether to evaporate at the requisite rate through long coils of metal pipes over the outer surfaces of which the moist air is drawn. The latent heat of the ammonia (or other) vapour is obtained at the expense of the heat of the moist air, which is thereby cooled; the vapour condenses on the pipes and the water trickles down into troughs and flows away. The ammonia (or other) gas is repeatedly used in a cycle of operations, being successively liquefied and evaporated. This process is highly efficient, but requires careful handling for economical working.

B. **Mechanical drying.** These methods are efficient when water forms a large proportion of the total weight, and when the solid material to be separated is porous in texture. They leave the solid damp or moist.

Drying by pressure.—There are very few cases in which direct mechanical pressure is used for removing water from substances, the most important of which is the direct squeezing of peat in specially designed machines, in order partly to remove the surplus water.

Filter presses are used for partly drying semi-solids, and leave them still containing about 20 p.c. of moisture. They are efficient in removing the large bulk of the water from granular substances in a state of thick mud. Essentially a filter press consists of a number of flat sections or chambers formed of iron plates covered with filtering cloths, and supported in a strong horizontal frame, in which they can be squeezed up tightly together. The chambers are made either round or square, and usually each has its own outlet cock, while the washing arrangement can be made reversible. The sludge to be filtered is fed in under moderate pressure, and all the outlet cocks opened. After water has ceased to flow out, the solid in the press is washed, if desirable, and the press then taken to pieces to remove the moist solid cakes from its interior. This process is used for filtering,

among other things, sewage sludge, gold slimes, and precipitated pigments.

Drying by centrifugal force.—This method is largely employed for drying clothes in laundries, when the centrifugal machines are termed hydro-extractors. It is also used for drying wool, cotton yarns, piece goods, &c., after they have left the dye houses, and for separating and drying sugar, gun-cotton, and starch.

The process consists in placing the material to be dried in a basket containing numerous holes, and rotating it in a horizontal plane at a considerable speed. The water is thrown off from the material very effectually, much more effectually than when simple filtration or filtration under moderate pressure is adopted.

A centrifugal machine consists essentially of a circular basket, rotated on a vertical central shaft and enclosed in an outer stationary casing. The circular basket is drum shaped, having an open top to introduce the material and sometimes a valve at the bottom to form an outlet for dried crystals. The periphery is perforated with holes of a suitable size. These baskets are made of steel, bronze, copper, aluminium, silver, or china, as may be suitable, and are lined with rubber, enamel, or lead when dealing with acid liquids. The outer stationary casing serves as a guard in case of accident and as a collector for the water. The successful working of a centrifugal machine depends upon the skill with which the vertical shaft is mounted and driven, since the apparatus must have sufficient freedom when running for the axis to take up the position it requires; otherwise vibrations will rapidly wreck the machine.

C. **Drying by evaporation.** This is by far the most efficient method of drying; indeed, several of the preceding processes are only employed as preliminary steps to the application of this more powerful method.

Drying by evaporation is a process in which the water is removed by first converting it into vapour and then conveying the vapour away. Water always has a tendency to pass into the gaseous state, and is constantly giving off vapour from its free surface. If this process occurs in a closed space, some of the vapour finds its way back into the liquid, and a state of equilibrium is set up when the rate at which vapour is leaving the surface has become equal to the rate at which it is passing back into the liquid. To the state of equilibrium at any particular temperature there corresponds a definite vapour pressure, which is a measure of the tendency of water at that temperature to pass into the gaseous state, and this vapour pressure rapidly increases with rise of temperature. When evaporation takes place in free space, no condition of equilibrium is reached, since, owing to diffusion of the vapour, the rate at which it passes back into the liquid can never equal that at which vapour leaves it. Evaporation therefore goes on until no more liquid remains. From these considerations, it follows that the two main practical principles in drying by evaporation are : (i.) to warm the material and thereby increase the tendency of its contained water to vapourise ; and (ii.) to remove the vapour as it is produced from the neighbourhood of the substance, in order that the evaporation shall proceed continuously.

In applying these principles it is necessary to bear in mind that the rate of drying permissible in any given instance is restricted by (a) the physical and chemical nature of the material, which put a limit to the rate at which heat may be safely applied; and (b) by the cost of drying, since the plant mechanically most sound may not be most economical in practice. It must always be remembered that the nature of the material governs the method of drying to be employed, and must be considered before the question of mechanical efficiency.

The various methods for applying heat and for removing vapour are indicated below, and in order to explain more definitely how these methods are employed in practice, brief descriptions follow of various types of drying installations in actual use, and of the purposes for which they are used.

Application of heat. In the majority of cases hot air is employed for conveying heat to the material, and its use is attended with many advantages. Air, although an extremely poor conductor of heat; the increase in volume resulting from this process naturally tends to disperse this heat and to warm surrounding materials by convection. The mobility of the air enables it to come into intimate contact with the surfaces of materials, thereby supplying the heat necessary to vapourise the moisture. Most important of all, the heated air can be thus supplied in large or small amounts, at any desired rate and at uniform pressure, while any of these factors may be rapidly and easily altered at will.

Of the various *sources of heat*, the cheapest is, of course, solar heat. Owing to its unreliability so far as quantity and continuity are concerned, its direct use is attended by considerable risks. Indirectly, however, it is of great value, in being the primary cause of natural air currents. Drying directly by furnace heat obtained by fuel combustion is economical, but the method is restricted in use to drying those substances which are not sensibly affected by high temperatures. For the commonest method of drying, by means of a warm blast of air, heat is usually supplied by passing the air over the surfaces of radiators. These are simply iron vessels, built to expose as much surface as possible, and through the insides of which steam, hot water, or hot gases are passed. Heat is conducted through the iron to the outer surface, and warms the surrounding air mainly by radiation.

The *dangers* encountered in the application of heat result from the nature of the material, and the factors involved, which are briefly discussed below, naturally affect various materials to very different degrees.

(a) Rate of application of heat Although the amount of heat required to vapourise a definite quantity of water is fixed, yet if this heat be applied at a rate faster than that to which the material can accommodate itself, injury will result, e.g. wet bricks will crack unless the greater part of their water is first driven off at a slow and uniform rate.

(b) Change in power of absorbing heat with loss of water. As a material dries, its heat capacity usually diminishes, and hence the risk of overheating increases as drying progresses.

(c) Uncertainty as to degree of dryness, which is often unavoidable.

(d) Local application of heat. This is the usual cause of distortion and cracking, since most materials shrink as they dry, and local shrinking sets up strain. This makes it advisable to keep wet material from actual contact with the source of heat, and to agitate the material to continually expose fresh surfaces, since evaporation is a purely surface phenomenon.

Methods for removal of vapour. The natural method by which vapour is removed is by means of *air currents*, and, excepting in the case of the vacuum process, this is the method upon which all artificial processes for vapour removal are based.

The ordinary *atmospheric* process for drying utilises the natural movements of the air, e.g. by utilising the action of the wind on floors, pans, gantries, sheds, &c. It requires no motive power, but, being dependent upon varying atmospheric conditions, it is not reliable.

In the *exhaust* process the moisture-laden air is drawn away from the wet material quicker than gravity would perform the removal For this purpose a propeller or fan is usually employed. Since the operation is carried out under slightly reduced pressure, vapourisation proceeds quicker than it otherwise would; on the other hand, the exhaust carries away the heat-bearing medium from the material to be heated, and unless proper control is exercised, this defect may more than counterbalance the increased rate of removal of vapour.

In the *vacuum* process the material is enclosed in an air-tight receptacle, from which the air may be exhausted to any desired extent. Heat is then applied, and the vapour pumped off as fast as it is produced. Considerable experience is necessary in the application of this process, which, properly applied, is highly efficient and rapid.

In the *plenum* process the vapour is removed by supplying sufficient warm air to create an augmentation in air pressure A fan is usually employed for this purpose, and drying must, of course, take place in an enclosed room with regulated egress for the air. This process is usually the best to employ, since it can be maintained strictly under control.

Drying installations. Drying floors. *Natural floors* are not often used, since serious difficulties arise as to heating, handling the material, and removing the vapour. Haymaking affords a good instance of its employment

Artificial floors warmed by the products of combustion from a furnace, by hot gases, or by steam passing in flues or pipes beneath, are a considerable improvement on natural floors. Advantage is taken in constructing them of any convenient sandy or porous ground floor; sand is put down if the natural ground is clayey. These floors are used for drying china clay, calcium phosphate, barytes, chalk, cement, and calcined quartz, materials which are not readily injured by excessive or irregular heating.

Drying gantries or racks. These are employed in order that as much surface as possible may be exposed to air currents. Their construction assumes various forms. According to

circumstances, they may be either skeleton shelves, or racks, or props, &c. Occasionally hot water or steam pipes are used as supporting racks, but their use is to be avoided as uneconomical, and tending to produce uneven drying and distortion.

Such substances as damp corn, peat, raw rubber, chalk, bricks, and clayware are frequently dried on open racks, while pigments in colour works are often dried in open gantries of skeleton shelves.

Drying sheds. These are merely drying floors or gantries provided with roofs to keep off rain and snow. These sheds are best constructed of light open framing in order to facilitate the removal of vapour, and the more open it is on all sides the better, provided that the substance is not such that direct sunlight must be excluded from it, e.g. rubber. Such sheds are highly efficient in producing 'air-dried' materials. Bricks are often dried in sheds erected on drying floors, while Chile saltpetre is dried in sheds without the application of artificial heat, as also are china clay and ochre in the quarry state.

Drying pans and troughs. Drying pans, correctly designed and handled, are very useful appliances. The oldest commercial use of such pans is in the evaporation of salt brine, which, as usually carried out, is not at all an economical process. The pans are usually rectangular, and each stands in its own shed. They are directly heated, three or four fires being beneath each pan.

Shallow earthenware pans are of great use in the colour trade, the pigments being readily dried if the pans are carefully arranged on gantries in well-heated and ventilated chambers.

Semi-cylindrical iron pans heated from below by gas or steam give good results in drying soft materials, especially powders. They are most efficient when provided with revolving grids for mechanically stirring the wet material and with valve outlets at the bottom for automatically discharging their dried contents.

Granulated sugar is dried in a type of troughed pan, through which passes a hollow conveyer' carrying hollow paddles. Steam is blown through the conveyer and paddles. The trough is jacketed on one side, and through this jacket air is blown into the bottom of the trough. The sugar is fed into the hot end, and automatically carried by the heated paddles to the outlet at the cool end of the trough.

Kilns. These are buildings containing a furnace, the direct heat of which is used for drying materials by allowing the products of combustion to pass through them. For substances which may be strongly heated without damage, kiln-drying is an economical method of procedure, since the walls of the kiln are very effective in saving heat that would otherwise be lost; but care must be taken to provide proper exits for the vapour.

A primitive type of kiln is one in which calcium phosphate is dried. It consists of a plain rectangular brick building with a wooden roof. The floor is piled with wood, and the phosphate placed upon it. Flues admit air for combustion and circulation. Such a kiln will burn for from 2 to 5 days and dry from 1000 to 1200 tons of phosphate.

Kilns for drying clays, fuller's earth, barytes, and chalk are constructed upon the same principle, the fire being placed so as to prevent the ashes mixing with the material; the latter is sometimes supported within the kiln on iron racks.

A rotating bed dryer is in extensive use for drying materials which allow of direct firing. The material is placed on a circular cast-iron bed, which slowly rotates on a vertical shaft. The bed is covered by a firebrick arch, into which the exit flue leads. Heating is done directly by fires, and stationary blades fixed in the arch stir the material as it is drying. The blades are fixed at such an angle that the material is slowly moved from the centre, above which the feed is situated, to the edge, where it is automatically discharged. This is a common type of drying kiln for ores.

Drying cylinders. This term includes those dryers in which the material to be dried is contained in a cylindrical tube, which is slowly rotated. The essential feature of their construction is that the rotation of the cylinder affords the means of moving the material along. With suitable materials and the necessary power, cylinders will automatically deliver large quantities of uniformly dried product, with the minimum of labour and fuel consumption. They are consequently extensively used, and many types of drying cylinders have been devised.

For materials that withstand high temperatures, the heating may be carried out by passing the hot gases from a furnace through the tube. The latter is constructed of steel, and is mounted nearly horizontally (slope of 1 in 12), with the furnace at the lower end. The feed is situated at the higher cold end, and the gases pass out through a flue at this end, connected with a fan or chimney. As the material gravitates down the tube it is dried, and on reaching the lower end, it drops out, quite dry, into trucks. A modification of this construction consists in enclosing the steel tube in a horizontal brickwork chamber and heating it externally by passing the furnace gases into this brickwork chamber, whence they pass through a series of external hooded openings into the steel cylinder itself. This arrangement allows of a more gradual and systematic heating, while dust and other objectionable parts of the products of combustion may be arrested prior to the gases entering the cylinders. Besides these two arrangements, many others have been devised, each having its particular advantages.

Cylinder dryers are very suitable for heating by steam, thus meeting the requirements of such substances as sugar, salt, soda, cocoa, coffee, &c., provided they contain not more than 25–30 p.c. of moisture. The drying cylinder may be either steam-jacketed externally, or internally, or by both methods united. The exhaust is best taken by means of a fan at the feed end of the cylinder. In using such dryers for sugar, they are employed in conjunction with a conveyer trough dryer (v. supra), into which the sugar falls after passing through the steam-heated cylinder.

Drying rollers. These are heated rotating cylinders, with the outside periphery of which the material to be dried is brought into contact. They are made of steel, cast iron, copper, or

tinned iron, and are usually heated by passing steam or hot air through their interior. Another method of heating consists in coating the cylinder externally with felt and rotating it in a polished iron bed, against the under surface of which steam is blown. The material to be dried is automatically passed between the roller and its bed, and the rollers are usually arranged in series of two to eight.

The latter method is largely employed in laundry work, and the use of drying rollers is extensive in the paper and textile trades.

Drying tunnels. These consist essentially of a stationary passage through which the material passes either continuously or intermittently as the drying proceeds. Drying in a tunnel is progressive from one end to the other. Heat may be applied either by direct firing or by heated air, which passes into the tunnel from beneath one end and travels along to the other. The warm air current usually travels in the opposite direction to that in which the material moves, but not always, as, for instance, in the drying of wool, where the pressure of the warm blast is utilised in blowing the material forward. The vapour-laden air may be removed either by chimney, exhaust, or by pressure fan, while the material may be handled in a very large number of ways, according to circumstances. This method of drying is economical, but the initial cost of plant is often considerable.

In drying timber, the material is carried on special trucks running on a tram track. The air is heated by means of a heater coil fed with steam and situated under the track at the discharging end. The air ascends, dries the timber, thereby becoming cooler and denser, and then, pressed forward by the incoming air, it gravitates into a large space beneath the feeding end of the tunnel and passes up the flue. Wool is dried in a tubular tunnel, being blown along by the warm air. Soap is dried by passing it on trolleys through narrow tunnels, usually arranged in fours, through which warm air is driven by means of a propeller. In particular, bricks and clayware are dried by passing them through drying tunnels, for which purpose a very large number of types of plant have been devised.

Drying rooms. These are enclosed spaces, which are warmed by means of hot air, and into which the loader or discharger has to enter. When not constructed of brick or stone, the material of the walls should be chosen for its insulating qualities.

The expense attached to drying by this method is due largely to the manual labour required in handling the material, which arises, in most cases, from the fact that the peculiar properties of the material render it impossible to utilise mechanical methods. Since manual labour in a heavily moisture-laden atmosphere is unhealthy, desiccation in drying rooms is restricted in practice to those materials for which the process is unavoidable. Such products as hops, confectionery, leather, paper, textile fabrics, pottery, and rubber are dealt with by this method.

The materials are supported in the most convenient manner within the chambers, and warm air circulated either through or over them. The warming of the air may be accom-plished either within or without the compartment, by means of radiators, and, if desired, the same air can be used continuously in a circuit (compare the condensation process).

Drying ovens. These are entirely enclosed drying chambers; the necessary heat for the purpose is not generated within them, neither is it necessary to enter them in order to charge or remove the material to be dried. Ovens can be adapted to suit a wide range of conditions, and some of the most scientific and economical dryers are of this type.

A great variety of methods are available for the purpose of heating, since the heat is generated outside the oven. Products of combustion are readily excluded from the material. There is no necessity for the plant to cool down before the dried product is removed, and hence heat losses are greatly minimised. Heat is applied to the material either by means of hot gases, usually hot air, or by direct conduction through metallic plates, as, for instance, in steam ovens. Vapour is usually removed mechanically, either by pressure or exhaust, but it may be pumped off, as, for instance, in all vacuum machines. Ovens are more efficient than drying rooms, since the latter are frequently used for other purposes than drying, whereas the former are designed exclusively for drying. Only a few types of drying ovens can be here described.

Laboratory ovens are rectangular boxes, constructed of copper, iron, or aluminium, which may be either steam- or air-jacketed, or in simple ovens not jacketed at all. The substances to be dried are supported on shelves inside. With air ovens heat is applied directly at the bottom of the oven or of the outer jacket. A ventilator situated at the bottom of the oven door allows air to enter, and one or more chimneys in the lid allow the warm vapour-laden air to escape. A convenient method of heating, which can be readily controlled, consists in heating electrically, by passing a current through a number of resistance coils embedded in the jacket surrounding the oven. (See also ANALYSIS, Vol. I.) Removable tray dryers are largely used for drying tea, coffee, cocoa, cinchona bark, &c. The trays are arranged in the oven in a series of rows. Each tray has a separate slide, and is independent of the others, and each column of trays has its own regulating damper in the hot air. The method of working is progressive, the wet material being first placed in the top tray of the column and passed downwards stepwise to the bottom. The heat required is supplied from a multitubular furnace, which also produces the air current which aërates the material. The hot air may be allowed to rise through the material, or be drawn down by two centrifugal fans on either side of the centre through the substance. The latter arrangement is more readily controlled, gives a larger output, and effects a considerable saving in height. A modification giving an even larger output consists in causing each horizontal line of trays, commencing with the lowest, to automatically tilt and discharge its contents into the base of the dryer. For drying other substances than those mentioned above, many other types of tray ovens have been devised.

Sliding-panel dryers are used in laundries, and can also be adapted for drying yarns, piece goods, &c. They consist of a row of vertical

sliding panels, built up with hanging rods to form rigid horses for the goods. They are readily movable on runner wheels, and each panel may be withdrawn independently of the others, with the minimum loss of heat, as the back of the panel closes the outlet and thus reshuts the oven. A hot-air blast is supplied from above, and after passing through the oven it discharges into the open.

The Lennox plate-oven dryer is a type which has many advantages, is compact, and occupies a small floor space. The outer vertical cylindrical casing is built up in sections to allow for extension and renewal. A concentric cylindrical drum slowly rotates inside. At each external section there is a horizontal metal plate within the apparatus, and each section plate contains a hole ; these holes are not vertically above one another. The material to be dried is fed in at the top, falls on the first section plate, and is slowly stirred round by horizontal arms on the rotating centre drum till it reaches the hole in the plate. It then falls through on to the next plate, is slowly stirred round till it falls on to the third plate, and so on, till it is discharged at the base. Hot air is blown in at the base, and passes upwards into the central drum, from which it issues, through numerous holes in its sides, passes through the material, and thence upwards and outwards.

A horizontal steam-jacketed cylindrical oven, containing a very powerful and thorough agitating gear inside, is used for drying wet pasty materials like meat, fish, &c. The material is fed in at the top, and discharged as a dry, mealy powder through a manhole in the bottom. The vapour is removed from the interior through a large outlet duct operated either by a fan or pump according to circumstances. In vacuum ovens the removal of vapour by means of air or other gases in motion is discarded in favour of pumping away the vapour from the warmed-up material, operating in a closed space and diminishing the pressure within it to any desired extent. The oven must be strongly built, and all joints must fit tightly to maintain the diminished pressure. The material may be supported inside in any suitable manner, for instance, on steam-heated grids. The necessary accessories are a vacuum pump, a condenser for the vapour and a receiver for the condensed water. The latter is provided with a sight glass in order to tell when no more water is given off by the material in the oven. The effective working of such a plant depends largely upon the observance of various mechanical and engineering points ; the chief feature of the vacuum process is the saving of time that it effects. The oven may be designed to suit either solids or liquids, and provision may also be made for effectively stirring the material during the drying process.

Desiccators. (Laboratory desiccators have already been described.)

A large-scale desiccator is any type of drying machine, which, working by evaporation, carries the degree of drying to the utmost possible extent. In some of the types previously described, it is difficult to prevent thorough desiccation, and, in fact, to avoid dehydration and calcination, but a number of machines have been devised for the effective desiccation of liquids and thin pastes, which work upon a common principle that may be briefly explained. It consists in spreading the liquid in a thin film over a heated metallic surface kept in motion, and, when the water has been removed, skimming off the solid residue with a knife. By suitable arrangements, this process can be made continuous, and it is employed on a large scale for desiccating milk to a dry powder. A modified method of removing the desiccated product is to cause the liquid to spread out on the upper part of an endless horizontal metallic belt, working over two rollers contained in a heated chamber under reduced pressure. The heated liquid, being fed on to the belt at one roller, is desiccated by the time it arrives at the other, and, on the belt passing over that roller, the dry powder falls into the delivery hopper beneath.

Literature.—Marlow's Drying Machinery and Practice, which contains a bibliography of the subject. *See* also a paper by E. A. Alliott, J. Soc. Chem. Ind. 1919, 38, 173 T.

DESICHTOL. Trade name for ichthyol ammonia deodorised by hydrogen peroxide.

DESOXYCHOLEIC ACID *v.* CHOLIC ACID.

DESPYRIN. Salicyl tartaric ester.

DETONAL. Diethyl acetyl urethane.

DETONATORS *v.* EXPLOSIVES.

DEVARDA'S ALLOY. An alloy of aluminium 45, copper 50, and zinc 5 parts.

DEVELOPED COLOURS. Colours formed on the fibre by coupling an azo dye after fixing with a second component. *V.* PRIMULINE.

DEXTRAN *v.* GUMS.

DEXTRINS $n(C_6H_{10}O_5)$. When diastase acts on starch paste (gelatinised starch), maltose is the final product, but, intermediate between the starch and maltose, various dextrins are formed as the reaction proceeds in successive stages. These dextrins are colloidal amorphous compounds, and do not form characteristic derivatives. They are soluble in water, and precipitated by alcohol. Only maltodextrin, which is possibly the simplest of them, has been prepared in anything like a state of purity, and most of the other dextrins described must be regarded as mixtures.

As diastatic hydrolysis proceeds, the optical rotatory power diminishes, and the cupric-reducing power increases. The change is rapid to a certain point, but then becomes arrested ; this behaviour is interpreted as proof of an essential difference between the higher and lower dextrins. The constants of this stage of hydrolysis are $[\alpha]_j = 162.5°$, K (cupric-reducing power) = 48.3, and correspond to the conversion of four-fifths of the starch into maltose. The remaining dextrin is hydrolysed with greater difficulty. According to H. Brown, it cannot have a simpler formula than $40(C_6H_{10}O_5)H_2O$.

The dextrin isolated from a starch conversion stopped at a stage which gives a deep brownish-red colouration with iodine is termed *erythrodextrin*. At a later stage iodine ceases to give a colouration, and the dextrin present is termed *achrodextrin*. These dextrins have little or no cupric-reducing action, this point being still undecided.

Dextrins are also formed by the action of hot dilute mineral acids, or of heat alone on starch. The final product in this case is dextrose instead

of maltose. These methods are used for the commercial preparation of dextrin.

Malfitano and Moschkoff (Compt. rend. 1912, 154, 443–446) have found that starch may be converted into dextrin merely by desiccation. When kept *in vacuo* at 25° over phosphoric oxide 28·1 p.c. of the starch was found to have become soluble in the course of 20 days. The authors conclude that the starch molecule is composed of dextrin complexes linked together by water molecules.

Oscar von Friedrichs (Arkiv. Kem. Min. Geol. 1913, 5, No. 3, 1–14) has studied the action of various yeasts upon the dextrins. Generally speaking, dextrins with higher molecular weights are not so readily attacked as those with lower.

Yeasts which split up α-methyl glucoside are capable of fermenting dextrins to a very limited extent, while *Sacchsia Suaveolens*, which is known to ferment β-methyl glucoside, is found to ferment achroodextrins energetically. The results support the view that β-glucoside linkings are present in the starch and dextrin molecules.

Crystalline dextrins may be prepared by the action of *Bacillus macerans* upon starches (Schardinger, Centr. Bakt. Par. 1911, ii. 29, 188–197). By this method two dextrins designated as α and β have been isolated, both in crystalline form.

According to Langhans (Ber. 1912, 45, 2533–2546), both forms are acetylated by acetic anhydride in presence of zinc chloride, but scission of the molecules occurs simultaneously; under this treatment the α- compound gives a hexa-acetate of a diamylose, the β- a nona-acetate of a triamylose, hydrolysis of the acetates yields a diamylose and triamylose respectively, both crystalline compounds.

The properties of these crystalline dextrins have been further investigated by Pringsheim and Eissler (Ber. 1913, 46, 2959–2974; *see* D. R. P. 279256, 1913), in which the dextrins are produced by the action of *Bacillus macerans* on starch and isolated by precipitation with light petroleum.

In presence of a little platinum black as catalyst, *l*-glucosan, heated to 180°, undergoes polymerization, and is transformed into a white amorphous substance, which exhibits the characteristic properties of a dextrin and yields dextrose when warmed with dilute sulphuric acid (Pictet, Helv. Chim. Acta, 1918, 1, 226).

Maltodextrin $6(C_6H_{10}O_5)H_2O$ has $[\alpha]_J+193·6°$, $[\alpha]_D+181°$; cupric-reducing power, 42. These figures agree with a mixture of 1 part maltose to 2 parts dextrin; but the facts (1) that it cannot be separated into maltose and dextrin by dialysis, (2) that it is not fermentable by yeasts, (3) that it is completely converted into maltose by diastase, prove maltodextrin to be a definite chemical compound. To prepare it, a starch transformation is carried out at 60°–65°, until $[\alpha]_J=+198°$. The solution is boiled, concentrated to a sp.gr. of 1·06, and the maltose removed by fermentation. The solution is filtered, evaporated to a syrup, and digested with alcohol first of 90 p.c., and then of 85 p.c. This last liquid is decanted hot, and the alcohol distilled off, when maltodextrin remains; it is purified by further treatment with alcohol.

On oxidation of maltodextrin with mercuric oxide, until the cupric - reducing power has disappeared, *maltodextrinic acid* is obtained. This behaviour proves maltodextrin to contain an aldehyde group, but the change goes further than the oxidation of this group to carboxyl (CO_2H), since it splits up the terminal C_{12} group into a C_6 acid residue, which remains attached to the rest of the molecule, and a C_6 residue which is eliminated.

(For a full account of the decomposition products of starch, *v.* STARCH.)

Manufacture. — The commercial products known as solid dextrin, British gum, starch gum, &c, are mixtures containing various dextrins, together with carbohydrates (copper oxide reducing substances). They consist mainly of erythrodextrin, and accordingly give a brown iodine colouration.

They are prepared (1) by the action of heat on dried starch; (2) by the action of heat on acidified dried starch.

The starch is first freed as much as possible from combined water by drying in suitable ovens, and then submitted to a temperature of 212°–275° in rotating sheet-iron drums. The heat is supplied by hot oil, rape oil being fairly generally used, or by direct fire. When the oil-bath is used, the control over the temperature is greatest, and the colour of the product can be varied at will from white to dark brown. When the drums are heated by direct fire, they are made to rotate on slightly inclined axes, the dried starch being fed in at the higher end of the revolving cylinder and the product discharged at the other. Sheet-iron ovens are also used; they are constructed singly or in sets. The heat is supplied by a furnace, the heated air from which is drawn over the top of the ovens. The material is kept continually stirred by flat iron oars. Boxes and trays are also used as converters, and, indeed, the maker has only to consider the variety and quality of product required, and to remember that the drier the starch and the lower the temperature of conversion, the whiter will be the product, and, further, that different starches yield different products, *i.e.* behave differently when submitted to the action of heat, to enable him to construct an apparatus that will suit his requirements. It must also be borne in mind that the conversion takes place more slowly at a low temperature.

The alternative method, in which less heat is required to yield a satisfactory product, is to spray or moisten the starch either with a mixture of dilute nitric and hydrochloric acids, or with each acid singly, or with dilute oxalic acid. The paste is dried and heated at 100°–120° or to 150°, till the transformation is complete, as determined by the iodine test; it must then be arrested promptly.

Payen recommended 1000 lbs. starch to be moistened with 30 gallons water containing 2 lbs. nitric acid (sp.gr. 1·38), the mixture to be well kneaded, made up into balls, and dried in a hot-air chamber; then powdered, spread on brass trays to the depth of 1½–2 inches, and submitted to a temperature of from 110°–120° in a hot-air oven.

The heat method is that which was most commonly used on the Continent, whereas the

use of weak nitric acid found most favour in this country.

The products thus obtained appear in commerce in the form of powders varying in colour from almost white to dark brown, through every shade of light yellow and brown. They are reduced to this state after roasting, by crushing in pans or passing through rollers, and then sifting through a rotating silk screen such as is used in flour mills.

Dextrins prepared from powdered starch are used by textile manufacturers and calico printers as vehicles for colours. They are also used for all kinds of gum, paste, sizings, and in the manufacture of paper boxes, wall paper, and for a variety of other purposes.

For a method of examination of commercial dextrin and related starch products, v. Babington, Tingle, and Watson, J. Soc. Chem. Ind. 1918, 37, 257 T.

On heating dry starch with formic or acetic acids, the starch nucleus is broken down and esters of dextrins are formed, which are soluble in cold water. The proportion of acid fixed depends on the time of treatment. After 15 hours' heating with glacial acetic acid at 90°, the product just ceases to give a blue iodine colouration, and the products of the further heating are soluble in cold water When care is taken to exclude moisture, and the heating is continued for 2 or 3 hours only, using equal weights of starch and glacial acetic acid, an acetylated starch, known commercially as *Feculose,* is obtained. This behaves like starch towards boiling water, but the jelly does not revert on standing. It forms very clear flexible films, and is said to give better results than dextrin as a textile finish (*see* Traquair, J. Soc. Chem. Ind. 1909, 28, 288).

Dextrin syrups find employment in a variety of industries. They are prepared from starch by heating it with hydrochloric or sulphuric acids in precisely the manner already described for dextrose (*v.* CARBOHYDRATES), with the exception that conversion is stopped at a much earlier stage. Thus in the modern American process of manufacture of corn syrup from maize starch, less than 10 minutes' heating is required. The product evaporated to 42°–45° B. forms a colourless viscous syrup, having the composition water, 19 p.c. ; dextrose, 38·5 p.c. ; dextrin, 42·0 p.c. ; ash, 0·5 p.c.

In America corn syrup is used extensively in making confectionery, preserves, and table syrups, being preferable to sugar or cane syrup, as the goods are not likely to grain.

According to Yano (J. Chem. Ind. Tokyo, 1918, 21, 865), dextrin prepared by adding 10 parts dilute nitric acid (5 parts of acid of sp.gr. 1·4 and 95 parts water) to 100 parts of sweet potato starch, drying the resulting paste at about 50°, and heating it for an hour at about 150°, is a suitable substitute for gum arabic as an adhesive.

Dextrin may also be prepared by the action of malt extract on gelatinised starch. E. F. A.

DEXTROFORM. A condensation product of dextrin and formaldehyde.

DEXTROSE *v.* CARBOHYDRATES.

DHAK GUM *v.* KINO.

DHAURA. A gum obtained from *Anogeissus latifolia* (Wall.), It is extensively used in India in calico-printing ; it occurs in clean straw-coloured elongated masses, sometimes honey-coloured or even brown from impurities. As an adhesive gum it is inferior in strength to gum arabic. In India, the reputation of this gum stands high with the calico printers, especially of Lucknow, and it is probable it possesses some specific peculiarity justifying the preference, since it is used with certain dyestuffs, such as with haldi (*Curcuma longa* [Linn.]), whilst gum arabic or ' babul ' is used with madder (*Rubia cordifolia* [Linn.]) (Watts' Economic Products of India).

DHURRIN *v.* GLUCOSIDES.

DIABASE. This name was introduced by the French mineralogist A. Brongniart, in 1807, for those varieties of basalt in which the light and dark minerals, respectively felspar and augite (or as he erroneously supposed, felspar and hornblende), are distinguishable to the unaided eye. As naturally defined by him, the term is therefore synonymous with the diorite of Haüy (1822), whilst with the correction of augite for hornblende it becomes a synonym of the dolerite of Haüy (1822). In the latter sense it is used by some authors at the present time (*v.* DOLERITE). Unfortunately, the term was re-defined by German petrographers, and it came to be applied to the older, or pre-Tertiary, dolerites, which differ from those of more recent date only in showing correspondingly more alteration, with the development of secondary minerals, such as chlorite. In consequence of this, the name ' diabase ' is now applied by most English authors to a partially altered or weathered dolerite. In this sense it has an economic bearing, since rocks of this class, being of wide distribution, are much quarried for road mending. For this purpose the fresher dolerites are somewhat brittle, whilst diabases are tougher and more durable, providing the decomposition has not proceeded too far. There is also a tendency to use the name ' diabase ' in a loose sense, like the popular terms ' greenstone,' ' whinstone,' ' toadstone,' and ' trap-rock.'

L. J. S.

DIABETIN. A trade name for a preparation of lævulose.

DIACETYL *v.* KETONES.

DIACETYLDIOXIME, DIMETHYLGLYOXIME *v.* KETONES.

DIACETYL MORPHINE *v.* OPIUM.

DIAL-CIBA. A trade name for diallyl-barbituric acid.

DIALKYL BARBITURIC ACIDS *v.* PYRIMIDINES.

DIALLAGE. An important rock-forming mineral belonging to the monoclinic series of the pyroxene group. It has the same composition as diopside and hedenbergite,

$$Ca(Mg,Fe)(SiO_3)_2$$
but with the addition of alumina passes into augite. It differs from the other members of the pyroxene group in possessing a fine lamellar structure, due to secondary twinning and partial alteration of the material. On the surfaces of foliation the mineral displays a shining metallic sheen, and on this account it is sometimes used as an ornamental stone. The colour is grey, brown, or green. Diallage is of common occurrence as a constituent of gabbro.

L. J. S.

DIALOGITE. *Manganese carbonate* (v. MAN-GANESE and RHODOCHROSITE).

DIALURIC ACID, *Tartronylurea*

$$CO<^{NH \cdot CO}_{NH \cdot CO}>CH \cdot OH$$
prepared by reducing alloxan with zinc and hydrochloric acid, or with sulphuretted hydrogen at the temperature of boiling water (Liebig and Wöhler, Annalen, 26, 276), or with ammonium sulphide, when ammonium dialurate is obtained and is readily converted into the acid by the action of hot dilute hydrochloric acid (Gregory, Chem. Soc. Mem. 1845, ii. 11). A mixture of potassium dialurate and oxalurate is obtained by adding potassium carbonate to a solution of alloxan containing potassium cyanide (Strecker, Annalen, 113, 53); it is prepared by reducing alloxantin with sodium amalgam, or dibromobarbituric acid with sulphuretted hydrogen (Baeyer, Annalen, 127, 12; 130, 133). Magnier de la Source showed that dialuric acid is obtained by prolonged boiling of uric acid with water (Bull. Soc. chim. 1875, 23, 529), or it can be obtained from uric acid on gentle heating with hydrochloric acid and potassium chlorate (Biltz and Damm, Ber. 1913, 46, 3662-3665). Grimaux effected its synthesis by treating tartronic acid and urea with phosphorus oxychloride (Compt. rend. 1879, 88, 85).

Dialuric acid forms colourless short four-sided prisms, or narrow thin leaflets with rounded ends, sparingly soluble in cold, more readily so in hot water; turns red at 180°, m.p. 214°-215° (corr.) (Biltz and Damm, *l.c.* 3664). The moist crystals or the aqueous solution rapidly absorbs oxygen from the air to form alloxan, which combines with the dialuric acid, forming alloxantin. The rate at which the change takes place is illustrated by the results obtained by Hartley (Chem. Soc. Trans. 1905, 87, 1804), in an unsuccessful attempt to obtain the absorption spectra of dialuric acid; 0·144 gram of pure dialuric acid was dissolved by agitation and warming in 100 c.c. of water, and immediately afterwards the solution yielded the same series of absorption spectra as a solution of 0·322 gram of alloxantin, dissolved in 250 c.c. of water. Alloxantin is also formed by mixing solutions of equivalent quantities of dialuric acid and of alloxan (cf. Richter, Ber. 1911, 44, 2155-2158). Dialuric acid is monobasic, and, contrary to the statements of Menschutkin (Ber. 1875, 8, 760; Annalen, 1876, 182, 70), forms only one series of salts of the type $C_4H_3O_4N_2M'$. The *sodium*, *potassium*, *ammonium*, and *barium* salts are crystalline (Koech, Annalen, 1901, 315; Behrend and Friederich, Annalen, 1906, 344, 1).

Acetyldialuric acid $CO<^{NH \cdot CO}_{NH \cdot CO}>CH \cdot OAc$

crystallises in white prisms or leaflets; m.p. 210°-212°; gives a violet precipitate with barium hydroxide; forms the *potassium salt* $C_6H_6O_6N_2K,H_2O$, and combines with alloxan to form *acetylalloxantin* $C_{10}H_6O_9N_4,H_2O$, m.p. 263°-265°; *benzoyldialuric acid* $C_{11}H_8O_5N_2$, crystallises in prisms, m.p. 209°-210°, yields with barium hydroxide a white precipitate, turning violet, and combines with alloxan to form *benzoylalloxantin* $C_{15}H_{10}O_9N_4,H_2O$, or $1\tfrac{1}{2}H_2O$, m.p. 253°-255° (Behrend and Friederich, Annalen, 1906, 344, 1-18).

Substituted dialuric acids of the type

$$CO<^{NH \cdot CO}_{NH \cdot CO}>C(OH)R$$ are obtained by the

condensation of alloxan with (1) aromatic ketones, *e.g.* phenacyldialuric acid, where $R=C_6H_5 \cdot CO \cdot CH_2-$; (2) aromatic amines, *e.g.* *p*-aminophenyltartronylurea, where

$$R = NH_2 \cdot C_6H_4-;$$
(3) pyrazolone bases, *e.g.* phenylmethylpyrazolonetartronylurea, where

$$R= \begin{matrix} NPh \cdot CO \\ | \\ NMe \cdot CMe \end{matrix} >C-;$$

(4) phenols, *e.g.* *p*-hydroxyphenyltartronylurea, where $R=OH \cdot C_6H_4-$. For the preparation and technical application of these compounds, *see* art. ALLOXAN.

Methyl dialuric acid $C_5H_6O_4N_2 \cdot H_2O$ may be prepared by reducing dimethyl alloxantin with sodium amalgam, crystallises in round clusters of silky needles or narrow lancet-shaped leaflets, m.p. 167°-168° (corr.), or directly from theobromine on careful treatment with finely divided potassium chlorate in presence of hydrochloric acid crystallises in bundles of colourless glistening filaments, many of which widen to slender narrow leaflets. The molecule of water is driven off at 110°-120°. From alcohol the acid crystallises in anhydrous, stout, lustrous rhombohedra, m.p. 184°-185° (Biltz and Damm, Ber. 1913, 46, 3665-3667).

Dimethyldialuric acid

$$CO<^{NMe \cdot CO}_{NMe \cdot CO}>CH \cdot OH$$
obtained by reducing amalic acid (tetramethylalloxantin) with sulphuretted hydrogen (Maly and Andreasch, Monatsh. 1882, 3, 92), or with sodium amalgam (Techow, Ber. 1894, 27, 3082), forms colourless compact crystals which become red at 100° and decompose at 170° (cf. Biltz and Damm, ibid. 3667-3668); the acid crystallises with one molecule of water, which is partly lost in vacuum and completely at 110°. The hydrated acid has m.p. just under 100°, and decomposes about 210°. The anhydrous acid begins to discolour at 190°, and has m.p. 218° (corr.) with decomposition. It forms crystalline alkali salts, and reduces cold solutions of silver and copper salts.

*iso-***Dialuric acid**

$$CO<^{NH \cdot CH(OH)}_{NH \cdot CO}>C(OH)_2,H_2O$$
or $CO<^{NH \cdot CH(OH)}_{NH \cdot CO}>CO,2H_2O$, obtained by

the action of bromine water on *iso*-barbituric acid
$$CO<^{NH \cdot CH}_{NH \cdot CO}>C(OH)$$ or aminouracil or hy-

droxyxanthine (Behrend and Roosen, Ber. 1888, 21, 999), crystallises in trimetric prisms sometimes a centimetre long (Weinschenk, Annalen, 1889, 251, 243), is readily soluble in water, less so in alcohol; it loses one molecule of water of crystallisation at 100°. The other molecule, which is regarded as water of constitution, is lost at 140°-150°, at which temperature the compound decomposes. *Iso*dialuric acid is converted into dialuric acid by the action of bases (Koech, Annalen, 1901, 315, 246). It yields uric acid on condensation with urea, reduces solutions of silver salts, and combines with hydroxylamine to form two isomeric oximino- compounds. The

2 K

α- oxime forms shining plates or prisms, becomes red and decomposes at 100°; the β- oxime crystallises in needles which do not become red at 110° (Behrend and Roosen, Annalen, 251, 244).

Methylisodialuric acid $C_5H_6O_4N_2$, prepared by oxidising methylisobarbituric acid (Lehmann, Annalen, 1889, 253, 80) with bromine water, crystallises in rosette-like aggregates from water, and in contradistinction to isodialuric acid, contains only 1 molecule of water, which is regarded as water of constitution. M. A. W.

$$HO \underset{NH_2}{\overset{NH_2}{\diamondsuit}} SO_3H$$
is obtained by reducing a solution of sodium 2 : 6-dinitrophenol-4-sulphonate by zinc dust and hydrochloric acid. Used in the manufacture of azo dyes (Farb. vorm Meister, Lucius, and Brüning, D. R. P. 148212).

DIAMINOSTILBENEDISULPHONIC   ACID

$$NH_2 \diamondsuit \overset{}{CH : CH} \diamondsuit NH_2$$
$$\quad SO_3H \qquad SO_3H$$
may be prepared by adding zinc dust to sodium p-nitrotoluene sulphonate in a hot solution of caustic soda, until the liquid is decolourised, filtering and acidifying with hydrochloric acid. The precipitated diaminostilbenedisulphonic acid may be purified by re-solution in sodium carbonate, and reprecipitation with acid (Leonhardt and Co. D. R. P. 38735 ; cf. Bender and Schultz, Ber. 1886, 19, 3234). May also be obtained by reducing dinitrostilbenedisulphonic acid with ferrous hydroxide and ammonia (Green and Wahl, Eng. Pat. 5351, 1897 ; Ber. 1897, 30, 3100).

DIAMOND. Carbon crystallised in the cubic system. The contrast presented by the physical characters of the two forms of crystallised carbon—diamond and graphite—is very striking. Diamond is the hardest of minerals, and, indeed, of all known substances, but at the same time it is very brittle ; on the other hand, graphite is one of the softest of minerals, and it is flexible and inelastic. The one is colourless and transparent and a bad conductor of electricity, whilst the other is black and opaque and a good conductor. There is also a considerable difference in density, diamond, 3·52 ; graphite, 2·25. The name diamond, in French and German Diamant, and similar in most other European

languages, is a corruption of the Latin Adamas, which was used for this mineral by Manilius (A.D. 16) and Pliny (A D. 100). This came from Ἀδάμας, meaning invincible, a word applied by the Greeks to hard metals and stones. The similar name adamantine-spar was used by the chemist Joseph Black for corundum. Although diamond and corundum are numbered respectively 10 and 9 in the mineralogist's scale of hardness, and with no other mineral falling between the two, yet, as shown by abrasive tests, diamond is 140 times harder than corundum, and more than a thousand times harder than quartz (No. 7 on the scale). It is on this high degree of hardness that all the technical applications of diamond depend ; and a faceted gem never shows any signs of wear. Lapidaries assert that stones from Borneo and New South Wales are harder than those from other localities.

Crystalline Form.—Crystals of diamond are almost always found singly and with faces developed on all sides ; thus indicating that they grew freely from individual centres in some surrounding medium. By far the commonest form is the regular octahedron, the faces of which are often delicately marked with minute triangular pits or ' etched figures,' whilst the edges are nearly always rounded and often marked with a pronounced furrow. Other forms are a hexakis-octahedron (six-faced octahedron), and less often the rhombic-dodecahedron and the cube, while crystals of distinctly tetrahedral habit are rare. Nevertheless, it is probable that crystals of diamond are really hemihedral (tetrahedral-cubic) ; the apparent octahedron consisting of two tetrahedra interpenetrating in twinned position. Distinctly formed twinned crystals are not uncommon. These are contact-twins with a face of the octahedron as twin-plane, and the two individuals flattened parallel to this plane, giving a triangular plate with re-entrant angles at the three corners. These are known to the Dutch cutters as ' naadsteenen ' (suture-stones). In addition to the rounded edges, noted above, the faces themselves are often curved, sometimes to such an extent that the crystals are almost spherical in form. This rounding, as well as the etched figures, indicate that the crystals have been corroded subsequent to their growth. An important crystallographic character of diamond is the existence of perfect cleavages in four directions parallel to the faces of the octahedron. (On the crystallography of diamond, v. A. Fersmann and V. Goldschmidt, Der Diamant, Heidelberg, 1911).

Physical Characters.—In its optical characters, diamond is remarkable for its very high refractive and dispersive powers, the indices being : for red light (B) 2·40735, yellow (D) 2·41734, violet (H) 2·46476, and the dispersive value (H–B) 0·05741. The critical angles of total reflection corresponding with these indices are 24° 33', 24° 26', and 23° 56', respectively. The angles between the facets of the brilliant form of cutting adopted for the diamond are so arranged that a ray of light entering the gem by the front facet will meet the back facets at a greater angle than the critical angle, and will be internally totally reflected, passing out again from the front of the stone, and with a chance that rays of different colours will be separately

effected. A cut stone, therefore, shows much brilliancy or 'fire,' together with flashes of prismatic colours. Corresponding with the high refractive index, diamond displays a high degree of lustre, which is of the quality known as 'adamantine' lustre. Uncut stones, especially when not quite clear, and with rough rounded surfaces, present a peculiar and very characteristic lead-grey metallic appearance. When pure, diamond is without colour and perfectly transparent. The best stones are described as of the 'first water' or 'blue-whites.' More often there is a tinge of colour ('off-coloured' stones), usually pale yellow, brownish, grey, or greenish. Stones of a good canary-yellow, coffee-brown, or black colour are not uncommon, but those of rich shades of green, blue, or red are very rare. The nature of the colouring matter is uncertain, but it is probably inorganic (e.g. iron and titanium in the brown stones). Changes in colour may be effected by the action of heat or by exposure to radium emanations. Crystals of diamond being cubic, they should be optically isotropic, but when examined under the polarising microscope they are frequently seen to possess anomalous double refraction, especially around enclosures in the stone. This is due to a state of strain, which in some stones is so great that they burst. Phosphorescence is readily produced in diamond by the action of sunlight, ultraviolet, Röntgen, cathode, and radium rays, or simply by rubbing (triboluminescence) Diamond becomes positively electrified by friction. It is very transparent to the Röntgen rays; whilst glass imitations are opaque. Being a good conductor of heat, it can be distinguished from a glass imitation by touching with the tip of the tongue, diamond feeling much colder than glass. The specific heat is less than that of graphite, and it increases rapidly with the temperature.

Chemical Characters.—The combustibility of diamond was first proved experimentally by the Florentine Academicians in 1694. Lavoisier, in 1772, found that the presence of air was necessary, and that 'fixed air' resulted; but it was Smithson Tennant, in 1797, who first proved that equal weights of diamond and carbon yielded equal weights of carbon dioxide More convincing experiments in this direction have been made by Davy, Dumas and Stas, A. Krause (1890), and H. Moissan (1893). Powdered diamond burns readily in air at a red heat. Moissan determined the temperature of ignition in oxygen to be 690°–790°; according to Joly, it is 850° in air. It burns with a small pale-blue flame, and in oxygen is able to support its own combustion. It is infusible even in the electric arc; and it can be heated at high temperatures (1500°) without alteration in various gases (hydrogen, nitrogen, sulphur dioxide and trioxide, and nitrous oxide). In carbon dioxide, however, at 1200° the crystals are corroded, with formation of carbon monoxide. It is unattacked by acids, caustic alkalis, iodic anhydride, hydrogen potassium sulphate, or a mixture of sodium chlorate and nitric acid, but is oxidised when heated to 180°–230° in a mixture of potassium bichromate and sulphuric acid. In fused potassium nitrate or sodium carbonate at about 900° small etched figures are slowly produced; at 1200° the action is more rapid

carbon dioxide being liberated. It is acted upon by sulphur vapour at 900°; and it combines with iron, yielding steel. Crystals are etched by molten olivine (magnesium silicate). The fact that diamond gives with oxidising agents only carbon dioxide, whilst graphite yields graphitic oxide has led to the suggestion that these two forms of carbon are chemical isomerides. Observations at high temperatures are somewhat contradictory; a mere blackening of the surface has often been observed, but not always confirmed. C. Doelter (1911), with crystals packed in charcoal or thorium oxide and heated to 2500°, obtained only a superficial blackening without any alteration in the physical characters of the material. Moissan (1893), however, records the conversion into graphite at the temperature of the electric arc (about 3600°); and Parsons and Swinton (1907) found that a diamond placed in the focus of cathode rays *in vacuô* swelled up into a coke-like mass when the temperature reached 1890°. In this connection the occurrence of cubes of graphite (cliftonite) in meteoric irons is significant; these have been supposed to be paramorphs after diamond.

The ash remaining when diamond is burnt amounts, for colourless crystals, to 0 02–0 05 p c., but in the less pure carbonado it may reach 4·8 p c. It consists mainly of iron oxide and silica, with some lime, magnesia, and titanium. The iron and titanium may represent the colouring matter present in the stone; but the frequent presence of minute enclosures in diamond is not to be overlooked. In addition to liquid enclosures (carbon dioxide and water), the following materials have been recorded: black carbonaceous matter, ilmenite or hæmatite, quartz, rutile, iron-pyrites, gold, chlorite (?), apophyllite, &c.

Varieties.—Differing in certain points from the general characters enumerated above, there are two varieties of diamond—bort and carbonado—which, for technical purposes, are more important than the purer crystals used for gems. These are crystalline aggregates, as distinct from single well-developed crystals

Bort (boart or boort) consists of a number of individual crystals with a radial grouping around a common centre, giving rise to rounded exterior forms These are sometimes quite spherical ('shot-bort'). They are usually rough on the exterior, it being only here that the fibres, or individual crystals, have been free to develop crystal faces—in the interior these have interfered with each other's growth. Although each individual possesses the cleavage characteristic of diamond, yet for the whole mass there is no continuous cleavage. For this reason, bort is tougher than the single crystals, which readily split along the cleavage directions, and is thus better adapted for boring, turning, and cutting tools. This, no doubt, is the explanation of the common statement that bort is harder than diamond; further, since in crystals the degree of hardness varies with the direction, a chance section of bort will present both maximum and minimum values. The rounded pieces of bort are translucent to cloudy and opaque. They are grey or black with a greasy to metallic lustre, and, usually, a peculiar leaden appearance; sp.gr. 3·50. In the trade

the term bort also includes fragments (such as those obtained by bruting), and all crystals and stones that are useless for gem purposes. Such material is of value as an abrasive, but not for tools.

Carbonado, or ' black diamond ' (known in the trade as ' carbon ' or ' carbonate '), is a finely granular crystalline material, dull, black, and opaque, and often more or less porous, with somewhat the appearance of coke. It forms irregularly-shaped masses, and consists of a confused aggregate of minute crystal grains of diamond. It therefore presents no cleavage as a whole, and is consequently tougher and less frangible than crystals. It is less pure than ordinary diamond, yielding more ash (up to 4·8 p.c.) when burnt. An analysis of the ash gave Fe$_2$O$_3$ 53·3, SiO$_2$ 33·1, CaO 13·2 p.c.; MgO trace. The sp gr. is less, 3·15–3·34 (the value for crystals being between the limits 3·516–3·525). The largest known piece of carbonado was found in Bahia, Brazil, in 1895. It weighed 631·9 grams, that is, slightly more than the famous ' Cullinan ' diamond (which weighed 621·2 grams). Both carbonado and bort show considerable variations in texture, and with increasing coarseness of grain they may pass insensibly into ordinary diamond.

Occurrence.—India, from very remote times until the middle of the eighteenth century, was the only source of diamond (with the unimportant exception of Borneo). Since the discovery of the Brazilian and South African deposits the output has gradually fallen off, amounting in 1916 to only 20 carats. The secondary deposits have, however, only been worked by native methods, and the original deposits have not been discovered. Indian diamonds, being of the best gem-quality, there is thus a possibility of further developments. They occur associated with pebbles of jasper and vein-quartz in thin beds of conglomerate in the ancient sedimentary rocks (sandstones and shales) of the Vindhyan system (probably pre-Cambrian), which rest directly on the crystalline rocks. With the weathering of these strata, the diamonds are left on the surface or are accumulated in the alluvial deposits of the present rivers. The districts where mining has been done fall into three main groups : a southern group in the basins of the Pennar, Kistna, and Godavari rivers ; an eastern group in the Mahandi valley ; and a northern group near Panna in Bundelkhand. A doubtful occurrence of diamond in pegmatite has been described from Wajra Karur near Bellary ; and, unfortunately, nothing is known as to whence the diamonds found in the ancient sedimentary rocks were derived. (On Indian diamonds, *v*. Manual of the Geol. of India, vol. 3, Economic Geology, 1881, by V. Ball ; vol. 4, Mineralogy, 1887, by F. R. Mallet.)

In *Brazil*, diamonds were discovered about 1725 in the alluvial gold-washings, at Tejuco (now Diamantina) in Minas Geraaes ; and, although they have been since found in several other districts, notably in Bahia, this has remained the principal diamond-mining centre. Here, as in India, the diamond-bearing alluvial deposits have been derived from conglomerates and sandstones (including the flexible sandstone known as itacolumite) of considerable geological age, and the original rock from which these were derived is not known. The Brazilian deposits are, however, remarkable for the variety of minerals found as well-worn pebbles (' favas ') in association with the diamond ; and the nature of these minerals, or indicators, has led to the suggestion that they, together with the diamonds, originally came from quartz-veins. (On Brazilian diamonds, *see* Mineralogical Papers by O. A. Derby and by E. Hussak ; also E. Hussak, Os Satellites do Diamante, Rio de Janeiro, 1917 ; H. Preston, J. Soc. Arts, 1909, lviii. 101.)

In *South Africa*, diamonds were first discovered in 1867 near Hopetown on the Orange River. In 1868 the important workings (' river diggings ') on the Vaal River were commenced ; and in 1870–1871 the diamonds were traced to deposits of an unique type, in the neighbourhood of which the town of Kimberley in Griqualand West, Cape Province, very quickly sprung up. Here are situated the famous mines De Beers, Kimberley, Dutoitspan, Bultfontein, and Wesselton. Other mines of the same type are the Jagersfontein and Koffyfontein mines in Orange Free State, and the great Premier mine (discovered in 1902) near Pretoria in the Transvaal. The diamond-bearing rock of these mines fills volcanic pipes, 200–300 yards (in the case of the Premier mine half a mile) across, penetrating vertically the surrounding beds of basalt, shale, diabase, and quartzite, and extending to unknown depths. The rock, known as kimberlite, or locally as ' blue ground,' consists mainly of a hydrated magnesium silicate with much the same composition as serpentine. It contains boulders and broken fragments of various rocks (basalt, shale, sandstone, quartzite, granite, mica-schist, eclogite. &c.) and minerals (ilmenite, pyrope, enstatite, chrome-diposide, iron-pyrites, &c.), and is of the nature of a volcanic agglomerate. Diamond is present in this rock on an average of one part in forty millions, and in the richest part of the Kimberley mine one part in two millions. Numerous pipes of a similar character, but containing few or no diamonds, are scattered over a wide area in South Africa. The diamond was brought from below up with the igneous material, which must have been derived from a basic magma rich in olivine. Although the origin of diamond has been the subject of much discussion, there seems no reason to doubt but that it crystallised from this basic magma. The rare presence of diamonds embedded in boulders of eclogite (a garnet-pyroxene rock) found in the blue ground has led to the suggestion that this is the mother-rock ; but it is quite conceivable that the mineral crystallised from more than one kind of basic magma.

The early open workings (' dry diggings ') at the Kimberley mines were soon replaced by a regular system of underground mining. The blue ground, when brought to the surface, is either directly crushed or is spread on floors and exposed to the action of the weather for about a year, when it is crumbly enough to enable the heavy minerals to be separated by washing. From this concentrate the diamonds are separated by means of a mechanical sorting table coated with grease, to which the diamonds adhere, whilst the other minerals pass over. Finally, the stones are cleaned by boiling in a

solution of caustic soda and in aqua regia or hydrofluoric acid. Diamonds also occur in gravels in the Somabula Forest in Southern Rhodesia, and kimberlite pipes have been described as present in this region. In 1908 large numbers of small diamonds were found in the sand-dunes on Lüderitz Bay in South-West Africa; in this case the source of the diamonds have not yet been traced. The output of South African diamonds amounted in 1913 to over five million carats (approximately one ton), valued at 11,389,807*l*. (On South African diamonds, *v.* G. F. Williams, The Diamond Mines of South Africa, 2nd edit. New York, 1907; P. A. Wagner, The Diamond Fields of Southern Africa, Johannesburg, 1914.)

Other diamond-producing countries of less importance are Borneo, New South Wales, and British Guiana. Finds have been reported from many of the states of North America, in British Columbia, Mexico, Dutch Guiana, Russian Lapland, the Ural Mountains, Siberia, China, Western Australia, South Australia, Queensland, Tasmania, Belgian Congo, Gold Coast, and Liberia. In most of these cases the mineral has been found as a few scattered stones in alluvial gold washings. But in Arkansas and British Columbia it has been found in an altered (serpentinised) peridotite of much the same character as the South African ' blue ground.'

The presence of diamond in certain *meteorites* is of special interest. It was first observed in the stone which fell on September 4, 1886, near the village of Novo-Urei on the Alatyr river in Govt. Pensa, Russia. This stone is composed of olivine (67·5 p.c.) and augite (23·8 p.c.), together with nickel-iron, troilite, chromite, black carbonaceous matter, and about 1 p.c. of diamond, the last as minute greyish grains. As dull black grains it has also been found in the meteoric stone of Carcote, Chili. In several, though not in all, of the masses of meteoric iron from Cañon Diablo in Arizona, it has been found as colourless crystals, and as black and colourless grains, the largest 1 mm. across. It is also recorded from the meteoric iron of Magura, Hungary. The cubic form of graphite (cliftonite), probably a pseudomorph after diamond, has been found in the meteoric irons of Youndegin (Western Australia), Smithville (Tennessee), Crosby's Creek (Tennessee), and Magura (Hungary).

Origin and Artificial Production.—The occurrence of diamond in acid igneous rocks and in quartz-veins is very doubtful. On the other hand, its presence in basic igneous rocks is well established ; *e.g.* in kimberlite and eclogite in South Africa, in serpentinised peridotite in Arkansas and British Columbia, and in diabase in New South Wales ; whilst in meteoric stones the matrix is also of the same general character. In these cases the diamond is very probably present as a primary mineral, and one of the first constituents to crystallise out from the basic silicate magma. In addition, we have the occurrence of diamond in the nickel-iron of meteorites. This may be regarded as a magma of a still more basic type, and it is thus probable that diamond may crystallise from basic magmas of widely varying composition.

Many attempts have naturally been made to constrain the abundant element carbon to crystallise as the rare and valuable diamond, but, as yet, with no great measure of success. The results have in many cases been doubtful, and have often not been confirmed. The products are always microscopic and their identification a matter of difficulty. In some cases the very hard carbides of silicon, &c., have probably been mistaken for diamond. The experiments of I. Friedländer (1898), and of R. von Hasslinger (1902–1903), in which carbon was dissolved in molten magnesium silicate (olivine or kimberlite), bear some relation to the natural occurrences, but doubts have been expressed as to whether the microscopic crystals so obtained were really diamond. E. de Boismenu (Fabrication synthétique du diamant, Paris, 1913) states that he obtained crystals up to 2 mm. across by the electrolysis of fused calcium carbide. The only method, however, that has been amply confirmed is that first used by R. S. Marsden (Proc. R. Soc. Edinburgh, 1881, xi. 20) and elaborated by Moissan (1893–1896 ; Le Four électrique, Paris, 1897 ; and The Electric Furnace, London, 1904), in which carbon is dissolved in silver or iron at a high temperature and the mass suddenly cooled by immersion in water or lead. A contracting crust is so formed and the molten interior subjected to great pressure. Sir C. A. Parsons (Bakerian Lecture, Phil. Trans. 1919, A 220, 67 ; and J. Inst. Metals, 1918, xx.) from a long series of experiments, however, concludes that pressure is not a necessary condition, and that the diamond has been formed from gases, probably carbon monoxide, occluded in the iron. O. Ruff (Zeitsch. anorg. Chem. 1917, 99, 73), in a systematic repetition of the various methods, also obtained negative results except by Moissan's method. The presence of microscopic diamonds in certain kinds of hard steel should finally be noted.

Applications.—The value of diamond as a gem depends on its high degree of hardness, enabling it to resist wear, and its high refractive and dispersive power. These optical characters are, however, only brought into full play when the stone is facetted in a particular manner ;
Brilliant-cut.   Rose-cut.
and for this reason, old stones cut by Indian lapidaries have often been re-cut. The form most suited for this purpose is the brilliant-cut, and stones so cut are known as brilliants. The rose-cut, or rosette, is only used for quite small stones usually mounted in number as a surround. The accompanying figures show a brilliant

viewed on the large front facet, or table, and a side-view; and the rose-cut, viewed from above and the side. Being the hardest known material, diamond can only be worked very slowly and tediously with its own powder. The ground-form of the brilliant is approximately an octa-hedron, and this can be obtained, if necessary, by cleavage, or more safely by the modern method of sawing with a thin metal disc charged with diamond dust. The brilliant is then roughly shaped out by rubbing two diamonds together—a process known as bruting. The final grinding and polishing of the facets is performed on a rapidly revolving cast-iron disc fed with diamond dust and olive-oil.

The large historical diamonds with their associations of mystery and romance are mostly of Indian origin; but these are now eclipsed by the numerous, much larger stones found in South Africa. The largest Indian stone still preserved is the 'Koh-i-noor,' which was re-cut in England in 1852 as a brilliant of $106\frac{1}{16}$ carats [1] ($=21\cdot786$ grams). The largest Brazilian stone, the 'Star of the South,' found in 1853, weighed in the rough $254\frac{1}{2}$ 'carats,' and when cut 125 'carats.' The largest known crystal of diamond is the 'Cullinan,' which was found in 1905 in the Premier mine, Transvaal. This showed a large cleavage surface, and was only a portion, probably about half, of the complete crystal. The portion as found weighed $621\cdot2$ grams (3106 metric carats, or nearly 1 lb. 6 ozs. avoir-dupois). Being too large to cut as a single stone, it was cleaved and cut as nine larger gems (weighing from $106\cdot04$ to $0\cdot88$ grams) and ninety-six small brilliants, the yield of cut material amounting to $34\frac{1}{2}$ p.c. The 'Cullinan,' although the largest crystal, is not the largest piece of diamond that has hitherto been dis-covered. A mass of carbonado weighing $631\cdot9$ grams was found in 1895 in Bahia, Brazil.

As an abrasive, diamond powder is the most effective agent available. It is the only material with which diamond itself can be worked, and it is much used by lapidaries for cutting other hard stones. A thin disc of soft iron charged on the edge with diamond powder is used for sawing stones, both for ornamental purposes and in the preparation of thin microscopic sections of rocks. The small steel tools used by engravers of cameos and intaglios, and also the steel points used for boring precious stones, &c., are charged with diamond dust. The material used for abrasive purposes, though included in the trade under the term bort, consists largely of the waste material from shaping the better stones as brilliants, and also the less clear and spotted crystals not suitable for cutting as gems. It is crushed in a diamond-mortar, splinters suitable for other purposes being picked out under a magnifying-glass, and the remainder reduced to a fine powder.

The glazier's diamond is a crystal or frag-ment bounded by two rounded crystal-faces meeting in a curved, or cusped, cutting edge.

[1] This was the old English carat of $205\cdot409$ mg. A later value of the English carat, as defined by the Board of Trade in 1888 and 1889, was $205\cdot304$ mg. The carat-weight has now been standardised in all countries as the *metric carat* of 200 mg. (5 carats = 1 gram). This is the only legal value of the carat in the British Isles since April 1, 1914. *

For writing, drawing, and engraving (*e.g.* fine scales and rulings) on glass, metal, stones, ivory, &c.) fine splinters are used, or the diamond may be cut to a rounded point or chisel-edge. Diamond points are also used for drilling hard stones, glass, porcelain, teeth, &c.

Carbonado and bort, by reason of their absence of cleavage, are much more suitable than ordinary diamond for mounting as small fragments (2–3 carats in weight) as cutting tools which may be subjected to shocks. These are mounted in the crowns of rock-drills, used in tunnelling, mining, and sinking bore-holes for artesian wells, &c.; and on the edges of blade, band, circular, or wire saws for sawing large blocks of marble, granite, &c. Fragments, either in a rough form, or fashioned to a suitable shape, are mounted as lathe tools for working stone, metal, &c. For example, for turning electric-light carbons, the edges of watch-glasses, finishing accurate turning work of the hard steel axles of instruments and machines of pre-cision, boring cannon, forming the sharp-edged furrows on the grinding surfaces of millstones, for dressing emery wheels, &c.

Small cleavage plates or flat crystals of diamond drilled from each side with fine conical holes are used for drawing fine wire, down to $0\cdot01$ mm. in diameter. For the tantalum, tungsten, and osmium filaments of electric lamps the metal is forced by pressure through the hole. Bored diamonds are also used for the pivot-supports of delicate instruments, such as chronometers, electric meters, &c.

The application of diamond for optical purposes is limited by the high cost and difficulty of working. Diamond lenses would need to have a much slighter curvature than those of glass, and they would be immune from scratch-ing. Microscope objectives with such lenses were constructed by Pritchard under the direc-tion of C. R. Goring, in 1824–1826. A hemi-sphere of diamond would also increase consider-ably the range and durability of refractometers.

DIASPIRIN. Trade name for succinyl salicylic acid.

DIASPORE. A native hydrated alumina, $Al_2O_3 \cdot H_2O$ or $AlO(OH)$, crystallising in the orthorhombic system and isomorphous with goethite and manganite. It is usually found as scales or foliated masses with a perfect cleavage in one direction on which the lustre is pearly ; but it is readily distinguished from other foliated minerals (mica, &c.) by its much greater hardness (H.$=6\frac{1}{2}$-7). Sp.gr. 3·4. When heated before the blowpipe it decrepitates violently, breaking up into pearly white scales (hence the name diaspore, from διασπείρειν, to scatter). In colour, it is usually grey or yellowish-brown, but pale-violet crystals are also found. It is usually found as an alteration product of corundum and emery, but occurs also as a mineral of contact-metamorphic origin in crystalline limestones. It is of importance as a constituent of bauxite, and in a particular type of bauxite, called diasporite, occurring in crystalline limestone in the Bihar Mountains, Hungary, it constitutes the bulk of the material. L. J. S.

DIASTASE or *Amylase* is the name given to the enzyme or mixture of enzymes which converts starch and glycogen into maltose. In France, the word ' diastase ' is used as a general term for all enzymes, a custom which causes considerable confusion, and which it is to be hoped will lapse.

Diastase is very widely distributed in plants and in animals. It is found in blood serum, in muscle, liver and pancreas, and particularly in the saliva, this latter enzyme being long known under the name *ptyalin*.

The power of germinated barley to hydrolyse starch was discovered by Kirchoff in 1814, and the enzyme preparation was first made by Payen and Persoz in 1833. Diastase is found very generally in the leaves and twigs, in the germinating seeds, in the bark, in the pollen grains, and in the latex of plants. It occurs in yeast and in most of the mould fungi, the enzyme of *Aspergillus oryzæ*, the so-called *Taka diastase* being well known on account of its industrial use in the manufacture of the Japanese beverage, koji.

Diastase, like all other enzymes, has not been prepared in anything approaching a pure state. Considerable uncertainty exists also as to whether it is a single enzyme or a mixture of enzymes acting in turn to convert starch into dextrin and dextrin into maltose. Modern evidence favours the view that it consists of a starch-liquefying enzyme or *amylopectase*, and a saccharifying enzyme able to hydrolyse soluble starch, but without much action on raw starch until this has been rendered soluble by the amylopectase. The two enzymes are found together, but in unequal proportions. Wheaten flour, for example, frequently has a deficiency of liquefying enzyme.

There are well-marked differences between the enzymes present in resting barley and in malt (*cf.* Lintner and Eckhardt, Zeitsch. Ges. Brauw. 1899, 389 ; J. L. Baker, Chem. Soc.

Trans. 1902, 81, 1177), one or the chief of these being that the diastase of raw grain possesses little if any starch-liquefying power. Baker has shown that the products of hydrolysis of starch by alcohol-precipitated enzymes from the two sources, are not the same. Brown and Morris have termed the enzyme of resting barley ' translocation diastase,' that of malt ' secretion diastase ' (Chem. Soc. Trans. 1890, 58, 458 ; 1893, 63, 604). They regarded these as not only different in their actions, but as formed from different materials. This latter assumption has been disputed (*cf.* Ling, J. Inst. Brewing, 1908, 14, 494 ; Ford and Guthrie, *l.c.*, 1908, 14, 61).

Some authors consider the saccharifying enzyme to be a mixture, attributing a different enzyme to each stage in the simplification of the starch molecule. It is impossible at present to make any definite statement on this point. In support of it, it appears that exposure to a temperature of 68° acts more injuriously on the conversion of dextrin to maltose than on that of starch into dextrin. Heating diastase does not affect the liquefying power, though the saccharifying action largely disappears.

The quantity of diastase contained in the barley grain increases gradually in the course of germination : it is said to reach a maximum in about 8 or 9 days, when the plumules are twice as long as the grains.

Diastase as it exists in cereals is partly present as an insoluble zymogen in combination with protein substances which are capable of attack by pepsin ; in solution the enzyme is free and unaltered by pepsin. The dissolved enzyme is more active as the amount of nitrogen in solution increases.

Preparation.—A great variety of methods have been proposed for the preparation of diastase, the majority of these starting from malt. According to O'Sullivan (Chem. Soc. Trans. 1884, 45, 2), finely ground pale barley malt is saturated with water, adding enough to slightly cover it and after 3–4 hours as much of the solution as possible is expressed by means of a filter press. After filtering, alcohol (sp.gr. 0·83) is added, as long as a flocculent precipitate forms, the addition being discontinued as soon as the liquid becomes opalescent or milky. The precipitate is collected, washed with alcohol of increasing strength until dehydrated, pressed between cloth and dried *in vacuo* over sulphuric acid.

Lintner (J. pr. Chem. 34, 378) treats 1 part of green barley malt or flour of air-dried malt with 2 to 4 parts of 20 p.c. alcohol for 24 hours, and precipitates the extract with $2\frac{1}{2}$ volumes of absolute alcohol. The precipitate is washed with alcohol and ether to dehydrate it, and dried *in vacuo*.

Loew extracts germinated barley with 4 p.c. alcohol, and precipitates the extract with basic lead acetate. The precipitate is suspended in water, lead removed with hydrogen sulphide, and the enzyme precipitated with a mixture of alcohol and ether.

Wroblewsky extracts finely powdered malt, first with 70 p.c. and then twice with 45 p.c. alcohol. Alcohol is added to the two last extracts until 70 p.c. is present, the precipitate formed is collected, washed with alcohol and ether, and dried.

For further purification, both Wroblewsky

and Osborne and Campbell dissolve the enzyme in water, and precipitate it with ammonium sulphate, which is added drop by drop, until the liquid contains 50 p.c. On standing, a very active yellowish flaky precipitate is obtained.

Green barley malt may also be extracted with glycerol, and the diastase precipitated by alcohol. Effront extracts with water and induces alcoholic fermentation in the extract so as to remove carbohydrate and protein matter. It is then filtered and the diastase precipitated by alcohol.

Animal diastase is best obtained from saliva. Cohnheim uses freshly prepared calcium phosphate as precipitant, extracts this precipitate with water, and adds alcohol to obtain the enzyme. Alcohol is also used for direct precipitation, likewise ammonium sulphate. Von Wittich extracts pancreas diastase with glycerol.

For the preparation of an active diastatic extract for laboratory use, ground malt should be extracted with twenty times its weight of distilled water at 21° for 3 hours and filtered bright.

The diastase of *Aspergillus oryzae* is sold in commerce as Taka-diastase. A pure form can be prepared from the commercial article by extracting with water, precipitating with ammonium sulphate, dissolving the precipitate in water, dialysing and finally precipitating fractionally with alcohol.

Preparations of diastase obtained as described above are colourless, amorphous, and friable, readily dissolving in water; but if allowed to dry without being dehydrated, they are horny and not easily penetrated by water. They invariably contain ash, which consists of potassium, calcium, and magnesium phosphates, with a trace of sulphate. They give a deep blue colour with a 1 p.c. alcoholic solution of gum guaiacum and hydrogen peroxide.

Lintner's diastase gave the reactions of the proteins, and was found to contain C, 46·66 p.c. ; H, 7·35 p.c. ; N, 10·42 p.c. : S, 1·12 p.c., calculated on the ash-free product. Osborne (Ber. 1898, 31, 254) found for his most active preparation, which had a diastatic power of 600 and contained 0·66 p.c. of ash, C=52·5 p.c., H =6·72 p.c.; N=16·1 p.c., S=1·9 p.c. ; and Wroblewsky gives N=16·5 p.c. for his purest diastase. Both authors regarded diastase as a protein combined, according to Osborne, with a proteose.

The most recent work of Frankel and Hamburg (Beitr. Chem. Physiol. n. Path, 1906, 8, 389) leads to the conclusion that diastase contains neither protein groups nor reducing carbohydrates in its molecule. Impurities were removed from the enzyme solution with lead acetate, the solution sterilised by filtration, and further purified by fermentation with a yeast which had been rendered nitrogen-hungry. This preparation could be divided by dialysis into two distinct enzymes, one of which — the saccharifying—passed through the paper, while the other—the liquefying—was left behind. It showed absence of typical protein reactions, but contained a pentose in small amount.

The purified diastase preparations obtained by Pribram (Biochem. Zeitsch. 1912, 44, 293) from malt extract contained 7·7 p.c. of nitrogen and 1·5 p.c. of ash ; one-sixth of the nitrogenous matter separated as a coagulum on heating. The filtrate on hydrolysis with sulphuric acid

yielded a reducing substance which was considered to be a polycarbohydrate acid which existed in the enzyme in combination with a simple polypeptide. The purified diastase was inactive, but is activated by the addition of traces of lactic acid.

Particularly active preparations have been obtained by Sherman and Schlesinger (J. Amer. Chem. Soc. 1913, 35, 1617) by extracting ground malt with two and a half times its weight of water or very dilute acid phosphate solutions at as low a temperature as possible, with subsequent dialysis, followed by fractional precipitation with alcohol or acetone. The products obtained had a diastatic power of 1800-2200 on the Lintner scale.

The most active preparations contained most nitrogen—about 14 p.c. in maximum. When tested by the Van Slyke method they contained combined nitrogen in all the usual eight forms, the proportions being within the range of variation shown by typical protein substances. The optimum hydrogen ion concentration expressed by Sörensen's exponent was between p_H^+ 4·2 and 4·6 (J. Amer. Chem. Soc. 1915, 37, 623). The purified amylases obtained from the pancreas and from malt are similar in physical properties, show the same qualitative reactions and have the same percentage of nitrogen distributed in the same way among the different types of amino acid radicals (J. Amer. Chem. Soc. 1915, 37, 1305).

The activity of diastase is very greatly influenced by the nature of the substrate on which it acts, more particularly as to whether this is alkaline or acid. Certain substances, such as the amphoteric amino- acids and asparagine, also ammonium and calcium phosphate, increase the activity, asparagine being especially effective in some instances. Vegetable diastase exhibits the maximum activity in presence of traces of weak organic acids. The very smallest quantities of alkali stop action, though this begins again as soon as the alkali is neutralised. In reality, the above accelerating substances are all of acid nature, and the apparently favourable effect of acid is due not to the acid *per se*, but to its neutralising alkaline impurities present. Maximum activity is attained in neutral (in the sense that water is neutral) solution. Minute traces of metallic impurities have an adverse influence. The temperature of maximum activity of diastase is about 55°; heated above this, it begins to show decomposition.

Estimation of diastatic power.—Since it has not been obtained in a pure state, the absolute estimation of diastase is an impossibility ; moreover, the very great influence of external conditions on diastatic activity, to which allusion has been already made, makes it difficult to do more than compare the relative activities of a number of materials under precisely similar conditions. As this is an important operation in brewery control, the methods of analysis have been accurately laid down. The diastatic power is often termed the Lintner value, and expressed in degrees Lintner. The standard is 100° when 0·1 c.c. of a 5 p.c. solution of malt, acting on a 2 p.c. solution of soluble starch for 1 hour at 70°F., produces reducing sugar equivalent to 5 c.c. of Fehling's (Barreswil's) solution.

To obtain accurate results, great stress must be laid on the purity of the distilled water and soluble starch used: commercial starches are frequently alkaline. All work must be carried out in hard-glass apparatus (cf. Ford, J. Soc. Chem. Ind. 1904, 23, 8).

The method adopted by the Malt Analysis Committee of the Institute of Brewing (J. Inst. Brewing, 1906) for malt, is as follows: 25 grams ground malt are extracted with 500 c.c. of distilled water for 30 hours at 70°F. and filtered bright. 3 c.c. is allowed to act on 100 c.c. of 2 p.c. soluble starch at 70°F. for 1 hour. Diastatic action is then stopped by the addition of 10 c.c. N/10-sodium hydroxide, and the liquid made up to 200 c.c. Sugar is then determined either volumetrically or gravimetrically. The results are calculated by the formula

$$\text{Diastatic power} = 1000/xy$$

where x=the number of c.c. of malt extract contained in 100 c.c. of the fully diluted starch-conversion liquid, and y=the number of c.c. of the same liquid required to reduce 5 c.c. of Fehling's solution. When the diastatic capacity exceeds 50°, 2 c.c. or less of malt extract are taken, particularly for the malts over 80° used by distillers and vinegar makers. The diastatic power of English brewing malt ranges between 35° and 40°, that of green malt from 110°–125°, showing that a large proportion of the enzyme is destroyed during the kilning.

Lintner tests solid preparations of the purified enzyme by dissolving 0·2 to 0·5 gram in 50 c.c. water and adding to a series of test-tubes, each containing 10 c.c. of 2 p.c. soluble starch solution, 0·1, 0·2, &c., up to 1 c.c. of the enzyme solution. After an hour, each tube is boiled in the water-bath with 5 c.c. of Fehling's solution, and that determined in which the copper solution is just completely reduced. A second series enables this point to be ascertained with greater accuracy.

Similar methods have been based on the colourations with iodine, shown by starch and dextrin solutions. Wohlgemuth sets increasing quantities of enzyme in a series of tubes with 5 c.c. of a 1 p.c. starch solution under precisely similar conditions. After 30 to 60 minutes at 40°, the tubes are cooled in ice and a drop of N/10 iodine solution added. Colours varying from dark-blue, blue-violet, reddish-yellow, and yellow are obtained. Wohlgemuth selects the tube in which the violet shows as indicating complete conversion to dextrin.

Diastase, like other enzymes which act on carbohydrates, is much affected by the products of its activity with which it forms adsorption compounds—hence the peculiarities exhibited in a starch conversion. Provided that the temperature and other conditions selected are such that the enzyme is not destroyed, the diastase recovered at the end of a reaction is just as active towards a second quantity of starch as an equal portion of fresh enzyme. Diastase is thus a true catalyst (cf. Van Laer, Bull Soc. chim. Belg. 1912, 26, 223).

Uses.—Diastase plays a most important part in the brewing, distilling, and baking industries. Malt extracts, concentrated in vacuo at a low temperature to viscid syrups, are largely used by bread bakers and in some food preparations. Considerable quantities of such active preparations, made from malts of high diastatic power, also find employment in laundries for the purpose of removing starch from stiff collars, shirts, &c. (See also articles STARCH; FERMENTATION; HYDROLYSIS.)   E. F. A.

DIATOMITE (Diatomaceous Earth, Infusorial Earth, Tripolite or Tripoli; Ger. Kieselguhr, Bergmehl). A form of opaline silica consisting of the siliceous remains of diatoms (Diatomaceæ). These are unicellular, free-swimming plants belonging to the large group of Algæ. The cell-wall, or frustule, of each minute individual consists of two shields or valves of siliceous material with elaborate and beautiful ornamentation. More than 10,000 species of diatoms have been described; they vary considerably in form—fusiform, elliptical, discoidal, globular, and acicular. Material composed of individuals of the acicular form, the length of which varies from 0.093 to 0.156 mm. and the thickness 0·00156–0·00468 mm., is best suited for technical purposes. Diatoms multiply extremely rapidly and inhabit both fresh and salt water, being more abundant in cold latitudes. On death, their remains accumulate, under certain conditions, at the bottom of swamps, lakes, or the open ocean. Besides being formed at the present day, such deposits are also met with in strata of Pleistocene and Tertiary age.

Diatomite is a loose, pulverulent material with a mealy or earthy texture, resembling soft chalk or dried clay in appearance. It is friable between the fingers with a harsh feel, and grates between the teeth. In colour it is white, grey, yellowish, brownish, or greenish. It is very light, floating on water; sp.gr. of air-dried material 0·24 and of calcined 0·34. Its high degree of porosity depends on the fact that the shells of the diatoms are hollow. Good material absorbs four or five times its weight of water. Further, it is a bad conductor of heat, electricity, and sound, and is resistant to heat and most chemicals. Of acids, only hydrofluoric attacks it, but it is slowly dissolved by a hot solution of caustic alkali. Chemically it consists of hydrated silica, mixed with various impurities, such as sand, hydroxides of iron, clayey, calcareous, and organic matter. 70–90 p.c. of SiO_2 may be present.

Analysis I, is of white material (dried at 105°) from Auxillac, Cantal, Auvergne; II, of green material from Auxillac; III, from Loch Cuithir (or Quire), Skye, Scotland; IV, from Richmond, Virginia; and V, of Tripolite from Bilin, Bohemia (including also SO_3 0·12, P_2O_5 0·24, NH_4 0·03).

	I.	II.	III.	IV.	V.

Organic matter	1·74	4·17	4·15	—	4·20

Tripolite (Ger. Tripel, Polierschiefer=polishing shale) differs from diatomite in being more compact with a laminated structure and consequently less light (sp.gr. 1·86) and porous. It merely represents the same material of a greater geological (Tertiary) age.

The most extensively worked deposits of typical diatomite (Kieselguhr) are those on the Luneburger-Heide (heath) in Hanover. Here beds with a thickness of 10–15 metres occur in basins in Pleistocene sands. The uppermost layers are white, below they are grey, and at the bottom of the deposit green. The green material contains from 15 to 30 p c. of organic matter, sufficient for calcination without addition of fuel. A bed of 5-7 metres covered by Tertiary clay and basalt is worked at Vogelsberg near Altenschlirf in Hesse. Similar deposits of recent to Miocene age are also widely distributed in the volcanic region of central France (Departments of Cantal and Puy-de-Dôme). Here the material is known as *randannite* and *ceyssatite*, from Randanne and Ceyssat respectively; and it is worked commercially under the name *tellurine*. (On the French and German deposits, see C. Schmidt, Ann. des Mines, Paris, 1910, xvij. 370.) Deposits are met with in peat-bogs at several places in Scotland, and beds up to 40 feet in thickness of good quality material are now worked at Loch Cuthir (or Quire) in the parish of Kilmuir in Skye (W. I. Macadam, Min. Mag. 1884, vi 87; 1886, vii. 30, 35; 1889, viii. 135. Special Reports on the Mineral Resources of Great Britain, Mem. Geol. Survey, 1916, vol. v.). Similar deposits also occur in Co. Antrim (J. H. Pollok, Sci. Proc. R Dublin Soc. 1899, ix. 33). Extensive deposits, many of them of Tertiary age, are of wide distribution in the United States, especially in California, (H. Ries, Economic Geology, New York, 1916). Other localities are Monte Amiata in Tuscany, Victoria,[1] Norway, Denmark, Hungary, Algeria. Chili, &c. The typical tripolite forms yellowish-white bands 0·5-1·5 m. thick in beds of clay, gypsum, and 'Saugschiefer' (absorbent shale) in a Tertiary basin near Bilin in Bohemia.

In the preparation of the material for the market, that of the purer white quality, after being dug out from open pits, is simply air dried in the open or in sheds. Organic matter is removed by calcination. Less pure material, containing sand, &c., is treated by washing and sedimentation. Iron is removed by the action of acids.

The varied uses of diatomite depend 'on its peculiar properties of porosity, lightness, nonconductivity, resistance to heat and acids. It was used by the Greeks and Romans for making light fire-proof tiles; and in the middle ages was mixed with meal for bread, under the impression that it had a medicinal value. As an absorbent it has been much used with nitroglycerine for the manufacture of dynamite. The so-called dry sulphuric acid is prepared by saturating calcined diatomite with three or four times its weight of acid. Such material can be transported with little risk. Diatomite packed around carboys of acid will soak up leakage in case the vessels become cracked. It has also been used as an absorbent of bromine, disinfectants, and liquid manures. On account of its non-conductive properties it is used, sometimes with asbestos, as a light packing material for boilers, steam-pipes, cooking-stoves, safes, refrigerators and refrigerating apparatus, fire-proof and sound-proof floors and partitions of buildings, bulkheads of ships, &c. Mixed with clay, lime, sawdust, &c., it can be used in the manufacture of fire-proof bricks and tiles; and having a low coefficient of expansion such material is specially adapted for making tubes, models, &c. It is used in the manufacture of various cements and artificial stones. Mixed with magnesia cement it gives a fire-proof cement for stoves; with shellac, sealing-wax and gramophone records are made. It is also used as a filtering material for liquids and gases; and various liquids (wine, beer, acids, oil, syrups) can be clarified by stirring with 1 p.c. of diatomite and allowing to settle. As a filler it is employed in the manufacture of rubber, cotton fabrics, paints, safety matches, paper, papier-mâché, soap, scouring-powders, tooth-powders, &c Fused with calcium and magnesium borates it yields a non-cracking glass for glazes and enamels, which can also be used for painting on glass. As a source of silica, it is used in the preparation of sodium silicate, ultramarine, smalt, &c. Finally, as an abrasive (*qv*) it, particularly the tripolite variety, is used for polishing metals and stoves. (*Ref.* B. Dammer and O Tietze, Die Nutzbaren Mineralien, Stuttgart, 1913, vol. i; Diatomaceous Earths (Kieselguhr) and their Utilisation, Bull. Imp. Inst. London, 1905, iii 88–103. L. J. S.

DIAZINE BLACK, -BLUE, -GREEN *v.* Azo-colouring matters.

DIAZO- COMPOUNDS. These organic substances, like the azo- compounds, contain the characteristic group —N_2—, but whereas, in the latter series, this bivalent radical is invariably attached to two carbon atoms, $C·N_2·C$, in the former it is generally, although not invariably combined with only one carbon atom, the other valency being satisfied by (1) an electro-negative ion $\bar{A}c$ in the *diazonium salts* $C·N_2·\bar{A}c$; (2) an oxygen atom in the *diazohydroxides* (' *diazohydrates* ') $C·N_2·OH$ and *diazo-oxides* (' *diazotates* ') $C·N_2·OR$; (3) a nitrogen atom in *diazoamines* (*diazoamino- compounds*)

$$C·N_2·NHR$$

and *diazoimines* (*azimino-compounds*)

$$C·N_2·NH·C;$$

(4) a sulphur atom in *diazosulphonates*

$$C·N_2·SO_3K$$

and *diazosulphides* $C·N_2·S·N_2·C.$

The *diazocyanides* $C·N_2·CN$ contain the azo-group attached to two carbon atoms, one of which belongs to a cyanogen group, and these compounds which, in general, are distinctly coloured, form an intermediate group between the fore-going diazo- derivatives and the azo- compounds.

Certain aliphatic diazo- compounds (*v. infra*) contain the group —N_2— attached by two active valencies to the same carbon atom.

I. Diazonium Salts.

These diazo- derivatives are generally, but not exclusively, prepared from aromatic amines, and the process, which is termed *diazotisation*, is

carried out with the undissociated salt of the amine, and not with the free base. In a hydrolysing solvent like water, it is therefore customary to diazotise aniline and its derivatives with sodium nitrite (1 molecule) and excess (2½ to 3 equivalents) of mineral acid.

AROMATIC DIAZONIUM SALTS.

The diazotisation of the benzenoid and naphthalenoid amines is frequently carried out on a manufacturing scale owing to the employment of aromatic diazonium salts in the production of azo- colouring matters. More than 1000 tons of para-nitraniline are diazotised annually in the production of ' para-nitraniline red '

The aromatic base is dissolved in dilute hydrochloric or sulphuric acid (3 equivalents in 10–20 p.c. aqueous solution) and the solution treated with an equivalent quantity (1 molecule) of sodium nitrite in 10–20 p.c. solution The diazotisation is completed when the liquid contains a slight excess of nitrous acid as indicated by starch and iodide paper.

With aniline and its homologues, the temperature of the diazo- solution is generally maintained at 0°–5° to prevent, so far as possible, the decomposition of the unstable diazonium salt, but in other cases, e g the nitranilines, naphthylamines, benzidine, and other diphenyl bases, the diazotisation is carried out most readily at 10°. The amino anthraquinones are diazotised at 30°–40° (Schaarschmidt, Ber. 1916, 49, 2678).

In the manufacture of soluble azo- dyes, the diazonium salts are generally employed in aqueous solution, but solid diazo- compounds, in dry or paste form, have been introduced to enable dyers to prepare ' ingrain ' azo- colours which are developed on the textile fibres (v Eng. Pat. 18429, 21227, 1894 ; 8989, 11757, 1895 ; 1645, 1896 ; 15353, 1897 ; D R. PP 85387, 88949, 94280, 1894 , 89437, 1896).

In alcoholic or acetic acid solution, diazotisation can be effected on the salt of the amine without using an excess of acid, and ethyl or amyl nitrite may, with advantage, be substituted for sodium nitrite. Gaseous methyl nitrite, which has been employed in certain diazotisation (Chem. Soc. Trans. 1913, 103, 1398), is very readily prepared and is a cleaner reagent than amyl nitrite.

Benzenediazonium chloride $C_6H_5 \cdot N_2Cl$, the simplest example of an aromatic diazonium salt, is prepared by adding the calculated quantity of amyl nitrite to aniline hydrochloride suspended in glacial acetic acid at 10° ; it is precipitated from the clear solution thus obtained by the addition of ether.

Benzenediazonium sulphate $C_6H_5 N_2 \cdot HSO_4$ is prepared in a similar manner from aniline sulphate suspended in glacial acetic acid, the precipitation being effected with alcohol and ether.

Benzenediazonium nitrate $C_6H_5 \cdot N_2 \cdot NO_3$, which was first precipitated from aqueous solution by ether and alcohol (Griess, Annalen, 1866, 137, 39), can be also produced in alcoholic or glacial acetic acid solution (Knoevenagel, Ber. 1890, 23, 2995 ; Bamberger, ibid. 1896, 29, 446 ; Hirsch, ibid, 1897, 30, 92 ; Hantzsch and Jochem, ibid. 1901, 34, 3337).

Diazonium salts have been obtained with a large variety of anions : *platinichlorides, aurichlorides, stannichlorides, ferricyanides, nitroprussiates* (Ber. 1879, 12, 2119, 1885, 18, 965), *chromates* (Jahresberichte, 1867, 915 ; Chem. Soc. Trans. 1905 87, 1), *carbonates* and *nitrites* (ibid, 1905, 87, 921), *fluorides* (Ber. 1903, 36, 2059), *perchlorates* (ibid. 1906, 39, 2713, 3146), *picrates* (Chem. Soc. Trans. 1907, 91, 1316), *azides* (ibid. 1910, 97, 1697 ; Ber. 1903, 36, 2056), *thiosulphates, tungstates* (J. Soc Dyers, 1901, 17, 279), *thioacetates* (Monatsh. 1907, 28,247), *borofluorides* (D. R. P. 281055), *phospho-molybdates* and *tungstates* (Chem. Soc. Trans. 1909, 95, 1319), *arylsulphonates* (Ber. 1911, 44, 1415 , *zincichlorides*, Rev. Gén. Mat Col. 1914, 18, 4 ; *β-naphthol-1-sulphonates*, Eng. Pat. 8989, 11757 of 1895 ; D. R. P 93305.

All diazonium salts are liable to explode in the dry state, for they are endothermic compounds (Berthelot and Vieille, Compt. rend. 1881, 92. 1076 ; Sventoslavsky, Ber. 1910, 43, 1479) and in some cases the explosion point has been determined (Ber. 1899, 32, 1691 ; 1900, 33, 527). The diazonium chromates and perchlorates decompose with considerable violence, so that the former have been suggested as explosives (Bull Soc. chim. 1867, [2] 7, 270 ; Fr. Pat. 73286).

Bisdiazonium salts (*Tetrazo- salts*). These compounds are produced from aromatic diamines which do not contain their aminogroups in *ortho-* or *peri-* positions (v. *Cyclic diazo- compounds*).

When the two amino- groups are in the same aromatic nucleus, complete diazotisation is effected only with some difficulty. Meta-phenylenediamine hydrochloride and sodium nitrite furnish the azo- colouring matters included under the term ' Bismarck brown ' (Ber. 1897, 30, 2111, 2899 ; 1900, 33, 2116), but when a solution of the base in excess of hydrochloric acid is added quickly to a large excess of well-cooled aqueous nitrous acid, complete diazotisation takes place and *benzene-m-bisdiazonium chloride* $C_6H_4[N_2 \cdot Cl]_2$ is produced. When the nitrite is added suddenly to the diamine hydrochloride, nitroso-m-phenylenediamine results. Para-phenylenediamine hydrochloride, when diazotised in the usual way, gives a mixture of diazonium and bisdiazonium chlorides, but when the hydrochloride is added to excess of nitrous acid, *benzene-p-bisdiazonium chloride* is obtained.

In the naphthalene series, 1:4-naphthylenediamine is diazotised with difficulty, owing to its oxidisability, but in producing its azo- derivatives, this difficulty is surmounted by working with its monoacyl- derivatives and diazotising in two stages with an intervening hydrolysis (Eng. Pat. 18783, 1891). The heteronuclear naphthylenediamines, excepting the 1:8- compound, can be completely diazotised, yielding *naphthalenebisdiazonium salts* (Ewer and Pick, D. R. PP. 45549, 45788 ; Badische Anilin und Soda Fabrik. D. R. P. 130475 ; Morgan and Micklethwait, Chem. Soc. Trans. 1910, 97, 2558). Benzidine, tolidine, dianisidine, and other similar heteronuclear diamines of the diphenyl and ditolyl series are readily diazotised, furnishing bisdiazonium salts (e.g. *diphenylbisdiazonium chloride* $Cl \cdot N_2 \cdot C_6H_4 \cdot C_6H_4 \cdot N_2 \cdot Cl$), which are employed in the manufacture of substantive

azo- dyes (v. *Congo red* and *Benzopurpurin* ; art. AZO-COLOURING MATTERS). There are certain substituted para-diamines in the benzene diphenyl and naphthalene series which have hitherto resisted all attempts at complete diazotisation (Ber. 1884, 17, 603 ; 1896, 29, 2285 ; 1905, 38, 3769 ; Eng. Pat. 2946 of 1896).

VELOCITY OF DIAZOTISATION.

Under the usual experimental conditions, diazotisation proceeds with great rapidity, but in N/1000 solutions, the velocity of this reaction has been determined by a colorimetric method for estimating the free nitrous acid. The reaction is of the second order, and the values of the constant $C = \dfrac{x}{t(a-x)}$ are 0·036 for aniline, 0·038 for *p*-toluidine, and 0·041 for *m*-xylidine, with one molecular proportion of free acid at 0°. At higher temperatures, the rate is increased (Hantzsch and Schümann, Ber. 1899, 32, 1691 ; 1900, 33, 527 ; Tassilly, Compt. rend. 1913, 157, 1148 ; 1914, 158, 335, 489). Both colorimetric and electrolytic determinations of the velocity of diazotisation show that, in the absence of disturbing influences, all the aromatic amines are diazotised at the same rate.

ALTERNATIVE METHODS OF PRODUCING AROMATIC DIAZONIUM SALTS.

Nitrosyl chloride or *bromide* has been suggested as a diazotising agent (Tilden and Millar, Chem. Soc. Proc. 1894, 59 ; Kastle and Keiser, Amer. Chem. J. 1895, 17, 91). *Nitrosyl sulphate* has been used with advantage (Pabst and Girard, D. R. P. 6034 ; Ber. 1879, 12, 365 ; Morgan and Micklethwait, Chem. Soc. Trans. 1910, 97, 2558). This reagent or sodium nitrite dissolved in concentrated sulphuric acid is employed in diazotising slightly basic amines (Morgan and Evens, Chem. Soc. Trans. 1919, 116, 1130 ; *cf.* J. pr. Chem 1906, [ii.] 74, 275). *Barium nitrite*, when employed in conjunction with sulphuric acid, furnishes diazo- solutions free from inorganic salts (Witt, Ber. 1903, 36, 4388). The last-named investigator has brought forward an interesting process which consists in dissolving the base in cold concentrated *nitric acid* and adding the calculated amount of *potassium metabisulphite* required to produce sufficient nitrous acid for the diazotisation (Ber. 1909, 42, 2953).

Diazonium bromides are formed by the inter action of *hydrazines* and *diazonium perbromides*

$$2R \cdot N_2Br_3 + RN_2H_3 = 3R \cdot N_2 \cdot Br + 3HBr$$
(Chattaway, Chem. Soc. Trans. 1908, 93, 958). An *electrolytic* process for the production of diazonium salts has been patented (Boehringer & Sons, D. R. P. 152926, and Eng. Pat. 2608 of 1904).

Diazonium salts can also be prepared from compounds not containing amino- groups ; mercury diphenyl and nitrous fumes give benzenediazonium nitrate (Ber. 1897, 30, 509), and the same salt is produced from nitrosobenzene and nitric oxide in chloroform solution (*ibid.* 1898, 31, 1528). Fuming nitric acid reverses the coupling process and regenerates the diazonium salt from its azo- derivatives (Meldola, Chem. Soc. Trans. 1889, 55, 608 ; 1894, 65, 841 ; and O. Schmidt, Ber. 1905, 38, 3201).

Diazonium chlorides are regenerated from azo-dyes by decomposing the latter with chlorine or hypochlorous acid (J. pr. Chem. 1912, [ii.] 85, 235.

Certain complex or highly substituted amines resist diazotisation unless treated under pressure (D. R. P. 143450) or with excess of nitrous and mineral acids (Annalen, 1873, 165, 187 ; 1891, 260, 224 ; Ber. 1900, 33, 520).

(For indirect methods of forming diazonium salts, *v.* Annalen, 1879, 199, 320 ; 1888, 243, 282 ; 1892, 270, 116 ; Ber. 1893, 26, 2190 ; 1899, 32, 1809 ; 1900, 33, 1718 ; J. pr. Chem. 1896, [ii.] 54, 496 ; Gazz. chim. ital. 1900, 30, 1526 ; Bull. Soc. chim. 1891, [ii.] 6, 94.)

REACTIONS OF AROMATIC DIAZONIUM SALTS.

In addition to their power of coupling with phenols, aromatic amines, and their sulphonic acids to form the technically important azocolouring matters, the diazonium salts are synthetical agents of the greatest value, and the following is a synopsis of the principal reactions in which they take part :—

1. Decomposition of Diazonium Salts by Water.

(*Cf.* Ber. 1874, 7, 1061 ; 1894, 17, 2704 ; 1899, 32, 1773 ; 1890, 23, 3635 ; 1902, 35, 89 ; J. pr. Chem. 1881, [ii.] 24, 476 ; Chem. Soc. Trans. 1902, 81, 77 ; 1903, 83, 688 ; 1905, 87, 5 ; 1906, 89, 19.)

The decomposition of soluble diazonium salts by water is a unimolecular reaction, and is represented by the well-known equation :

$$C = \frac{1}{t} \log \frac{A}{A-x}$$

The relative stability of the diazonium salts is ascertained by comparing the values of the constant C for a given temperature. The most successful method of making this determination consists in heating solutions of the diazo- compounds at a fixed temperature, and measuring the rate at which nitrogen is evolved. A convenient apparatus, which can be used in this determination and also for studying the decomposition of diazo- compounds in general, is indicated in the following figure.
These quantitative decompositions show that the diazonium salts from aniline and ortho- and meta-toluidine are among the least stable of the series, whereas considerably greater stability is exhibited by the diazotised nitranilines and the diazonium sulphonates derived from the benzenoid and naphthalenoid aminesulphonic acids.

The rate of decomposition of diazo- compounds increases with the temperature and in accordance with Arrhenius's formula for the temperature coefficient

$$Cf_1 = Cf_0 e^{A(T_1 - T_0)/T_1 T_0}$$

The rate of decomposition is independent of the quantity of mineral acid present, and equivalent solutions of benzenediazonium chloride, bromide, sulphate, nitrate, and oxalate decompose with the same velocity; this change is, however, accelerated by colloidal platinum or silver, owing to catalytic action (Hantzsch, Ber. 1900, 33, 2517; Hausser and Muller, Bull. Soc. chim. 1892, [iii.] 7, 721; 1893, 9, 353; Compt. rend. 1892, 114, 549, 669, 760, 1438; Schwalbe, Zeitsch. Farb. Ind. 1905, 4, 433; Ber. 1905, 38, 2196, 3071; 1909, 42, 196; Cain, Chem. Soc. Trans. 1902, 81, 1412; 1903, 83, 206, 470; 1905, 38, 2511; Euler, Annalen, 1902, 325, 292; Veley and Cain, Trans. Faraday Soc. 1909, 5, 1).

In general, the decomposition of a diazonium salt by water leads to the formation of a phenol

$$R \cdot N_2 \cdot HSO_4 + H_2O = R \cdot OH + H_2SO_4 + N_2$$
The sulphate is the best salt to employ in this reaction, because the chloride and nitrate are apt to lead respectively to alternative or secondary changes. Benzenediazonium sulphate and its homologues furnish phenol and the cresols and xylenols; diphenyl-4:4'-bis-diazonium sulphate gives rise to 4,4'-dihydroxy-diphenyl. Aurin is similarly obtained from diazotised rosaniline (Annalen, 1878, 194, 306).

In certain cases, more especially in the naphthalene series, the product is contaminated by azo- compounds, resulting from the coupling of the hydroxy- derivative with a portion of the still undecomposed diazonium salt (Chem. Soc. Trans. 1903, 83, 221). To obviate this difficulty, so far as possible, excess of acid is used in the decomposition. The manufacture of the α-naphtholsulphonic acids (e.g. OH : SO₃H = 1 : 4 and 1 : 8) from the corresponding α-naphthyl-aminesulphonic acids furnishes typical examples of the technical application of the process.

Secondary reactions occur even in the simplest cases (Ber. 1890, 23, 3705), and in many instances, where the boiling is protracted owing to the great stability of the diazo- compound, not a trace of the hydroxy- derivative can be isolated (Amer. Chem. Soc. Trans. 1889, 11, 319; Cain, Chem. Soc. Trans. 1903, 83, 688). When the phenolic product is volatile in steam, the normal change is facilitated by operating with solutions boiling above 100°. A good yield of guaiacol is obtained by adding the diazo- salt of ortho-anisidine to a mixture of sodium sulphate and dilute sulphuric acid boiling at 135°–145°, the volatile product being removed at the moment of formation (Kalle & Co., Eng. Pat. 7233 of 1897; cf. Annalen, 1889, 253, 281; Ber. 1874, 7, 1008; D. R. P. 167211; Chem. Soc. Trans. 1906, 87, 19; cf. Willstätter and Schudel, Ber. 1918, 51, 782.

(For other exceptional decompositions of diazo- compounds, v. Ber. 1874, 7, 1061; 1884, 17, 2704; 1899, 32, 1773; 1902, 35, 89; Chem. Soc. Trans. 1896, 69, 1327; 1902, 81, 77, 1905; 87, 5; 1906, 89, 19).

The diazo- compounds are very sensitive to light, which induces the phenolic decomposition

even in certain cases where the action of hot water or acids is very slight (Chem. Soc. Trans. 1907, 91, 35; cf. Compt. rend. 1881, 92, 1074; Ber. 1890, 23, 3131; 1901, 34, 1668; D. R. PP. 53455, 56606; J. Soc. Chem. Ind. 1890, 9, 1001).

2. Decomposition of Diazonium Salts by Alcohols.

The reaction between diazonium salts and alcohols may proceed in two different ways:

1. $R \cdot N_2 \cdot X + C_2 H_5 \cdot OH = R \cdot H + C_2 H_4 O + N_2 + HX$
2. $R \cdot N_2 \cdot X + C_2 H_5 OH = R \cdot O \cdot C_2 H_5 + N_2 + HX$

The former of these changes was originally regarded as the general reaction, but more recent researches have shown that the second is the normal change. The factors determining the course of the reaction are, however, numerous and complicated, involving (1) the nature of the alcohol; (2) the influence of substituents in the diazonium salt; (3) the pressure and temperature at which the decomposition is affected.

The tendency to replace the diazo- group by hydrogen increases with the molecular weight of the alcohol employed. Benzenediazonium chloride or sulphate and methyl alcohol give anisole exclusively. With ethyl alcohol, these salts yield chiefly phenetole, but benzene is also produced. The diazonium sulphates from p-chloro- and p-bromo-aniline furnish only p-chloro- and p-bromo-benzene with ethyl alcohol, but with methyl alcohol they give rise mainly to the methyl ethers of p-chloro- and p-bromo-phenol (Amer. Chem J. 1898, 20, 229; cf. Annalen, 1871, 159, 191; Ber. 1901, 34, 3337; 1903, 36, 2061; Amer. Chem. J. 1893, 15, 518; 1897, 19, 531, 547, 561).

The diazo- salts of the simpler amines (aniline and its homologues) react chiefly in the direction indicated by the second of the foregoing equations, and yield mixed ethers, but the presence of acid substituents

(Cl, Br, NO_2, CO_2H, $NH \cdot SO_2R$)
favours the predominance of the first change. The nitranilines (ortho-, meta-, and para-) give respectively 87, 51, and 40 p.c. of nitrobenzene the 1 : 2-, 2 : 1-, and 1 : 4-nitronaphthylamines furnish the corresponding nitronaphthalenes, whereas α- and β- naphthylamines yield α- and β-ethoxynaphthalenes (Remsen and others, Ber. 1885, 18, 65; Amer. Chem. J. 1886, 8, 243; 1887, 9, 587; 1891, 13, 153; 1892, 14, 15).

The yield of alkyl ether increases with rise of pressure, but the addition of zinc-dust or an alkali (sodium hydroxide or ethoxide, potassium carbonate) inhibits almost entirely the formation of mixed ether and leads to the substitution of the diazo- group by hydrogen (Amer. Chem. J. 1893, 15, 105, 301, 320, 379; 1894, 16, 235; 1895, 17, 454; 1897, 19, 163, 531; 1898, 20, 298; 1904, 31, 119).

3. Replacement of the Diazo- Group by Hydrogen.

In addition to the action of alcohol, the diazo- group can be eliminated by the use of a variety of reducing agents :—

(i.) The diazonium salt is reduced to the corresponding *hydrazine* and the hydrazino- group $NH \cdot NH_2$ removed by boiling with *copper sulphate* (Baeyer and Pfitzinger, Ber. 1885, 18, 90, 786).

(ii.) Reduction of the diazo- compound with *alkaline sodium stannite* (Friedländer, Ber. 1889, 22, 587).

(iii) By various other reducing agents, *stannous formate* (Ber. 1885, 18, 357; J. pr. Chem. 1889, [ii.] 40, 97), *hypophosphorous acid* (Ber. 1902, 35, 162), *sodium hyposulphite* (*ibid.* 1907, 40, 858), *formic acid* and *copper powder* (*ibid.* 1890, 23, 1632), *aluminium powder* in alcohol (Morgan and Evens, *l.c.*).

4. Replacement of the Diazo- Group by Halogen, Cyanide, Cyanate, and Thiocyanate Radicals.

Fluorine may be introduced into the aromatic nucleus in place of the diazo- group by treating the diazonium salt with hydrofluoric acid. Diazoamino- compounds (*v. infra*) are also employed in bringing about this replacement, and when treated with concentrated hydrofluoric acid they yield the corresponding fluoro- derivative; fluorobenzene is thus produced from diazoaminobenzene or diazobenzene-piperidide (J. pr. Chem. 1870, [ii.] 1, 395; Ber. 1875, 8, 893; 1879, 12, 581; 1889, 22, 1846).

The first really successful process for replacing the diazo- group by *chlorine* (or *bromine*) was discovered by Sandmeyer, it consists in adding the diazotised solution to cuprous chloride (or bromide) dissolved in warm hydrochloric (or hydrobromic) acid, when nitrogen is evolved and the corresponding chloro- or bromo-derivative is produced (Ber. 1884, 17, 1633, 2650; 1885, 18, 1492, 1496, 1886, 19, 810, 1890, 23, 1628, 1880; Annalen, 1893, 273, 141).

The first stage in the *Sandmeyer reaction* is considered to be the formation of an additive compound of diazonium salt and cuprous chloride; the decomposition of this intermediate product proceeds readily only above a certain temperature, which is different for each diazonium salt (Erdmann, Annalen, 1893, 272, 141; *cf.* Votoček, Chem. Zeit. Rep. 1896, 20, 70; Hantzsch and Blagden, Ber. 1900, 33, 2544). The substitution of bromine for diazo-nitrogen follows a similar course (Phil. Trans. 1864, 154, 673; Annalen, 1866, 137, 49; Amer. Chem. J. 1891, 13, 486; Gazz. chim ital 1890, 20, 631).

The foregoing substitutions are also effected by the addition to solutions of diazonium chlorides or bromides of finely divided copper or the copper bronze of commerce (Gattermann, Ber 1890, 23, 1218; 1892, 25, 1074; Ullmann, *ibid.* 1896, 29, 1878; *cf.* Angeli, *ibid.* 1891, 24, 952).

Iodine is readily substituted for the diazo-complex by treating the acid diazo- solutions with potassium iodide even in the absence of copper or cuprous salts.

The Sandmeyer reaction includes the important synthetical operation of replacing the diazo- group by a *cyanide* radical, the diazonium salt being added to a warm solution of potassium cuprocyanide. The Gattermann process is also applicable to this synthesis, the addition of copper powder to a mixture of diazonium salt and potassium cyanide inducing a similar replacement (Ber. 1890, 23, 1218). The *cyanate* radical is introduced in the place of the diazo- group by adding successively to a solution of diazonium salt, potassium, cyanate, and copper powder (Ber. 1890, 23, 1220; 1892, 25, 1086). The *thiocyanate* group is introduced by adding potassium thiocyanate and cuprous

thiocyanate to a solution of diazonium sulphate (*ibid.* 1890, 23, 738, 770).

5. Replacement of the Diazo- Group by Sulphur and Sulphur-containing Radicals.

These reactions are of importance as furnishing methods for the synthetical production of sulphonic acids.

Thiophenols or *disulphides* are obtained by treating diazonium salts with potassium xanthate and then hydrolysing the resulting aromatic xanthate (Leuckart, J. pr. Chem. 1890, [ii.] 41, 179; *cf.* Ber 1887, 20, 349; Chem. Soc. Proc 1895, 11, 141). Phenyl sulphide is produced by treating benzenediazonium salts with hydrogen sulphide or ammonium sulphide (Ber. 1882, 15, 1683). Benzenoid diazonium salts yield sulphides on treatment with sodium cuprous thio-sulphate, but diazotised α-naphthylamine only gives α-azonaphthalene (Ber 1901, 34, 3968).

The replacement of a diazonium by a *sulphonic* group is effected by saturating with sulphur dioxide an acid solution of diazonium sulphate and adding copper powder; nitrogen is evolved and the resulting sulphinic acid extracted with ether (Gattermann, Ber 1899, 32, 1136; Eng. Pat. 26139 of 1896; D. R. P. 95830).

The foregoing thiophenols, disulphides and sulphinic acids yield the corresponding *sulphonic acids* on oxidation (D. R. P. 70286; Eng. Pat. 11865 of 1892).

6. Replacement of the Diazo- Group by Nitro-, Nitroso-, and Amino- Radicals.

The introduction of a *nitro-* group is brought about either by heating the diazonium salt with nitrous acid and cuprous oxide or by mixing the diazonium sulphate with cupro-cupric sulphite and adding excess of alkali nitrite. By the latter process, 2.4.6-tribromobenzenediazonium sulphate gives 65 p.c. of 1-nitro-2 : 4 : 6-tri-bromobenzene and diazotised β-naphthylamine gives 25 p c of β-nitronaphthalene, a substance prepared with considerable difficulty by other processes (Ber. 1887, 20, 1497; 1900, 33, 2544). The introduction of a *nitroso-* group is effected by treating a diazonium chloride with alkaline potassium ferrocyanide (Ber. 1893, 26, 471). The addition of hydroxylamine to a solution of diazonium salt results in the regeneration of the original amine (Ber. 1892, 25, 372; 1902, 35, 2593, 3920).

7. Formation of Azoimides.

The introduction of the azimino- group N_3 into the aromatic nucleus is effected by the following reactions: (1) action of hydroxyl-amine on diazonium sulphates (Ber. 1892, 25, 372; 1893, 26, 1271; Forster and Fierz, Chem. Soc. Trans. 1907, 91, 855, 1350); (2) interaction of ammonia and diazonium perbromides; (3) direct action of sodium azide on diazonium salts in excess of sulphuric acid (Nölting and Michael, Ber. 1893, 26, 86; Forster and Fierz, Chem. Soc. Trans. 1907, 91, 1942). The last of these processes is carried out so readily that the production of an azimino- compound may be used to estimate the number of diazo- groups in a diazonium salt (Meldola and Hawkins, Chem. Soc. Proc. 1892, 8, 133; Morgan and Mickle-thwait, Chem. Soc. Trans. 1910, 97, 2560). Aromatic azoimides are also produced by the interaction of chloroamine, NH_2Cl, and diazo-nium chlorides (Forster, Chem. Soc. Trans. 1915,

107, 260), and by removing water from the nitrosoarylhydroxylamines.

These aryl azoimides can be employed synthetically as a means of transforming an amine into the corresponding aminophenol when warmed with moderately concentrated sulphuric acid, two-thirds of the nitrogen are eliminated and a hydroxyl group is introduced into the nucleus (Ber. 1894, 27, 192; Morgan and Porter, Chem. Soc. Trans. 1915, 107, 651).

Miscellaneous substitutions, v. Chem. Soc. Trans. 1888, 53, 460; Amer. Chem. J. 1888, 10, 368 ; Ber. 1902, 35, 1964.

For the replacement of the diazo- group by arsinic and stibinic complexes consult ORGANIC ARSENICALS and ORGANIC ANTIMONIALS.

CONDENSATIONS EFFECTED BY MEANS OF AROMATIC DIAZONIUM SALTS.

Azo- compounds are formed, to a slight extent, during the Sandmeyer reaction, and this condensation takes place to a greater extent when the usual order of mixing is reversed and the cuprous chloride added to the cold solution of diazonium salt. Aniline, o-chloraniline, and o- and p-toluidine give considerable quantities of azo- derivatives, but the nitranilines and their homologues furnish diphenyl compounds (Niementowski, Ber. 1901, 34, 3325 ; Ullmann and Forgan, *ibid.* 3802 ; D. R. P. 126961). Cuprous oxide dissolved in ammonia or hydroxylamine also promotes the diphenyl condensation (Annalen, 1902, 320, 122), diphenyl itself being readily prepared by adding copper, zinc, or iron powder to benzenediazonium sulphate in dilute alcohol (Ber. 1890, 23, 1226) ; ββ-dinaphthyl is similarly produced from β-diazonaphthalene sulphate (Chem. Soc. Trans. 1895, 67, 653) 2:2'-Dimethyl-1:1'-dianthraquinonyl results from the condensation of 2 mols. of 2-methylanthraquinone-1-diazonium sulphate when stirred with acetic anhydride and copper bronze powder (Scholl and Kunz, Ber. 1907, 40, 1697; Eng. Pat. 14578 of 1905).

INTERCHANGE OF GROUPS IN DIAZONIUM SALTS.

The diazonium salts of the more highly substituted amines frequently undergo remarkable transformations, some of which have been suggested for use in the technical production of azo- compounds.

The dinitroanisidines, containing nitro- groups either in ortho- or para- positions with regard to the amino- group, exchange these radicals for hydroxyl during the process of diazotisation. In certain instances, the methoxyl group present in these compounds undergoes demethylation, &c., with the production of internal diazo- oxides (quinonediazides). The nitro- group is set free in the form of nitrous acid, which continues the diazotisation process on further quantities of the base (Meldola and others, Chem. Soc. Trans. 1900, 77, 1172 ; 1901, 79, 1076 ; 1902, 81, 988 ; 1905, 87, 1205). Methoxyl or chlorine radicals in para- positions with respect to the diazo-complex are rendered labile by contiguous nitro- groups so that para- diazo-oxides are produced (Klemenc, Ber. 1914, 47, 1407; Morgan and Porter, Chem Soc. Trans. 1915, 107, 653), but an accumulation of acidic (nitro) groups favours the removal of adjacent

nitro- groups and the formation of ortho-diazo-oxides (Meldola and Reverdin, Chem. Soc. Trans. 1910, 97, 1204). A sulphonic group is replaced by hydroxyl in the diazotisation of m-phenylenediaminedisulphonic acid (Eng. Pat. 18283 of 1903), and certain of the dinitronaphthylamines, when diazotised, yield internal diazo-oxides, owing to the initial replacement of a nitro- group by hydroxyl (Ber. 1894, 27, 2211 ; 1895, 28, 1951; cf. Chem. Soc. Trans. 1895, 67, 908).

The replacement of an acidic (electronegative) substituent by hydroxyl frequently occurs on treating the diazonium salt with alkalis.
A sulphonic acid group may be similarly eliminated as in β-naphthylamine-1 . 5 : 7-trisulphonic acid which, when diazotised and treated with weak alkali, yields naphthylene-2-diazo-1-oxide-5 . 7-disulphonic acid (D. R. P. 141750 ; Eng. Pats. 16811, 20551, of 1901 ; 1561, 6615, 23993, of 1902 ; 16995, 27372, of 1903 ; 4997, of 1904).

These replacements sometimes take place even when the diazo- solutions are diluted with water, or spontaneously when the diazonium base is present as the salt of a weak acid (acetate, oxalate, carbonate, &c) (v. Orton, Proc. Roy. Soc. 1902, 71, 153 ; Chem. Soc. Trans. 1903, 83, 796 ; 1907, 91, 1554 ; Nolting and Battegay Ber. 1906, 39, 79).

p-Chlorobenzenediazonium thiocyanate

$$Cl \cdot C_6H_4 \cdot N_2 \cdot CNS$$

undergoes a remarkable molecular transformation when dissolved in alcohol containing a trace of hydrochloric acid. The thiocyanate and chlorine radicals change places, and on adding ether to the solution, p-thiocyanobenzene diazonium chloride is precipitated (Hantzsch, Ber. 1896, 29, 947). Similarly, 2 : 4 : 6-tribromobenzenediazonium sulphate in presence of excess of potassium thiocyanate is converted into 2.4:6-trithiocyanobenzenediazonium thiocyanate and many brominated diazonium chlorides pass into chlorinated diazonium bromides (Ber. 1897, 30, 2334 ; 1898, 31, 1253 ; 1900, 33, 505 ; cf. Chem. Soc. Trans. 1902, 81, 1376). The last of these transformations has been studied quantitatively, and the following generalisations have been established :—

(i.) Bromine atoms are replaced by chlorine only when present in the ortho- or para- position with respect to the diazonium group, those in ortho- positions being most readily removed. A bromine atom in the meta- position is not affected.

(ii.) The ease of transformation increases with the number of bromine atoms present.

(iii.) The transformation constant, calculated from the equation for a unimolecular reaction $K = 1/t(\log A/A - x)$, increases with the temperature and is also influenced by the solvent, having its minimum value in water, and becoming greater as the series of alcohols is ascended.

(iv.) Diazonium salts containing two bromine atoms are stable when dry, but are rapidly transformed in ethyl alcohol; 2:4:6-tribromobenzenediazonium chloride becomes transformed in the dry state.

These changes do not occur either with iodinated diazonium chlorides or with brominated diazonium fluorides (Hantzsch, Ber. 1903, 36, 2069).

CONSTITUTION OF AROMATIC DIAZONIUM SALTS.

Aromatic diazonium salts are generally soluble in water to a neutral solution, thus showing, by an absence of hydrolytic dissociation, that the diazonium base is a stronger base than the aromatic amine from which it was derived. The strength of the diazonium base has been confirmed by physico-chemical measurements.

Determinations of the electrical conductivity of solutions of benzenediazonium chloride and nitrate show that the benzenediazonium radical is strictly comparable with other quaternary ammonium ions. The rate of migration of the benzenediazonium ion at 25° is 45·7, the corresponding constants for the methylpyridinium and tetramethylammonium ions being 44·3 and 43·6 respectively. The molecular electrical conductivity of solutions of diazonium salts increases with dilution, just as in the case of the corresponding potassium and ammonium compounds.

The affinity constant of benzenediazonium hydroxide at 0° is 70 times greater than that of ammonium hydroxides, and somewhat exceeds that of piperidine. The affinity constants of p-methoxybenzenediazonium and ψ-cumidinediazonium hydroxides are even greater, and approximate closely to those of the alkali hydroxides. A comparison of the electrical conductivity experiments, with the results obtained in the hydrolysis of ethyl acetate by benzenediazonium hydroxide, shows that in N/128 solutions at 0°, approximately 33 p.c. of the base exists in the ionised condition (Ber. 1890, 23, 3220 ; 1895, 28, 1737 ; 1898, 31, 1612).

Benzenediazonium (Diazobenzene) behaves like an alkali or a complex ammonium cation.

Benzenediazonium hydroxide (Diazobenzene hydrate or hydroxide) is only known in solution, and is produced by treating aqueous benzenediazonium chloride with the calculated amount of silver oxide, or by adding barium hydroxide to a solution of benzenediazonium sulphate (Hantzsch, Ber. 1898, 31, 340). The solution is strongly alkaline, and gives at once an azo-compound with β-naphthol ; the dissolved base decomposes, however, fairly rapidly even at 0°.

The striking similarity in the physical and chemical properties of the diazonium and quaternary ammonium salts suggests the existence of quinquevalent nitrogen in the former compounds, and on these grounds the following formula, formerly proposed by Blomstrand (1869), Strecker (1871), and Erlenmeyer (1874), has now been generally adopted for benzenediazonium chloride and its homologues :

$$\text{C}_6\text{H}_5\text{---N}^\text{V}\text{---Cl}$$
$$\overset{|}{\text{N}}$$
although, for many years, the alternative configuration, $\text{C}_6\text{H}_5\cdot\text{N}=\text{N}\cdot\text{Cl}$, suggested by Kekulé, was usually employed.

The close analogy existing between the diazonium and alkali salts is shown further by the facility with which the former yield double salts with cobaltic nitrite and with the chlorides of platinum, gold, and mercury. Diazonium perhalides are also known, corresponding with the perhalides of potassium, rubidium, cæsium, and quaternary ammonium bases (Ber. 1895, 28, 1736, 2754).

The benzenoid diazonium salts with colourless anions (nitrates, sulphates, chlorides) are generally colourless, but the corresponding bromides, iodides, and thiocyanates are coloured, and the deeper the colour the more explosive the salt. When cooled in liquid air, these coloured salts become less coloured ; moreover, their aqueous solutions are colourless.

The development of colour and increase in explosibility are considered by Hantzsch to indicate a change in constitution, the coloured substance being regarded as an equilibrium mixture of diazonium salt and syn-diazocompound (v. infra). This equilibrium is disturbed in the sense of forming more colourless diazonium salt by lowering the temperature or by dissolving the substance in water (Hantzsch, Ber. 1897, 33, 2179 ; 1900, 33, 2179 ; Euler, Ber. 1895, 31, 4168). But although in the benzene series the diazonium chlorides, nitrates, and sulphates are colourless, yet in the diphenyl and naphthalene series, many diazonium salts with these anions are coloured and comparatively stable. Moreover, this colour (yellow or orange) is retained either in aqueous solution or at the temperature of liquid air. Apart from their colour, these salts have all the properties of the simpler diazonium salts (neutral solutions, coupling with phenols, &c.). These facts indicate that increase in the complexity of the organic portion of the diazonium cation leads to the development of colour in normal diazonium salts.

(Coloured diazonium salts, v. Hantzsch, Ber. 1900, 33, 3183 ; 1901, 34, 4168 ; Annalen, 1900, 312, 126 ; Cain, Chem. Soc. Trans. 1905, 87, 5 ; Morgan and others, ibid. 1907, 91, 1311, 1505 ; 1908, 93, 614 ; 1909, 95, 1319.)

The idea embodied in Blomstrand's diazonium formula (v. supra) fails to express one important point, namely, the dependence of the stability of the diazo- complex on the presence of an unsaturated group. Yet this is a matter of fundamental importance, for hitherto no amine in which the basic nitrogen is attached to a fully saturated ring or complex has yielded a diazonium salt.

Cain has suggested an alternative formula, (2), giving expression to this circumstance (Chem. Soc. Trans. 1907, 91, 1051), in which the diazonium salt is represented as having a para-hemiquinonoid constitution ; and this conception has been extended by Morgan (ibid. 1908, 93, 617 ; 1910, 97, 2563) so as to include the equally admissible ortho-hemiquinonoid configurations (1) and (3) :

(1)   (2)   (3)
Euler has also advocated a para- hemiquinonoid structure for diazonium salts (Ber. 1908, 41, 3979).

NON-AROMATIC DIAZONIUM SALTS.

The foregoing hypotheses of the constitution of aromatic diazonium salts, which bases their existence on the unsaturated nature of the aromatic complex, accord with the fact that certain non-aromatic primary amines containing unsaturated organic groups manifest, in some degree, the property of diazotisability. Among these bases are aminotriazole (I.) and its derivatives, and aminoantipyrine (II.) :

$$NH_2-C \underset{\underset{N-CH}{\|}}{\overset{NH\cdot N}{<}}$$
I.

$$\overset{N(CH_3)\cdot N(C_6H_5)\cdot CO}{\underset{C(CH_3)---C\cdot NH_2}{|}}$$
II.
(Thiele and Manchot, Annalen, 1898, 303, 33 : Knorr and Stolz, ibid. 1896, 293, 67 ; cf. Ber. 1900, 33, 1158; 1906, 39, 2925 ; Annalen, 1900, 312, 133). In addition to amino derivatives of the pyrazoline group (Michaelis, Annalen, 1906, 350, 288), the 4- and 5-amino derivatives of the pyrazole group give rise to remarkably stable diazonium salts (Morgan and Reilly, Chem. Soc. Trans. 1914, 105, 436 ; Michaelis and others, Annalen, 1911, 385, 1 ; 1915, 407, 229, 274; Mohr. J. pr. Chem. 1914; [ii.] 90, 569). 2-Aminothiazole, a heterocyclic base containing sulphur and nitrogen in the ring, furnishes diazonium salts of the oxyacids (Morgan and Morrow, Chem. Soc. Trans. 1915, 107 1291). Distinct evidence of diazotisability has been adduced in the indole and pyrrole series (Angeli and d'Angelo, Atti. R. Accad. Lincei, 1904, [v.] 13, i. 258; Angelico, l.c. 1905, 14, ii. 167). It has also been shown ;K. A. Hofmann, Hock and Roth, Ber. 1910, 43, 682, 1087) that aminoguanidine gives rise to diazonium salts, derived, however, not from the salts of aminoguanidine itself, but from a more complex molecule containing two guanidine residues, and having a greater degree of unsaturation. The diazonium nitrate, for example, is represented by the formula :

$$NH \underset{\overset{}{}}{\overset{NO_2\cdot N_2\cdot NH\cdot C(:NH)}{\underset{C(NH_2)\cdot NH-NH\cdot N}{\diagdown}}} N$$
containing a diazo- complex associated with an open chain having three unsaturated linkings.

II. CYCLIC DIAZO- COMPOUNDS.

In certain instances, the action of nitrous acid on substituted aromatic amines leads to the formation of compounds having their diazonitrogen in a cyclic complex, this result being due to the subsequent interaction of a substituent group.

1. INTERNAL DIAZONIUM SALTS.

Sulphonated amines of the benzene and naphthalene series furnish diazo- derivatives which are generally misnamed diazo-sulphonic acids. These compounds, however, do not contain ionic hydrogen, and are really internal diazonium salts ; No. 1, the so-called 'diazobenzenesulphonic acid,' being benzenediazonium-p-sulphonate, whilst No. 2 is naphthalene-1-diazonium- 5-sulphonate
(1.)   (2.)

These internal diazonium sulphonates are of great technical importance in the manufacture of azo- dyes (v. AZO- COLOURING MATTERS). They are prepared either by adding sodium nitrite to an acid suspension of the amino sulphonic acid or by acidifying a solution containing nitrite and the alkali salt of the aminosulphonic acid (Rev. prod. chim. 1917, 20, 21).

Of a similar nature are the cyclic diazo-derivatives obtained by diazotising aromatic aminocarboxylic acids (cf. Bülow and Haas, Ber. 1911, 44, 601), e.g. 'diazo-anthranilic acid' or benzenediazonium-o-carboxylate

which is employed in the production of methyl red (v ACIDIMETRY and ALKALIMETRY).

2. CYCLIC DIAZO- COMPOUNDS DUE TO INTERNAL CONDENSATION.

Aromatic ortho- and peri-diamines do not yield diazonium salts, inasmuch as their interaction with nitrous acid leads at once to the formation of cyclic diazoimines (Azimino-compounds)

(1.)   (2.)

Phenylene-o-diazoimine (1) (Aziminobenzene) and **naphthylene-1:8-diazoimine** (2) (1:8-Azimino-naphthalene) are typical members of this series of diazo- compounds.

The triazole rings thus set up are remarkably stable, and in the case of the ortho- derivatives (No. 1) are not opened by mineral acids without complete rupture of the molecule. The peri-diazoimines (No. 2) occupy a position intermediate between the ortho-diazoimines (No. 1) and the para-diazoimines (v. infra).

The 1:2- and 2:3-naphthylene-diamines furnish respectively 1:2- and 2:3-naphthylene-diazoimines (1:2- and 2:3-aziminonaphthalenes). (Constitution of ortho-diazoimines and their acyl- derivatives, Griess, Ber. 1882, 15, 2195 ; Kekulé, Lehrbuch, ii. 739 ; Morgan and Godden, Chem. Soc. Trans. 1910, 97, 2557 ; cf. Ber. 1874, 7, 316 ; 1876, 9, 221 ; 1887, 20, 2999 ; 1894, 27, 874 ; Annalen, 1889, 255, 344 ; Chem. Soc. Trans. 1906, 89, 4.) Although Griess's formulation for the azimino- compounds

$$C_6H_4 \underset{\overset{}{}}{\overset{N}{\underset{N}{<}}} NH \text{ still persists in chemical litera-}$$
ture, it has been disproved completely, and that of Kekulé substantiated by the preparation of three pairs of isomerides having respectively

2 L

the following formulæ, where R=acetyl, benzoyl, or benzenesulphonyl.
This form of isomerism could not exist with Griess's symmetrical configuration (Morgan, Micklethwait and Scharff, Chem. Soc. Trans. 1913, 103, 1394; 1914, 105, 117). Although these diazoimines do not couple with phenols and aromatic bases to form azo-dyes, yet a synthetic employment has been found for them in the production of carbazole derivatives which are obtained on heating these cyclic diazo-compounds (Ullmann, Ber. 1898, 31, 1697; 1914, 47, 380).

Similar stable cyclic diazo- compounds are obtained by diazotising the ortho-aminothiophenols, o-**phenylenediazosulphide** being a colourless crystalline substance with a sweetish odour and feebly basic properties

$$C_6H_4<^S_N>N$$

(Jacobsen, Annalen, 1893, 277, 209, 218, 232, 237).

3. CYCLIC DIAZO-COMPOUNDS DUE TO COMBINED INTERNAL CONDENSATION AND SALT FORMATION.

In this group are found certain diazo-derivatives of amines containing slightly acidic substituents in ortho- or para-, but not meta-positions with respect to the aminic nitrogen.

(I.) **Internal diazo- oxides** are produced from ortho- and para- aminophenols and their derivatives. In some cases, an intermediate diazonium salt is formed which condenses to the diazo-oxide on treatment with silver oxide or an alkali (Schmitt, Ber. 1868, 1, 67; Hantzsch and Davidson, ibid. 1896, 29, 1522; Cameron, Amer. Chem. J. 1898, 20, 229). The first diazo-compound prepared by Griess (Annalen, 1858, 106, 123), namely, **dinitrobenzenediazo-oxide**.

$$(NO_2)_2C_6H_2<^O_{N_2}>|$$

belongs to this class; it is produced by diazotising picramic acid, and has been utilised in the production of azo- colours (D. R. P. 151332). The 1:2-, 2:1-, 2:3-, and 1:8 aminonaphthols and their sulphonic acids similarly give rise to internal diazo-oxides which are so stable that they can be nitrated. These internal diazo-oxides are readily transformed into diazonium salts by mineral acids, and are therefore available in the production of azo-dyes (Eng. Pat. 28107, of 1897; 10235, 15025, of 1904; Fr. Pat. 353786 of 1905; D. R. PP. 155083, 164665, 171024, 172446, 175593, 176618, 176619, 176620).

Internal diazo-oxides can also be produced by leaving the diazonium salts of highly substituted amines (e.g. 2:4:6-trichloroaniline) in aqueous solutions containing no free mineral acid (Orton, Proc. Roy. Soc. 1903, 71, 153; Chem. Soc. Trans. 1903, 83, 796).

These diazo- derivatives have been formulated either as cyclic diazo-oxides (I.) or as quinonediazides (II.):

$$O\cdot C_6H_4\cdot N_2$$
I.

$$O:C_6H_4<^N_N$$
II.
(cf. Wolff, Annalen, 1900, 312, 126; Morgan and Micklethwait, Chem. Soc. Trans. 1908, 93, 607).

Repeated attempts to prepare internal diazo-oxides from m-aminophenol and its nitro-derivatives, which have been quite unsuccessful, strengthen the view that these diazo- derivatives are to be regarded as quinonediazooxides (II.), with the reservation that similar complex compounds are producible from 1:8-aminonaphthol, ' H acid,' and other peri- derivatives (Morgan and Porter, l.c.). In the case of aminophenolsulphonic acids the NH_2:OH=1:2 compounds give these coloured o-quinonediazides; the NH_2:OH=1:4 compounds yield diazonium sulphonates changing to p-quinonediazides on partial neutralisation; the NH_2:OH=1:3 compounds give rise only to diazonium sulphonates which lose diazo-nitrogen and furnish complex azo derivatives on treatment with alkali (Morgan and Tomlins, Chem. Soc. Trans. 1917, 111, 497).

(II.) **Para-diazoimines and diazoimides.**

The simplest example of the para-diazoimines is obtained by the action of alkalis on the diazonium salts of p-aminodiphenylamine (Annalen, 1888, 243, 282; Ber. 1902, 35, 895). The following alternative formulæ (III. and IV.) have been given to this product :—

$$C_6H_5\cdot N\cdot C_6H_4\cdot N_2$$
III.

$$C_6H_5N:C_6H_4<^N_N$$
IV.
corresponding respectively with the foregoing formulæ (I. and II.) for the internal diazo-oxides. Successive nitration of the phenyl group gradually increases the stability of these p-diazoimines (Chem. Soc. Trans. 1908, 93, 604).

The para- diazoimides are produced from the acyl- and arylsulphonyl- derivatives of the para-diamines, and similar products are obtained from the arylsulphonyl-1 : 8-naphthylenediamines. The production of these diazoimides takes place in two stages, the diazonium salt first produced being decomposed by sodium acetate or mild alkali, yielding the internal condensation product ·

$$R\cdot SO_2\cdot NH\cdot C_6H_4\cdot N_2\cdot Cl \underset{HCl}{\overset{NaAc}{\rightleftharpoons}} R\cdot SO_2\cdot N\cdot C_6H_4N_2$$
V.   VI.
These para-diazoimides (VI.) are yellow sparingly soluble substances readily reconverted by strong acids into the corresponding diazonium salts. They combine additively with phenols, naphthols, naphthylamines, and their sulphonic acids, yielding azo- colouring matters (Morgan and Micklethwait, J. Soc Dyers and Colourists, 1909, 25, 107; cf. Chem. Soc. Trans. 1905, 87, 74, 921, 1302; 1906, 89, 1162; 1907, 91, 1509; 1908, 93, 615; Badische Anilin- und Soda-Fabrik D. R. P. 205037).

The foregoing general reaction has been extended further by the device of diazotising with liquid nitrogen trioxide in an anhydrous solvent such as acetone. In this way the simplest members of the series $Ac\cdot N:C_6H_4\cdot N_2$ have been obtained containing formyl, acetyl, and benzoyl groups (Morgan, Upton and Cleaze, Chem. Soc. Trans. 1917, 111, 187; 1918, 113.

III. DIAZOAMINES.

The diazoamines or diazoamino- compounds have the general formula $XN_2 \cdot NHY$, and may be either aromatic, mixed aromatic-aliphatic, or aliphatic in character, according as to whether X and Y are aromatic or aliphatic hydrocarbon radicals.

1. AROMATIC DIAZOAMINES.

The aromatic diazoamines are produced (1) by the action of nitrous acid (1 molecule) on two molecular proportions of a primary benzenoid amine ; (2) by coupling a diazonium salt with a primary or secondary benzenoid amine.

Diazoaminobenzene $C_6H_5 \cdot N_2 \cdot NH \cdot C_6H_5$, yellow crystals, m.p. 98°, is produced in quantitative yield by dissolving 10 parts of aniline in two parts of water containing 12 parts of hydrogen chloride, diazotising with 8 parts of sodium nitrite, and adding the diazo- solution to a solution of 10 parts of aniline in the calculated amount of hydrochloric acid. The diazoamine is precipitated on the addition of sodium acetate. (Absorption spectrum of diazoaminobenzene, Purvis, Chem. Soc. Trans. 1914, 105, 590.)

When warmed with aniline containing aniline hydrochloride, diazoaminobenzene is transformed into p-aminoazobenzene (v. AZO-COLOURING MATTERS), the velocity of transformation obeying the law of unimolecular reactions. When the transformation occurs below 40° a small proportion (about 4 p.c.) of o-amino-azobenzene is produced (F. H. Witt, Ber. 1912, 45, 2380 ; 1913, 46, 2557).

Diazoamino-p-toluene $C_7H_7 \cdot N_2 \cdot NH.C_7H_7$ is prepared in a similar manner, and undergoes transformation into an ortho-azo- compound, but the velocity of this change is only about one-ninth of that of the preceding transformation to para-azo- derivative.

The coupling of diazonium salts with meta-phenylenediamine, diphenylamine, the naphthylamines and their alkyl derivatives, leads directly to the production of azo- derivatives ; in these cases, intermediate diazoamines have not been isolated, except when the reactive ortho- or para- positions are already substituted (Morgan, Chem. Soc. Trans. 1902, 81, 91 ; 1907, 91, 370).

When an aromatic base, XNH_2^-, is coupled with a diazonium salt YN_2Cl, the resulting diazoamine is identical with that produced from XN_2Cl and YNH_2, and is generally regarded as being an equilibrium mixture of the two isomerides $XNH \cdot N_2Y$ and $XN_2 \cdot NHY$. This explanation assumes the migration of the diazo- group which has been observed to occur in several instances (Ber. 1882, 15, 2190 ; 1896, 29, 287 ; 1897, 30, 1412).

(For the constitution of the unsymmetrical aromatic diazoamines, $XNH \cdot N_2Y$, v. Meldola and Streatfeild, Chem. Soc. Trans. 1886, 49, 624 ; 1887, 57, 102, 434 ; 1886, 53, 664 ; 1889, 55, 412 ; 1890, 57, 785 ; cf. Forster and Garland $ibid.$ 1909, 95, 2051.)

2. ALIPHATIC-AROMATIC DIAZOAMINES.

The diazoamines containing one aliphatic and one aromatic group can be produced by (1) coupling a diazonium salt with an aliphatic amine (Ber. 1888, 21, 1016, 1112 ; 1889, 22, 938,

1302) ; (2) by treating an azide with Grignard reagent :

$$R \cdot N{\overset{\displaystyle N}{\underset{\displaystyle N}{\langle\;\|}}} + R' \cdot MgBr = R \cdot N(MgBr) \cdot N{:}NR'$$

$$H_2O \rightarrow R \cdot NH \cdot N{:}NR' + MgBr \cdot OH$$
(Dimroth, Ber. 1903, 36, 909 ; 1905, 38, 670, 2328 ; 1907, 40, 2390). Diazoamines present the possibility of stereoisomerism, but their relative stability and the fact that they couple only slowly with β-naphthol, confirm the view that they are generally $anti$-diazo- compounds.

(For stereoisomeric diazoamines, v. J. Russ. Phys. Chem. Soc. 1906, 38, 578 ; Zeitsch. angew. Chem. 1900, 13, 762 ; 1902, 15, 1209.)

$Aromatic$ $bisdiazoamino$- $compounds$, e.g. $(C_6H_5 \cdot N_2)_2N \cdot C_6H_5$, have been obtained by the action of 2 molecular proportions of a diazonium salt on one of an aromatic amine (Ber. 1894, 27, 1863, 2597 ; 1895, 28, 170).

$Mixed$ $aliphatic$-$aromatic$ $bisdiazoamino$- $derivatives$ (v. Ber. 1888, 21, 1016 ; 1889, 22, 933 ; 1907, 40, 2390).

$Diazo$-ψ-$semicarbazines$ (v. Forster, Chem. Soc. Trans. 1906, 89, 223).

3. ALIPHATIC DIAZOAMINES.

Dimroth's general method may be applied to the production of purely aliphatic diazoamino- compounds. In this way, the simplest member of the series, **diazoaminomethane (dimethyltriazene)** $CH_3N{:}N \cdot NH \cdot CH_3$, has been prepared from methyl azide and magnesium methyl iodide. This substance, which is isolated by distilling its copper derivative with diazoaminobenzene under reduced pressure, is a colourless liquid, solidifying at $-12°$ and boiling at 92° (Dimroth, Ber. 1905, 38, 1575 ; 1906, 39, 3905).

IV. DIAZO- OXIDES.

When a diazonium salt couples with a phenol the product is generally an ortho or a para- hydroxyazo- compound (the C-azo- derivative), but in all probability, the O-azo- derivative is first produced, for in a few instances, when the velocity of transformation has been lessened by substitution, the intermediate O-azo- compound or diazo-oxide has been isolated. p-Bromo-benzenediazonium chloride and p-nitrophenol give p-$bromobenzenediazoate$-4 $oxynitrobenzene$

$$C_6H_4Br \cdot N{:}N \cdot O \cdot C_6H_4 \cdot NO_2$$
which, at 80°, becomes transformed into its isomeride, p-$bromobenzene$-2-azo-4-$nitrophenol$

$$C_6H_4BrN{:}N \cdot C_6H_4(NO_2)OH$$

(Ber. 1908, 41, 4027, 4304).

Occasionally traces of these intermediate diazoamines and diazo-oxides can be detected in the commercial azo- colouring matters (Vaubel, Zeitsch. Farben. Textil. Ind. 1902, 1, 3).

V. METALLIC DERIVATIVES OF DIAZO- COMPOUNDS.

In 1894 Schraube and Schmidt (Ber. 27, 514) found that on adding a 10 p.c. solution of p-nitrobenzenediazonium chloride to 18 p.c. aqueous sodium hydroxide at 50°–60°, a sodium diazo- derivative separated in yellow bronzy leaflets, to which they gave the formula

$$NO_2 \cdot C_6H_4 \cdot NNa \cdot NO_2H_2O$$
regarding the compound as the *sodium deriva-tive* of *p-nitrophenylnitrosamine*. This view of the constitution of the product was confirmed by the action on the compound of methyl iodide when *p*-nitrophenylmethylnitrosamine

$$NO_2·C_6H_4·N(CH_3)·NO$$
was obtained.

This sodium salt, which was regarded by Hantzsch as having the constitution of an anti-diazo- compound, **sodium *p*-nitrobenzenediazo-oxide** (*v. infra*), has been manufactured for use in the production of ' nitrosamino red ' (Badische Anilin- und Soda-Fabrik D. R. PP. 78874, 80263, 81134, 81202). The addition of excess of mineral acid to this metallic diazo- derivative, determines the regeneration of the original diazonium salt, but treatment with dilute acetic acid leads to the formation of a yellow product, *p-nitrophenylnitrosamine* $NO_2·C_6H_4·NH·NO$, a substance showing little tendency to couple with β-naphthol.

The silver derivative obtained from the foregoing sodium salt yields on methylation an oxygen ether $NO_2·C_6H_4·N:N·O·CH_3$, a re-action suggesting the possibility of tautomeric change. In many instances, two isomeric modifications of these metallic diazo- deri-vatives have been isolated.

Benzenediazonium chloride and cold concen-trated potassium hydroxide yield the normal *labile* form of *potassium benzenediazo-oxide* (I.), which readily couples with β-naphthol. The *stable* modification of *potassium benzenediazo-oxide* (II.) is produced by heating the strongly alkaline solution of the normal or labile salt at 130°-140°; this isomeride couples only very slowly with β-naphthol.

According to Hantzsch, these isomerides have respectively the following formulæ :—

$$\begin{array}{cc} C_6H_5·N & C_6H_5·N \\ \| & \| \\ KO·N & N·OK \end{array}$$

I. *Syn*- (labile form).　II. *Anti*- (stable form).
Dobbie and Tinkler (Chem. Soc. Trans. 1905, 87, 273) have found, however, that these iso-meric potassium salts have totally different ultra-violet absorption spectra. But as stereo-isomerides, like the benzaldoximes, have iden-tical absorption spectra, it seems probable that the above isomeric salts are structurally dis-similar. Confirmation of the stereochemical theory would be obtained by isolating the *anti-*diazohydroxide from the stable (*anti-*) potassium salt, but on treating this with an acid, the nitro-samine separates. Moreover, the product sup-posed by Hantzsch and Pohl to be an *anti-*diazohydroxide (Ber. 1902, 35, 2964) was shown by Orton to be a mixture of quinonediazide and a hydroxyazo- compound (Proc. Roy. Soc. 1903, 71, 153 ; Chem. Soc. Trans. 1903, 83, 796).

The existence of the *syn-* diazohydroxides is doubtful, and diazonium hydroxides (*v. supra*) are only known in solution.

Diazo-anhydrides $R·N:N·O·N:NR$ or $R·N·O·N:NR$ are very unstable explosive com-
Ṅ
pounds produced by the action of acetic acid on the metallic *syn-* diazo-oxides. The *anti-* diazo-oxides, when thus treated, give nitro-samines.

Aromatic diazoic acids $Ar·N_2O_2H$. Benzene-

diazoic acid, produced by oxidising potassium diazoic acid, produced by oxidising potassium benzenesyndiazo-oxide or -isodiazo-oxide with potassium ferricyanide in alkaline solution, is obtained in sparingly soluble white leaflets (m.p. 46°) dissolving readily in organic solvents or alkalis. With mineral acids it is transformed into *o*- and *p*-nitroaniline, and with hypo-chlorites it yields 4-chloro-2-nitroaniline. Its sodium salt gives the α- or *N*-ester $C_6H_5·N(CH_3)·NO_2$, the silver salt furnishes the β- or *O*-ester, $C_6H_5·N:NOO·CH_3$. Since the acid is also obtained by the action of nitrogen pentoxide on aniline it is probably a tautomeric substance $C_6H_5·NH·NO_2 \rightleftharpoons C_6H_5·N:NO_2H$ (Bam-berger, Ber. 1893, 26, 471; 1894, 27, 359, 914, 584, 1273; Hantzsch, Ber. 1902, 35, 258).

VI. DIAZO- CYANIDES.

The addition of the calculated amount of potassium cyanide to a cold acid solution of a diazonium salt determines the formation of a sparingly soluble diazo- cyanide. In many instances, two modifications of the diazo-cyanides can be distinguished, and these varieties are regarded by Hantzsch as being stereoiso-meric forms. *p*-Chlorobenzenediazonium chlor-ide, from *p*-chloraniline, yields first the yellow labile *syn-p*-**chlorobenzenediazocyanide** (I.), which readily evolves nitrogen, yields

$$\begin{array}{cc} C_6H_4Cl·N & C_6H_4Cl·N \\ \| & \| \\ CN·N & N.CN \end{array}$$
I. *Syn*-diazocyanide.　II. *Anti*-diazocyanide.

p-chlorobenzonitrile on treatment with copper powder, and passes into the stable *anti-p*-**chloro-benzenediazocyanide** (II.). The latter sub-stance, which is not affected by copper powder, may be distilled in steam without decomposition.

Confirmation of this stereochemical theory of the constitution of the diazo-cyanides has been obtained by a study of the cyanides de-rived from *p*-methoxybenzenediazonium chlor-ide. This salt with potassium cyanide in alcoholic solution yields the *syn-*diazocyanide (III.), an orange-red insoluble substance (m.p. 51°), which couples with β-naphthol and slowly changes into the non-coupling *anti - diazo-*cyanide (IV.), a brownish - red compound, melting at 121°.

$$\begin{array}{cc} CH_3·O·C_6H_4·N & CH_3·O·C_6H_4·N \\ \| & \| \\ CN·N & N·CN \end{array}$$

III.　　IV.
The existence of a third isomeric cyanide is indicated by evaporating at the ordinary tem-perature in the presence of excess of hydro-cyanic acid, an aqueous solution of *p*-methoxy-benzenediazonium hydroxide. The colourless crystalline product has the composition :

$$CH_3O·C_6H_4·N_2·CN, HCN, 2H_2O$$
and possesses all the properties of a true metallic salt ; it is very soluble, and its solution is an electrolyte. Moreover, this double salt couples with β-naphthol, and is converted by alkalis into the yellow *syn-*diazo cyanide. These properties correspond with those of the normal diazonium salts, and the foregoing soluble cyanide is re-garded as having the following constitution :

$$CH_3·O·C_6H_4·N·CN$$
$$Ṅ$$
(Hantzsch, Ber. 1900, 33, 2161 ; 1904, 34, 4166).

The two pairs of diazo- cyanides from *p*-chloraniline and *p*-anisidine were examined spectroscopically by Dobbie and Tinkler, who found that each pair gave almost identical ultra-violet absorption spectra, whereas the above soluble diazonium cyanide gave an entirely different spectrum. These results are in accordance with Hantzsch's view of the configuration of the diazo- and diazonium cyanides (Chem. Soc. Trans. 1905, 87, 273).

It has, however, been suggested by several workers in this field that the isomerism of the diazo- cyanides is structural, the *syn*- compounds being *iso*-cyanides R·N:N·NC and their *anti*-isomerides, cyanides R·N:N·CN (Ber. 1895, 28 861 ; Chem. Soc. Trans. 1903, 83, 805).

VII. DIAZO- SULPHONATES.

Although the stereochemical theory of the constitution of diazo- cyanides is supported by physical as well as chemical evidence, yet it is significant that the only other series of salts in which this isomerism has been detected is one derived from sulphurous acid, a substance resembling hydrocyanic acid in giving rise to organic isomeric derivatives which are structurally dissimilar.

The diazo- sulphonates, prepared by adding potassium sulphite to aqueous solutions of benzenoid diazonium chlorides, frequently exist in two differently coloured modifications, but in most cases the *syn*- isomeride is too unstable to be isolated in a pure state.

Potassium syn-2.4-diiodobenzenediazosulphonate (I.) is an orange substance, whilst the *anti*-salt (II.) is yellow :

$$C_6H_3I_2\cdot N \qquad\qquad C_6H_3I_2\cdot N$$
$$\parallel \qquad\qquad\qquad\qquad \parallel$$
$$KSO_3\cdot N \qquad\qquad\quad N\cdot SO_3K$$
$$I. \qquad\qquad\qquad\qquad II.$$
The diazotised naphthylamines behave exceptionally, yielding only *syn*-diazosulphonates, which, on warming pass, not into their *anti*-isomerides, but into the corresponding azo-naphthalenes (Ber. 1897, 30, 71).

The *syn*- and *anti*- modifications of **potassium benzenediazosulphonate** $C_6H_5\cdot N$:$N\cdot SO_3K$, were found by Dobbie and Tinkler (*l.c.*) to have identical ultra-violet absorption spectra. This fact supports the stereochemical theory of their structures (*cf.* Ber. 1894, 27, 1726, 2099, 2586, 2930, 3527 ; 1895, 28, 242, 447, 834, 861 ; J. pr. Chem. 1894, [ii.] 50, 239 ; Meyer and Jacobsen, Lehrbuch der Org. Chem. ii. 303).

VIII. ALIPHATIC DIAZO- COMPOUNDS.

The amines of the aliphatic series, when treated with nitrous acid, generally lose their basic nitrogen, the amino- group becoming replaced by hydroxyl. In some cases, however, the nitrogen is retained and an aliphatic diazo-compound is produced, having the general

$$\text{formula } RH\cdot C\begin{array}{c} N \\ \parallel \\ N \end{array}\text{ with the azo- group attached}$$

entirely to the same carbon atom.

An alternative formulation has been suggested for the aliphatic diazo- compounds in which one nitrogen is quinquevalent, so that

the general formula becomes :$>$C:N$\vdots$N (Thiele, Ber. 1911, 44, 2522; Forster and Cardwell, Chem. Soc. Trans. 1913, 103, 861; *cf.* Ber. 1912, 45, 1654; 1916, 49, 1884.

Although glycine is converted by nitrous acid or alkyl nitrites into glycollic acid, yet its ethyl ester gives rise to **ethyl diazoacetate** N_2:$CH\cdot CO_2\cdot C_2H_5$, a yellow liquid freezing at 24° and boiling at 143°-144°/72 mm. (Curtius, Ber. 1883, 16, 2230).

One kilogram of ethyl aminoacetate hydrochloride and 750 grams of sodium nitrite are added successively to 2 litres of water containing 5 grams of sodium acetate. The mixture is shaken until the temperature falls to 0°; 5 c.c. of 10 p.c. sulphuric acid and 500 c.c. of ether are added and the liquids thoroughly agitated. The ethereal layer is separated and the treatment with dilute acid and ether repeated until red fumes are evolved. The ethereal extracts are washed with dilute aqueous sodium carbonate till alkaline, dried with calcium chloride, and the solvent removed on the water-bath. The yield of ethyl diazoacetate is 94·7 p.c. of the calculated quantity (Silberrad, Chem. Soc. Trans. 1902, 81, 600).

With iodine, ethyl diazoacetate yields diiodoacetic acid, and with aldehydes it condenses to form ketonic esters :

$$R\cdot CHO + N_2\text{:}CH\cdot CO_2\cdot C_2H_5$$
$$\to R\cdot CO\cdot CH_2\cdot CO_2\cdot C_2H_5$$
One of the most remarkable reactions of this diazo- ester is its condensation with benzene and its homologues, giving rise to a series of esters containing seven-membered hydrocarbon rings (Bucherer, Ber. 1896-1903, 29, 106 ; 30, 632, 1949 ; 31, 399, 402, 2004, 2241, 2247 ; 32, 705 ; 33, 184 ; 36, 3509 ; Annalen, 1908, 358, 1).

Ethyl diazoacetate, when heated with alkalis undergoes a series of complex polymeric changes (Curtius, Ber. 1885, 18, 1283 ; 1906, 39, 1383, 3398, 4140 ; 1907, 40, 84, 815, 1176, 1194, 1470 ; 1908, 41, 3116, 3140, 3161 ; J. pr. Chem. 1888, [2] 38, 408 ; Hantzsch, Ber. 1900, 33, 58 ; *cf.* Chem. Soc. Trans. 1902, 81, 598).

Diazo- derivatives are not obtained from free α-amino-carboxylic acids, and only from those amino-esters of aliphatic acids containing the amino- group in the α-position with respect to alkylated carboxyl group. The esters of those polypeptides which contain the amino-group in the α-position to a carboxyl- group can also be transformed into diazo- derivatives.

$$NH_2\cdot CH_2\cdot CO\cdot NH\cdot CH_2\cdot CO_2Et$$
$$\to N_2\text{:}CH\cdot CO\cdot NH\cdot CH_2\cdot CO_2Et$$
The α-aminoketones (*e.g.* α-aminoacetophenone $C_6H_5\cdot CO\cdot CH_2\cdot NH_2$) give diazo- compounds (Ber. 1904, 37, 2080), and so also do certain uric acid compounds, *e.g.* aminomethyluracil.

Diazomethane $CH_2\begin{array}{c} N \\ \diagdown \parallel \\ N \end{array}$, or CH_2:N:N, the

simplest aliphatic diazo- compound, is prepared by adding methyl-alcoholic potassium hydroxide to an ethereal solution of nitrosomethylurethane

$$C_2H_5\cdot O\cdot CO\cdot N(CH_3)\cdot NO$$
and distilling the mixture on the water-bath, when the distillate consists of an ethereal solution of the diazo- compound, the yield being

50 p.c. of the calculated quantity. This substance is also produced by the action of hydroxylamine on dichloromethylamine

$$CH_3 \cdot NCl_2 + H_2NOH = CH_2:N_2 + H_2O + 2HCl$$
Diazomethane is a poisonous yellow gas condensing in snow and calcium chloride to a yellow liquid boiling below $0°$. It is a powerful methylating agent, converting hydroxyl groups into methoxyl, and alkylating primary and secondary bases.• With iodine, diazomethane gives nitrogen and methylene iodide, and aldehydes are converted into methyl ketones (*cf.* Monatsh. 1905, 26, 1295, 1311; Ber. 1907, 40, 479; 1908, 41, 3199; 1909, 42, 2559; Chem. Soc. Trans. 1908, 93, 242).

Diazomethane combines additively with unsaturated compounds; with acetylene it gives pyrazole (Ber. 1898, 31, 2910), and with ethyl fumarate it furnishes ethyl pyrazolinecarboxylate.

Diazoethane $CH_3 \cdot CH : N_2$ and **phenyldiazomethane** $C_6H_5 \cdot CH:N_2$ have both been prepared (Ber. 1902, 35, 897). The former closely resembles diazomethane, the latter is a dark-red oil.

Substitution increases considerably the colour of these diazo- derivatives; dimethyldiazomethane $C(CH_3)_2:N_2$ is red and diphenyldiazomethane is obtained in bluish red needles melting at $20°$ (Staudinger, Ber. 1916, 49, 1884).

Diazomethane should not be confused with **azomethane** $CH_3 \cdot N:N \cdot CH_3$, the simplest azo-compound which is produced by oxidising symmetrical dimethylhydrazine (hydrazomethane) with chromic acid (Thiele, Ber. 1909, 42, 2575). Azomethane is a colourless gas condensing to a pale yellow liquid (b.p. $1·5°$).

Diazomethanedisulphonic acid, a noteworthy example of an aliphatic diazo-compound, results from the interaction of potassium cyanide and potassium bisulphite in presence of caustic potash. The solution, acidified and treated with nitrous acid, yields successively ammomethanedisulphonic acid and the diazo- compound. Sulphurous acid and diazomethanedisulphonic acid yield an additive compound which, on boiling, furnishes hydrazine (V. Pechmann, Ber. 1895, 28, 2374; 1896, 29, 2161).

Diazoacetone $CH_3 \cdot COCH:N_2$, a pale yellow liquid, is obtained from aminoacetylacetone by converting this base into diazoacetylacetone anhydride and treating this product with aqueous caustic alkali (Wolff, Annalen, 1912, 394, 23).

Metallic diazo- derivatives of the aliphatic series are produced by treating nitrosoalkyl urethanes with concentrated caustic potash solution or ethereal potassium ethoxide. **Potassium methyldiazo-oxide** $CH_3 \cdot N:B \cdot OK, H_2O$ separates in white crystals, when nitrosomethylurethane is added to concentrated aqueous caustic potash at $0°$. **Potassium benzyldiazo-oxide**

$$C_6H_5 \cdot CH_2 \cdot N:N \cdot OK, H_2O$$
is similarly prepared from nitrosobenzylurethane. These metallic derivatives are very unstable; they are decomposed by water with explosive violence, yielding respectively diazomethane and phenyldiazomethane (Hantzsch and Lehmann, Ber. 1902, 35, 897).

DIBASIC ACIDS. *Oxalic acid series.* A numerous and important group of acids, having the general formula $C_nH_{2n-2}O_4$. The lowest member of the series is *oxalic acid* $C_2H_2O_4$, and the highest member at present known, *dicetyladipic acid* $C_{36}H_{74}O_4$. As the radical C_nH_{2n} is capable of existing in a variety of ways, it follows that these acids may exist in many isomeric forms. Unlike the fatty acids, the lowest members of the oxalic acid series are solids.

The naturally occurring acids exist partly free and partly as salts or esters. Thus oxalic acid occurs chiefly as the potassium salt in different varieties of *Oxalis* and *Rumex*; malonic acid, as the calcium salt, is found in the sugar beet; succinic acid in amber, certain varieties of lignite, resins, turpentine oils, and animal fluids; rocellic acid in *Rocella tinctoria* (D. C.). Other members of this series are obtained by the oxidation of naturally occurring substances. Thus suberic acid is obtained by boiling cork with nitric acid; azelaic acid by the oxidation of castor oil; adipic acid by the oxidation of suet or tallow, whilst homologues of succinic, glutaric and adipic acids are frequently obtained in the oxidation of derivatives of the terpene compounds. The higher members of the series are prepared by the oxidation of members of the fatty acid series.

General methods of preparation.

(1) By the oxidation of the diprimary glycols, primary hydroxyaldehydes, dialdehydes, primary hydroxy- acids, or aldehyde-acids; *e.g.* glycol, glycollic acid, glyoxal, or glyoxylic acid → oxalic acid.

(2) By the oxidation of the fatty acids or of acids of the oleic acid series; *e.g.* erucic acid → brassylic acid.

(3) By the reduction of unsaturated dicarboxylic acids; *e.g.* fumaric acid → succinic acid.

(4) By the action of silver (powder) on mono-iodo- (or bromo)- fatty acids; *e.g.* β-iodopropionic acid → adipic acid.

Exception.—The reaction is abnormal when α-bromisobutyric acid is used, di- and tri- alkylglutaric acids being produced. •

(5) By the conversion of monohalogen- substituted fatty acids or of the halogen addition products of the alkylenes C_nH_{2n} into cyanderivatives and saponification of the latter;

e.g. cyanacetic acid → malonic acid; ethylene dicyanide → adipic acid.

(6) By the replacement of the hydrogen atoms of the CH₂ group in the malonic esters by various alkyl- groups; *e.g.* sodium malonic ester and methyl iodide → *iso*-succinic ester.

(7) By the electrolysis of concentrated solutions of potassium alkyl salts of the dicarboxylic acids; *e.g.* potassium ethyl malonate →diethyl succinate.

(8) By the introduction of acid residues into the acetoacetic esters, and decomposition of the product with alkali; *e.g.* acetosuccinic ester → succinic acid.

(9) By the decomposition of tricarboxylic acids containing two carboxyl- groups attached to the same carbon atom; *e.g.* ethanetricarboxylic acid → succinic acid.

The acids of this series behave differently on the application of heat, depending upon the position of the carboxyl groups. Oxalic acid, the first member of the series, breaks down on heating mostly into carbon dioxide, carbon monoxide, and water, and partly into carbon dioxide and formic acid. This latter decomposition is typical of those homologues of oxalic acid in which the two carboxyl- groups are attached to the same carbon atom; they are the β-dicarboxylic acids, and of these malonic acid is the type. On application of heat, malonic acid splits into acetic acid and carbon dioxide. The next class, the γ-dicarboxylic acids, in which the two carboxyl- groups are attached to adjacent carbon atoms, when heated, lose a molecule of water and pass into anhydrides. Succinic acid is the type of these acids. Acids, such as glutaric acid, in which the carboxyl- groups are attached to two carbon atoms separated by a third, behave similarly to the γ-dicarboxylic acids, but form anhydrides less readily. When the carbon atoms to which the carboxyl- groups are attached are separated by two carbon atoms, *e.q.* adipic acid, they do not influence one another on the application of heat. For these reasons, the paraffin dicarboxylic acids are arranged in different groups, the general properties of which will be discussed under MALONIC ACID, SUCCINIC ACID, and GLUTARIC ACID, which are types of the several groups mentioned above.

DIBENZIL *v.* KETONES.

DI-*iso*-BUTYLACETIC ACID *v.* DECATOIC ACIDS.

2·6·DI-*iso*-BUTYLPIMELIC ACID

$$CH_2[CH_2·CH(C_4H_9)·CO_2H]_2$$
Prepared by heating 1·5·di-*iso*-butylpentane-tetracarboxylic acid at 200°-220° (Perkin and Prentice, Chem. Soc. Trans. 1891, 842); m.p. 82°-84°.

DICENTRINE $C_{20}H_{21}O_4N$ occurs with protopine in *Dicentra pusilla* (Sieb. and Zucc.) and possibly in *D. formosa* (Walp.). Prismatic crystals, m.p. 168°-169°, $[a]_D +62°$ in chloroform. Salts crystalline (Heyl. Arch. Pharm. 1903, 241

313; Asahina, *ibid.* 1909, 247, 201). Produces slight narcosis (Iwakawa, Arch. expt. Path. Pharm. 1911, 64, 369). Gadamer has stated (Arch. Pharm. 1911, 249, 680) that dicentrine resembles glaucine in its properties, and suggests that it is glaucine in which the two —OMe groups in positions 5 and 6 are replaced by a dioxymethylene group.

DICETYLADIPIC ACID $C_{38}H_{74}O_4$. Prepared by heating dicetylbutanetetracarboxylic acid to 205° (Lean, Chem.`Soc. Trans. 1894, 1016). Two isomerides are thus produced, which may be separated by crystallisation from alcohol, α-acid, m.p. 42°-43°; β-acid, m.p. 32°-34°.

DICETYLIC ACID $CH(C_{16}H_{32})_2COOH$ is obtained by heating dicetylmalonic acid; m.p. 69°-70° (Guthzeit, Annalen, 206, 365)

DICETYLMALONIC ACID

$$(C_{16}H_{33})_2C(CO_2H)_2$$
The ethyl ester is formed by treating diethylmalonic ester with sodium methoxide and cetyl iodide; the ester is decomposed with a concentrated solution of caustic potash; m.p. 86°-87° (Guthzeit, Annalen, 206, 362).

DICHLORAMINET. Toluene-*p*-sulphone dichloramine.

2 : 5-DICHLOROANILINE

Prepared by reducing 2 : 5-dichloronitrobenzene with iron and hydrochloric acid; m.p. 50°; b.p. 246°/744 mm. Used in making the chloramine dyes.

2 : 5 - DICHLOROANILINE - 4 - SULPHONIC ACID

2 : 5-dichloroaniline. Soluble in hot water. Sodium salt with 5 molecules H_2O readily soluble (Noelting and Kopp, Ber. 1905, 38, 3513).

1 : 5-DICHLOROANTHRAQUINONE

is obtained by boiling an aqueous solution of alkali anthraquinone-1 : 5-disulphonate with hydrochloric acid and sodium chlorate (Ullmann and Knecht, Ber. 1911, 44, 3125; Farbenfab. vorm. F. Bayer & Co., D. R. P. 205195). Also by suspending 1 : 5-diaminoanthraquinone in hydrochloric acid, diazotising at 5°-10°, and treating the solution with cuprous chloride dissolved in hydrochloric acid (*idem.* D. R. P. 131538). Citron-yellow needles, readily soluble in hot toluene, sparingly soluble in alcohol; m.p. 251°. Used in making indanthrene violet (*q.v.* art. INDANTHRENE).

3 : 3′-DICHLOROBENZIDINE
Prepared by chlorinating a sulphuric acid solution of diacetyl benzidine (made by boiling benzidine with glacial acetic acid) with bleaching

powder or sodium hypochlorite solution, filtering, adding hydrochloric acid, and hydrolysing the product (Levinstein, Eng. Pat. 25725, 1896). May also be obtained by reducing o-chloronitrobenzene in an alkaline solution by means of zinc dust (cf. Cohn, Ber. 1900, 33, 3551).

DICHLOROCARBAMIDE v. HYDRAZINES.

DICHLOROPHTHALIC ACIDS v. PHTHALIC ACID.

2′ : 5′-DICHLORO-4′-SULPHO-1-PHENYL-3-METHYL-5-PYRAZOLONE. Prepared by condensing ethyl acetoacetate with 2 : 5-dichlorophenylhydrazine-4-sulphonic acid (D. R. P. 222405). Used in making Xylene yellow (see PYRAZOLONE COLOURING MATTERS).

DICHROITE v. IOLITE.

DICYANDIAMIDE, Cyanoguanidine

$$NH_2(NH:)C\cdot NH\cdot C:N$$
Obtained by the polymerisation of cyanamide in aqueous solution on long standing or on warming, especially after addition of a drop of ammonia (Beilstein and Geuther, Annalen, 108, 99 ; 123, 241 ; Haag, ibid. 122, 22) ; by treating thiourea with mercuric amline (Montecchi, Gazz. chim. ital. 28, ii. 434) Prepared by heating ammonium sulphate and sodium cyanamide on the water-bath ; cyanamide separates as a yellow oil, which, after some hours, with frequent shaking, changes into dicyandiamide (Hermann, Monatsh. 1905, 1025). Soll and Stutzer (Ber. 1908, 4534) make crude calcium nitride into a paste with water and heat to boiling. The hot liquid is filtered by suction, and dicyandiamide separates out from the filtrate. Crystallises in needles ; m.p. 205° (Pohl, J. pr Chem. 77, [2] 533). By warming with dilute acids, it is transformed into dicyandiamidine (guanyl urea) $NH_2(NH:)C\cdot NH\cdot CO\cdot NH_2$. It is used in quantitative analysis to separate nickel from cobalt. The solution containing nickel and cobalt is made alkaline, and to it is added a small quantity of sugar solution. To this is added dicyandiamidine sulphate (prepared by dissolving dicyandiamide in dilute sulphuric acid), whereby the nickel salt of dicyandiamidine is precipitated, the cobalt remaining in solution. The precipitate is filtered through a Gooch crucible, dried at 115°–160°, and weighed as anhydrous nickel dicyandiamidine $Ni(C_2H_3N_4O)_2$ (Grossmann and Schück, Analyst, 1910, 247 ; 1909, 455 ; 1907, 273, 394). Dicyandiamide is reduced by zinc and dilute hydrochloric acid at the ordinary temperatures to methylamine and guanidine, the methylamine being formed by the reduction of the prussic acid first produced (Bamberger and Seeberger, Ber. 1893, 1583) ; a mixture of nitric and sulphuric acids converts it into nitrodicyanodiamidine (Thiele and Uhlfelder, Annalen, 303, 107) ; it condenses with dialkylcyanacetic or malonic esters yielding pyrimidine derivatives ; thus with diethylcyanacetic ester a condensation product is obtained which yields diethylbarbituric acid on treatment with sulphuric acid (Bayer & Co., D. R. P. 165223 ; Chem. Zentr. 1906, i. 514). All manures containing calcium cyanamide contain also dicyandiamide, formed by the spontaneous polymerisation of the calcium cyanamide ; it is not poisonous to plants if not used in too large quantities (Perotti, Atti. R. Accad. Lincei, 15, i. 48 ; Chem. Zentr. 1909, i. 1497 ; Inouye, J. Soc.

Chem. Ind. 1909, 1054 ; Aso, ibid.). The Cyanide-Gesellschaft (Chem. Zentr. 1904, ii. 1079 ; D.R.P. 154505) treat calcium carbide or a carbide-forming mixture with nitrogen, lixiviate the mass with water, and use the product, which contains calcium cyanamide, dicyandiamide, &c., as a manure (v. also Frank, Zeitsch. angew. Chem. 19, 835). The constitution of dicyandiamide is regarded as $NH_2(NH:)C\cdot NH\cdot C:N$ or the tautomeride $(NH_2)_2C:N\cdot C:N$ (Bamberger, Ber. 1883, 1459 ; 1891, 899 ; Biltz, J. pr. Chem. 77, [ii.] 533 ; Pranichnikov, J. Soc. Chem. Ind. 1909, 724).

DIDYMIN v. SYNTHETIC DRUGS.

DIDYMIUM v. PRASEODYMIUM and NEODYMIUM.

DIETHYLACETIC ACID. Pseudo-caproic acid (v. CAPROIC ACID).

DIETHYLALLOXAN v. ALLOXAN.

DIETHYLAMINE v. under Ethylamines, art. ETHYL.

p-DIETHYLAMINOBENZOIC ACID

$$CO_2H\langle\ \rangle N(C_2H_5)_2$$
Prepared by the action of carbonyl chloride on diethylaniline or by ethylating p-aminobenzoic acid ; m.p. 188°.

DIETHYL-m-AMINOPHENOL

$$\overset{OH}{\underset{}{\langle\ \rangle}} N(C_2H_5)_2$$
Formed by heating m-aminophenol hydrochloride with ethyl alcohol under pressure (Bad. Anil. und Soda Fabrik, D. R. P. 44002) ; by heating resorcinol with diethylamine (Leonhardt & Co., D. R. P. 49060) ; by alkali fusion of diethylaniline-m-sulphonic acid (Soc. Chem. Ind. Basle, D. R. P. 44792). For details of the last-named process as used on the large scale, see Cain, Intermediate Products for Dyes ; m.p. 78° ; b.p. 201°/25 mm. Used in the manufacture of rhodamine B.

DIETHYLANILINE $\langle\ \rangle N(C_2H_5)_2$. Obtained by heating aniline hydrochloride with ethyl alcohol under pressure ; or, better, by heating aniline hydrobromide with ethyl alcohol at 145°–150° (Stadel, D. R. P. 21241), or by treating aniline with ethyl alcohol in presence of iodine at 235° (Knoll & Co., D. R. P. 250236) ; m.p. −38·1° ; b.p. 216·5° ; sp.gr. 0·930 at 18°.

DIETHYLANILINE-m-SULPHONIC ACID

$$\overset{SO_3H}{\underset{}{\langle\ \rangle}} N(C_2H_5)_2$$
Is prepared by acting on diethylaniline with fuming sulphuric acid.

DIETHYLDIACETOSUCCINATE v. KETONES.

DIETHYL OXALACETATE v. KETONES.

DIETHYLSAFRANIN v. AZINES.

DIETZEITE. A double iodate and chromate of calcium crystallising in the monoclinic system, discovered in 1891 in the sodium nitrate deposits of Atacama, Chile. Analyses lead to the formula $7Ca(IO_3)_2\cdot 8CaCrO_4$, but the simple double salt formula $Ca(IO_3)_2\cdot CaCrO_4$ appears more probable. Distinct crystals are rare, the mineral usually forming crystalline fibrous aggregates of a dark gold-yellow colour. Sp.gr.

3·698. It is soluble in hot water; on cooling crystals of hydrated calcium iodate $(Ca(IO_3)_2 + 6H_2O)$ separate, leaving the calcium chromate in solution. The simple calcium iodate $(Ca(IO_3)_2)$ called lautarite occurs in the same deposits.

L. J. S.

DIFFUSION. In any gaseous mixture or liquid solution, even when protected from mechanical disturbances and kept at a uniform temperature throughout, the composition ultimately becomes the same at all points, whatever the original distribution of the gaseous or dissolved substances may have been. The process by which this condition is reached is termed 'diffusion,' and it depends, not on the circulation of the unequally distributed substances as a whole, but on molecular movement. According to the kinetic theory, a mass of gas which, as a whole, is at rest, is yet the scene of great activity on the part of the constituent molecules. These are endowed with a high velocity, and alter the direction of their motion only when they collide with one another or with the walls of the containing vessel. If this point of view is adopted, then the occurrence of diffusion in a mixture of irregularly distributed gases becomes intelligible. There are, moreover, many experimental grounds for extending the kinetic theory to the liquid state, and for the view that the molecules of a liquid also are in a state of constant motion. With this conception the phenomenon of diffusion of a dissolved substance is obviously in harmony.

Diffusion of Gases.

When two vessels containing different gases at the same temperature and pressure are put into free communication, each gas penetrates the other until its partial pressure is uniform in both vessels. The experimental investigation of this phenomenon on quantitative lines is not easy, but it appears to be well established that the diffusion coefficient of each gas varies from point to point of the diffusion system (*see* Loschmidt, Sitzungsber. Akad. Wiss. Wien, 1870, 61, 367; 1870, 62, 468; von Obermayer, *ibid.* 1880, 81, 1102; 1882, 85, 147, 748; 1883, 87, 188; 1887, 96, 546; Waitz, Ann. Physik, 1882, 17, 201, 351; ·Lonius, *ibid,* 1909, 29, 664).

When the concentration of a gas is maintained constant at one point of a gas system and zero at another point, a static condition of affairs is established analogous to what is observed when one end of a metal bar is kept at a high temperature and the other end at a low temperature. If, for instance, a tall cylinder, communicating freely with the atmosphere, contains at the bottom a layer of caustic alkali, there is a regular concentration gradient from the top downwards, tlfe carbon dioxide being completely absorbed at the surface of the alkali. Provided the concentration difference between the top and bottom of the cylinder is maintained constant, a steady condition of diffusion is attained, and the rate of flow of the carbon dioxide, as deduced from the amount absorbed by the alkali, is inversely proportional to the length of the diffusion column (*see* Brown and Escombe, Phil. Trans. B, 1900, 193, 223; *also* Winkelmann, Ann. Physik, 1884, 22, 1, 152).

Much attention has been devoted to the phenomenon of diffusion across porous diaphragms, through capillary tubes, and from narrow apertures. Graham showed (*see* Chemical and Physical Researches, p. 44) that the exchange of two gases across a porous diaphragm, the pressure on the two sides remaining the same, takes place in such a way that the volumes of the gases diffused in a given time are inversely proportional to the square roots of their densities. This observation is of very great interest in connection with the kinetic theory, from the assumptions of which it follows that the mean velocity of the molecules of a gas is inversely proportional to the square root of its density. Graham's law is not accurate except when the diaphragm is extremely thin, but it is nevertheless the basis of a method for separating two gases of different densities. Thus, for instance, when a mixture of hydrogen and oxygen in the proportion of 2 : 1 by volume is passed at a suitable rate through a train of clay-pipe stems, the gas collected at the further end will ignite a glowing splint. By experiments of this kind it was shown that atmospheric nitrogen is a mixture of at least two gases of different density (*see* Rayleigh and Ramsay, Phil. Trans. 1895, 186, 206). The operation of separating gases by this method is termed 'atmolysis.'

In the passage of a gas through a capillary tube—'transpiration,' as it is sometimes called—friction generally plays a considerable part, but it has been found that if the diameter of the tube is small in comparison with its length and with the mean free path of the gas molecules, then the quantity of gas passing through a given tube in unit time is inversely proportional to the square root of the density (Knudsen, Ann. Physik, 1909, 28, 75).

The time required for the escape or 'effusion' of a given volume of gas through a fine aperture in a thin plate into a vacuum is approximately proportional to the square root of the density of the gas. The thinner the plate and the smaller the aperture, the more nearly is this relationship fulfilled (*see* Graham, Chemical and Physical Researches, p. 88; Bunsen, Gasometry, p. 121; Timoféeff, Zeitsch. physikal. Chem. 1890, 6, 586; Donnan, Phil. Mag. 1900, 49, 423; Emich, Monatsh. 1903, 24, 747; Knudsen, Ann. Physik, 1909, 28, 999). An apparatus for determining the relative density of two gases, based on this principle, has been described by Bunsen (*l.c.*) (*v.* SPECIFIC GRAVITY).

The passage of a gas across a diaphragm takes place, not only when the diaphragm is porous In the ordinary sense, but also when it has the power of dissolving or absorbing the gas. Thus, at high temperatures, platinum and palladium absorb considerable quantities of hydrogen, and this gas readily diffuses through the walls of a vessel made of either metal. Winkelmann (Ann. Physik, 1901, 6, 104; 1902, 8, 388 1905, 16, 773; 17, 589; Richardson, Nicol & Parnell, Phil. Mag., 1901, 8, 1; Schmidt, Ann. Physik, 1904, 13, 747) has shown that the rate of diffusion of hydrogen through glowing platinum or palladium is not, as might be expected, proportional to the pressure of the hydrogen; at lower pressures the gas diffuses relatively more rapidly. The experimental data seem to indicate that it is the atoms, not the molecules, of hydrogen which can pass through the metal.

On the ability of hydrogen and the inability of other gases to diffuse through heated palladium, there is based the osmotic cell described by Ramsay (Phil. Mag. 1894, 38, 206).

The rate of diffusion of gases across a layer of water or aqueous solution depends mainly on the solubility and the density of the gas. According to Exner, who made experiments on the diffusion of gases across a film of soap solution, the velocity is, *cæteris paribus*, directly proportional to the absorption coefficient of the gas, and inversely proportional to the square root of its density (Exner, Sitzungsber. Akad. Wiss. Wien, 1874, 70, ii. 465; *cf.* Müller, Ann. Physik, 1891, 43, 554). Other workers, who have studied the diffusion of gases through a jelly, through a layer of water supported by a plate of hydrophane, or through a rubber membrane, find that Exner's law is only an approximate statement of the facts (*see* Wroblewsky, Pogg. Ann. 1876, 158, 545; Ann. Physik, 1879, 8, 29; Hüfner, Zeitsch. physikal. Chem. 1898, 27, 227; Hagenbach, Ann. Physik, 1898, 65, 673). Except for oxygen, the diffusion coefficients of gases are smaller in gelatine solution than in pure water. •

Diffusion of Dissolved Substances.

The foundation of our knowledge of this subject was laid by the classical experiments of Thomas Graham (*see* Chemical and Physical Researches, pp. 444–600). In his experiments, 700 cub. cm. of water were placed in a cylindrical jar, and then 100 cub. cm. of the solution to be diffused were carefully conveyed to the bottom of the jar by a pipette. After a suitable time, portions of 50 cub. cm. were successively drawn off; these portions were evaporated, and the amount of substance that had diffused into each layer was thus ascertained. Graham's comparative experiments on the diffusive power of different substances in aqueous solution led him to draw a distinction, which has become of the highest importance, between the behaviour of easily crystallisable substances, and that of substances which are marked by the absence of the power to crystallise. So far as diffusibility is concerned, the distinction in question is based on the following figures, representing approximate times of equal diffusion : hydrochloric acid, 1; sodium chloride, 2·3; sucrose, 7; magnesium sulphate, 7; albumin, 49; caramel, 98. The difference in diffusive power of crystalloids and colloids is very evident from these figures.

The significance of the quantitative results obtained by Graham was emphasised by Stefan (Sitzungsber. Akad. Wiss. Wien, 1878, 78, ii. 957; 1879, 79, ii. 161), who showed that they were in harmony with Fick's diffusion law; that is, the diffusion of substances in aqueous solution is comparable with the distribution of heat in conductors. Fick's law is expressed algebraically by the formula $dS = -kq\frac{dc}{dx}dt$, where dS is the amount of substance crossing a section of the diffusion column in time dt, the sectional area of this column being q sq. cm., and dc/dx being the concentration gradient; k is known as the 'diffusion coefficient.'

The diffusion of dissolved substances, notably electrolytes, has been the subject of repeated investigation, but the method employed has not differed materially from that of Graham, described above (*see* Scheffer, Zeitsch. physikal. Chem. 1888, 2, 390; Arrhenius, *ibid.* 1892, 10, 51; Abegg, *ibid.* 1893, 11, 248; Euler, Ann. Physik, 1897, 63, 273; Abegg and Bose, Zeitsch. physikal. Chem. 1899, 1, 17; Thovert, Compt. rend. 1902, 134, 826; Graham, Proc. Roy. Soc. 1903, 72, 212; Oholm, Zeitsch. physikal. Chem. 1904, 50, 309). The general result of these investigations has been to substantiate the validity of Fick's law, although the opposite opinion also has been expressed (*see* Wiedeburg, Zeitsch. physikal. Chem. 1892, 10, 509).

Special interest has attached to the diffusion of electrolytes since the enunciation of Arrhenius's dissociation theory, according to which the ions of an electrolyte in aqueous solution are to be regarded in many respects as separate units. The researches of Kohlrausch have proved that the contribution which the one ion of an electrolyte makes to the equivalent conductivity is independent of the other ion associated with it, and Nernst has shown that the mobility which is thus characteristic of each ion must be a determining factor in the diffusive power of any electrolyte of which the ion forms a part (Zeitsch. physikal. Chem. 1888, 2, 613). He has further deduced a theoretical relationship between the diffusion coefficient of a binary electrolyte and the conductivities of the two ions, and the values of the diffusion coefficient calculated on this basis are in good agreement with the results of experimental work.

By allowing substances to diffuse into a jelly the effects of convection currents and mechanical disturbances are eliminated and the difficulties attending the experimental study of liquid diffusion are diminished. The rate of diffusion is, at most, very slightly lower in a jelly than in water at the same temperature. Experiments, in which the ends of cylinders of agar-agar jelly were immersed in aqueous solutions of various substances, have shown that the total amount of substance diffusing into the jelly is proportional to the square root of the time during which diffusion has taken place. This is a result in harmony with Fick's law (*see* Voigtländer, Zeitsch. physikal. Chem. •1889, 3, 316; *cf.* Chabry, Journ. de Physique, 1888, 7, 115; Morse and Pierce, Zeitsch. physikal. Chem. 1903, 45, 589; Hausmann, Zeitsch. anorg. Chem. 1904, 40, 110).

Experiments have been made also on the diffusion of various electrolytes and non-electrolytes in alcohol (Kawalki, Ann. Physik, 1894, 52, 166, 300; 1896, 59, 637), of various metals in mercury, fused lead, &c. (Meyer, *ibid.* 1897, 61, 225; 1898, 64, 752; Humphreys, Chem. Soc. Trans. 1896,·69, 243, 1679; Roberts-Austen, Phil. Trans. 1896, 187, 383; von Wogau, Ann. Physik, 1907, 23, 345), and of chlorine, bromine, and iodine in some organic solvents (Euler, Ann. Physik, 1897, 63, 273; Walden, Zeitsch. Elektrochem. 1906, 12, 77). In the last-mentioned connection, Walden has shown that, when a given halogen is considered, the product 'diffusion coefficient × viscosity of solvent ' is a constant, independent of the nature of the solvent. The value of the product for the different halogens is inversely proportional to the square root of the molecular

weight (cf. Pissarjewsky and Karp, Zeitsch. physikal. Chem. 1908, 63, 257).

The different rates of diffusion found by Graham for different substances suggested to him that the process of diffusion might be useful in separating the constituents of an aqueous solution. In this connection, he found that the difference in diffusive power between crystalloids and colloids, referred to above, was greatly accentuated by the interposition of a colloid membrane between solution and solvent, and the method of separation by diffusion through a septum of gelatinous matter he termed ' dialysis.' A sheet of parchment paper, for instance, is tied tightly over the end of a cylindrical or bell-shaped glass vessel, provided with a flange, and into the receptacle so formed, a ' dialyser,' as it is called, the mixed solution of crystalloids and colloids is poured. The outside of the parchment membrane is bathed with water, which is frequently renewed, and the result is that the contents of the dialyser, after a few days, are found to be practically free from crystalloids. Instead of the apparatus just described, a sausage-skin dialyser may be employed : the parchment tube is charged with the solution of crystalloid and colloid, and is hung up by its ends in a vessel of water.

Collodion may be used as a membrane instead of parchment, and it is obtainable in any desired form by the evaporation of the ordinary collodion solution (see Lillie, Amer. J. Physiol. 1907, 20, 127 ; Schryver, Proc. Physiol. Soc. 1908, 23).

Dialysis plays a considerable part in the technical production of beet sugar. In the diffusion process for the extraction of the sugar, beet cuttings are treated with hot water. Such treatment kills the protoplasm, and the cell membrane, which in the living state is impermeable to sugar, now allows this substance to pass out into the water. The high temperature also favours rapid diffusion. The albuminous substances in the beet juice, however, cannot readily penetrate even the dead protoplasm, which acts as a differential membrane, and thus leads to a dialytic separation of the sugar from some of the non-sugar constituents of the cell sap. In the treatment also of beet sugar molasses dialysis with parchment membranes is employed. The result of this procedure is to reduce the salt content of the molasses, and so make possible the crystallisation of a further portion of the sugar (v. SUGAR).

Diffusion of Solids.

The efficiency of certain cementation processes indicates that one solid can slowly penetrate another. The occurrence of diffusion in solids has been proved by experiment of Roberts-Austen (Phil. Trans. 1896, 187, 383), who finds that at temperatures between 100° and 200° there is an appreciable diffusion of gold into solid lead in 30 or 40 days, although the penetration is much slower than into the fluid metal. Experiments lasting over four years have shown that gold diffuses into solid lead, even at the ordinary temperature (Roberts-Austen, Proc. Roy. Soc. 1900, 67, 101).

DIFORMIN v. FORMINS. •

DIGALENv. DIGITALIS and SYNTHETIC DRUGS.

DIGALLIC ACID (*Gallotannic acid, tannin*) v. TANNIC ACIDS.

DIGESTER v. AUTOCLAVE.

DIGIFOLIN, DIGIPAN, DIGITALEÏN, DIGITALIN, DIGITALOSE, DIGITALYSATUM, DIGITOFLAVONE, DIGITONIN, DIGITOPHYLLIN, DIGITOXOSE v. DIGITALIS.

DIGIPOTENE. A preparation of digitalis leaves.

DIGIPURATUM v. DIGITALIS.

DIGITALINUM VERUM v. DIGITALIS.

DIGITALIS. *Foxglove. Digitalis folia*, B.P. *Digitalis*, U.S.P. (*Digitale*, Fr. ; *Fingerhut*, Ger.) The foxglove, *Digitalis purpurea* (Linn.), had been for some centuries a popular remedy for dropsy, when it was introduced into scientific medicine by Withering, about 1775. It is principally used for its action on the heart ; it slows the beats, and makes them more powerful and regular, so that the output is increased. Only the leaves are official ; the seeds have a similar action, due, however, to different principles. •

Foxglove is a biennial plant, and the Brussels conference agreed that only the second year's leaf should be used ; but, except for the greater difficulty of identification, there is no objection to using the first year's rosettes, which are as good as the flowering plant (Straub, Arch. Pharm. 1917, 255, 198). Cultivated plants up to the beginning of the flowering period, are fairly constant in activity ; variations appear when the seeds ripen. It would probably be the more economical to cultivate only first-year plants. Mature wild plants differ greatly in various localities (Straub). The time for gathering these is July and August, the British Pharmacopœia prescribes leaves from plants beginning to flower. For further detail, see Nativelle (J. Pharm. Chim. [iv.] 20, 81), and for culture, harvesting, and conservation, Newcomb (Amer. J. Pharm. 1912, 84, 201). For *D. Thapsi*, which has a similar action to *D. purpurea*, but is three times as strong, see Farwell and Hamilton, Amer. J. Pharm. 1917, 89, 147.

The active principles of *digitalis* (as of other plants with a like action, such as *strophanthus* and *squill*) are complex glucosides, often amorphous, and this explains the great difficulties and numerous contradictions with which the chemistry of *digitalis* is beset. The confusion is increased by the use of the same name (digitaline) for different substances, and by the application of different names to the same substance. According to our present knowledge, cold water extracts from the leaves a mixture of glucosides, but hardly dissolves digitoxin, which may be subsequently extracted by alcohol. From the aqueous extract chloroform removes the ' gitalin ' fraction, and leaves behind one or more glucosides, designated as the ' digitaleïn ' fraction, which is less active than either gitalin or digitoxin, and has not been obtained even approximately pure. Historically, the first moderately pure, but amorphous, active preparation was ' *digitaline* ' of Homolle (J. Pharm. Chim. 1845, [iii.] 7, 57), undoubtedly a mixture. Nativelle (J. Pharm. Chim [iv.] 1869, 9, 225 ; 1872, 16, 430 : 1874, 20, 81) later prepared a • *digitaline cristallisée,*' a commercial specimen of which Schmiedeberg

(Arch. exp. Path. Pharm. 1874, 3, 16) declared to consist very largely of a substance to which he gave the name *digitoxin*, and as this substance was afterwards principally investigated in Germany, under this name, Nativelle's designation has been displaced, in spite of French protests (*e.g.* Arnaud, Compt. rend. 1889, 109, 679) Kiliani, who has published something like forty papers on the chemistry of digitalis (Ber. 1890, 23, 1555 to 1918, 51, 1613 ; and Arch. Pharm. 1892, 230, 250 to 1916, 254, 255), at one time did not agree with the identification of Nativelle's digitaline with Schmiedeberg's digitoxin, and considered the former substance identical with a crystalline leaf glucoside described by himself as *digitophyllin* (Arch. Pharm. 1897, 235, 425). Later, Kiliani (Ber. 1898, 31, 2454) considered digitaline cristallisée and digitoxin very closely similar, but doubtfully identical. An attempt to restore the historically correct name for this glucoside would lead to still greater confusion, especially as German writers mean by digitalin a totally different glucoside from the seeds.

The 'gitalin' fraction is, on account of its solubility in water and its physiological action, probably of most importance therapeutically ; it was little studied until Kraft (Schweiz. Wochenschr. Chem. Pharm. 1911, 49, 161, 173, 236 ; Arch. Pharm. 1912, 250, 118) described the isolation of a crystalline glucoside *gitalin*. Kiliani (Arch. Pharm. 1914, 252, 13) has declared Kraft's preparation to be a mixture, but in any case it contains one or more crystalline substances of great activity, having the advantage over digitoxin of solubility in water, at least in the crude state. Indeed, the gitalin fraction seems to have been utilised some years before Kraft by Cloetta (Muench. mediz. Wochenschr. 1904, 51, 1466), whose 'digitoxinum soluble' is not digitoxin in a water soluble form (Kiliani, Ber. 1907, 40, 2996), but consists largely of gitalin (Gottlieb, *e.g.* Arch. exp. Path. Pharm. 1918, 83, 117).

For the preparation of their substances, both Homolle and Nativelle extracted the powdered leaves with 50 p.c. alcohol, and purified the extract with lead acetate. After removal of the excess of lead, Homolle evaporated to a syrup and precipitated in the cold with tannic acid. The tannic acid precipitate was washed with tepid water, mixed with an equal weight of lead oxide, dried, and extracted with 90 p.c. alcohol. After treatment with charcoal and evaporation, the residue was extracted with ether to remove impurities. Tannin, apparently introduced by Homolle, was later applied to the separation of *k*-strophanthin (*q.v.*), and seems to be still in use for such commercial preparations as digipuratum (*see* below) ; but it is, of course, only a general colloidal precipitant, and cannot be expected to act specifically. Nativelle moistened the powdered leaves with a solution of neutral lead acetate, then extracted with 50 p.c. alcohol, and purified the extract repeatedly with charcoal and lead acetate. He finally extracted with chloroform, and thus separated off the 'digitalein' fraction, which enabled him to obtain a crystalline substance. Schmiedeberg (*l.c.*) introduced the preliminary extraction of the leaves with cold water, thus removing the gitalin and digitalein fractions,

and then, after pressing the leaves, he extracted with 50 p.c. alcohol. After precipitation with basic lead acetate, and removal of the excess with ammonia, the alcohol was evaporated, while the solution was kept neutral. A partly crystalline substance separated, which was dried on the water-bath and extracted with chloroform. The residue, after evaporation of the chloroform, was washed with ether (which removes fat, luteolin, &c.), or with boiling petroleum ether, and then crystallised the digitoxin from 80 p.c. alcohol with charcoal. Kiliani's method of preparing digitoxin (Arch. Pharm. 1895, 233, 311) is similar.

Digitaline cristallisée, Digitoxin $C_{34}H_{54}O_{11}$ (Kiliani) forms hydrated needles and leaflets from aqueous alcohol, which become anhydrous and sinter at 145°-150°, and anhydrous prisms from methyl alcohol and chloroform, melting at 245° (243°-245° Arnaud). Kraft (Arch. Pharm. 1912, 250, 418) could not obtain the hydrated form, and concludes Kiliani's supposed hydrate was contaminated with gitalin.

The yield of digitoxin is said to be 0·1 p.c. of the leaves, but Straub (*l.c.*) has concluded from physiological evidence that the amount present is very variable, and may considerably exceed 0·1 p.c. Merck's commercial preparation is stated by Kiliani to be about 90 p.c. pure. 0·65 gram digitaline (digitoxin) dissolves at 14° in 100 c.c. absolute alcohol (Arnaud). Digitoxin dissolves readily in chloroform, only slightly in ether, not in water. It gives a characteristic colour reaction ; glacial acetic acid and concentrated sulphuric acid are employed, 100 c.c. of each being previously diluted with 1 c.c. of 5 p.c. aqueous ferric sulphate solution. A trace of digitoxin is dissolved in 1 c.c. of the acetic acid, and 2 c.c. of the sulphuric acid are allowed to flow underneath, in a narrow test tube. The zone of contact becomes dirty brown, and after a few minutes the acetic acid begins to become indigo blue. This, Keller's reaction, is still positive with 0·1 mg. in 1 c.c. of acetic acid. Concentrated hydrochloric acid dissolves digitoxin in the cold to a colourless solution, becoming bluish-green on warming. Alcoholic sodium hydroxide hydrolyses to *digitoxinic acid* $C_{34}H_{56}O_{12}$, mineral acids hydrolyse to two molecules of *digitoxose*

$$CH_3 \cdot CHOH \cdot CHOH \cdot CHOH \cdot CH_2 \cdot CH \cdot O$$
m.p. 101°, and one of *digitoxigenin* $C_{22}H_{32}O_4$, m.p. 230° (*v. e.g.* Kiliani, Arch. Pharm. 1913, 251, 562). Digitoxose is a peculiar sugar, and gives Keller's reaction, digitoxigenin does not.

Gitalin $C_{28}H_{46}O_{10}$ (?), m.p. 150°-155°, is amorphous, and was obtained by Kraft by a method analogous to that of Homolle (*v. supra*), and extracting the glucoside from aqueous solution by shaking with chloroform ; after drying, the chloroform solution is precipitated by light petroleum. Gitalin is soluble in 600 parts of water, and very readily in chloroform. By dissolving in 1·5 parts of alcohol and adding 0·75 part of water, a crystalline *gitalin hydrate* $C_{28}H_{46}O_{10}, 4H_2O$, m.p. 75°, is separated. Solutions of gitalin deposit on keeping mixtures of gitalin and *anhydrogitalin* $C_{28}H_{46}O_9$, m.p. 255°, crystallising from dilute alcohol and almost insoluble in chloroform. On hydrolysis by acids, gitalin, its hydrate, and its anhydride all

yield digitoxose (see above), and hence they all give Keller's reaction; the other fission product is anhydrogitaligenin $C_{22}H_{24}O_5$, m.p. 216°–219°, crystallising from alcohol. As already stated, Kiliani considers gitalin to be a mixture, of anhydrogitalin with other substances, but this does not dispose of Kraft's contribution to the subject.

Digitaleïn (Schmiedeberg) differs from gitalin and digitoxin in not producing the typical systolic arrest of the heart.

Commercial Preparations of Digitalis.—A considerable number of these have been introduced of late years, mostly in Germany. Digalen (Hoffmann-Laroche & Co.), introduced in 1904, has been one of the most successful. It is Cloetta's 'digitoxinum solubile'=impure gitalin? (see above). Digifolin and digipan are similar impure active principles. Digipuratum (D. R. P 227552, 245193, 246571, of Knoll & Co.) is a purified leaf extract freed from digitonin, and apparently consists of the tannin compounds of the gitalin fraction. From adigan the digitonin has been removed by cholesterol (see below). Digitalysatum, from fresh press-juice, and other preparations, are purified by dialysis. Digitalone (Parke, Davis & Co.) is a sterile extract of older type. For a physiological examination of these preparations, see Rapp, Pharm. Zentral-H 1914, 55, 961, 978. ·

Methods of Assay.—There is a great variation in the content of active leaf glucosides. Thus Straub (l.c.) found, in percentages of the air-dry leaf :—

Gitalin + digitalein, cultivated, 0·4–0·64, wild, 0·22–0·89 ; digitoxin, cultivated, 0·053–0·11, wild, 0·01–0·15.

This variability has led to the introduction of standardised leaves (' folia digitalis titrata ') and to methods of assay of pharmaceutical preparations (official in the U.S.P. for digitalis, strophanthus, and squill). A chemical assay (of digitoxin ?) has been described by Keller (Ber. Deut. pharm. Ges. 1897, 7, 125), but Ziegenbein (Arch. Pharm. 1902, 240, 454) has shown that there is no relation between physiological activity and the ' digitoxin ' found by Keller's method. Barger and Shaw (Pharm. J. 1904, [iv.] 19, 249) have confirmed this, and shown that of added crystalline digitoxin less than half is recoverable by Keller's method. The chloroform extract, weighed in this method, consists, according to Kraft (l.c.), largely of gitalin. The assay must therefore be physiological, and is generally based on Houghton's method (J. Amer. med. Assoc. 1898), by which the minimum amount is determined necessary to arrest the frog's heart in systole, in, say, 1 hour (for length of time, cf. Gottlieb, below). The isolated frog's heart may also be employed, with graphic registration of its action (Schmiedeberg, Arch. exp. Path. Pharm. 1910, 62, 307). For earlier investigations, see Edmunds and Hale (Bull. No. 48, Hygienic Lab. Washington, 1909) and Focke (Arch. Pharm. 1910, 248, 365) ; for the later ones, Holste (Zeit. exp. Path. Ther. 1917, 19, 153), Focke (ibid. 1914, 16, 443), Straub (Arch. exp. Path. Pharm. 1916, 80, 52), and Gottlieb (ibid. 1918, 83, 117). The susceptibility of frogs is greater in winter than in summer, and it has been suggested that they should themselves be standardised with a pure sub-

stance, such as digitoxin (Rapp, l.c.), or g-strophanthin (ouabaïn) (q.v.), suggested by Heinz, and adopted by the U.S.P. This presupposes a constant ratio of sensitiveness to dissimilar preparations, which has not been proved. Indeed, Gottlieb (l.c.) states that the sensitiveness of frogs to g-stropanthin is fairly constant throughout the year.

Digitalis seeds contain entirely different glucosides, which have been examined chiefly by Kiliani. From an alcoholic extract, purified with lead acetate, the mixed glucosides' are precipitated with tannic acid (cf. Homolle's method). This gives the commercial so-called digitalinum germanicum, which may be separated, according to Kiliani (Ber. 1918, 51, 1613), into ' digitalinum verum,' or digitalin, digitonin, gitonin, and a fourth glucoside.

Digitalin $C_{75}H_{56}O_{14}$, m.p. 210°–217°, is less active than digitoxin, and forms amorphous granules, soluble in 1000 parts of water. It dissolves in sulphuric acid with a yellow colour, which, on standing, or in the presence of ferric salts or other oxidising agents, becomes cherry-red and purple. It is hydrolysed by acids to equimolecular proportions of glucose, digitalose $C_7H_{14}O_5$, and digitaligenin $C_{22}H_{30}O_3$, needles, m.p 210°–212°. Digitalose is a syrup, and is oxidised by nitric acid to methoxydihydroxyglutaric acid (Kiliani, Ber. 1905, 38, 3622 ; 1916, 49, 709).

Digitonin $C_{54}H_{92}O_{28}$ or $C_{55}H_{91}O_{28}$, m.p. 225°–235°, $[\alpha]_D = -49·25°$, is obtained in the crude state in a yield of about 45 p.c. of the ' German digitalin' employed. It is important as an example of a crystalline saponin, and probably also occurs in the leaves. It has no stimulant action on the heart, and is therapeutically undesirable. Digitonin dissolves to a clear solution in 50 parts of cold 50 p.c. alcohol, is more soluble on heating, and crystallises on cooling in fine needles. It is hardly soluble in chloroform, and forms an opalescent solution in water, which froths. Keller's reaction is negative. Acids hydrolyse to two molecules of glucose, two of galactose, and one of digitogenin $C_{30}H_{48}O_4$ or $C_{31}H_{50}O_4$, needles, m.p. 240°. Like other saponins, digitonin combines with cholesterol. On mixing a (preferably hot) solution of 1 gram digitonin in 100 c.c. of 90 p.c. alcohol with 0.4 gram cholesterol in 60 c.c. of 95 p.c. alcohol, the addition compound $C_{55}H_{94}O_{28} \cdot C_{27}H_{46}O$ crystallises (Windaus, Ber. 1909, 42, 238). Similar compounds with lower alcohols and phenol had already been observed by Houdas (Compt. rend. 113, 648). This reaction has met with wide application. On the one hand, digitonin can be removed from digitalis preparations (adigan, above), on the other hand, sterols can be estimated in fats, for as little as 0·1 mg. of cholesterol in 1 c.c. of 90 p.c. alcohol may be detected (Windaus). (Cf. Panzer, Zeitsch. physiol. Chem. 1912, 78, 414 ; Marcusson and Schilling, Chem. Zeit. 1913, 87, 1001 ; Berg and Angershausen, ibid. 1914, 38, 978 ; Prescher, Zeitsch. Nahr. Genussm. 1914, 33, 7.)

Gitonin.—Commercial digitonin (Merck) contain 5–14 p.c. of a closely similar glucoside gitonin $C_{49}H_{80}O_{23}, 7H_2O$, m.p. 225° (Kraft, l.c. ; Windaus and Schneckenburger, Ber. 1913, 46, 2628), which may be crystallised (Kiliani, ibid.

1916, 49, 701), and also forms cholesterol addition compounds.

Straub (Biochem. Zeitsch. 1917, 82, 48) finds that on germination the first pair of foliage leaves already contains the typical leaf glucosides, and in 4 months the maximum of 1 p.c. of total glucoside is already nearly attained. This is made up of gitalin fraction, $\frac{1}{5}$ p.c. ; digitalein fraction, $\frac{1}{4}$ p.c. ; and digitoxin fraction, $\frac{1}{4}$ p.c. For variations, see above.

Digitalis leaves contain *luteolin* (='*digito-flavone*') $C_{15}H_{10}O_6,H_2O$, which imparts a yellow colour to ethereal extracts (Kiliani and Mayer, Ber. 1901, 34, 3577).

Other Drugs with a Digitalis-like Action.— Schmiedeberg (Arch. exp. Path. Pharm. 1883, 16, 149, especially 162) has enumerated a considerable number of these. Strophanthus and squill (*q.v.*) are therapeutically the most important ; *see* also euonymus, hellebore, and the alkaloid erythrophlœine.

Cymarin, a glucoside from the root of *Apocynum cannabinum* has been obtained crystalline (D. R. P. 255537, of · Bayer & Co.) 1000 parts of the root are extracted with boiling carbon tetrachloride until no ,longer bitter. After evaporation, the residue is dissolved in 1000 parts of alcohol, and water at 50° is added, until no more resin is precipitated. After filtration, basic lead acetate is added, and the excess of lead is removed, after a second filtration, by means of hydrogen sulphide. After evaporation to 100 parts, the solution is extracted with chloroform, and the chloroform dried with sodium sulphate. Impurities are then precipitated with ether, and next the cymarin with light petroleum. It is·crystallised from methyl alcohol, and then has the composition :

$$C_{30}H_{44}O_9,CH_3OH,\tfrac{1}{2}H_2O$$
$[a]_D^{20}=+23\cdot5°$ in chloroform. It gives Liebermann's cholesterol reaction (*v.* STROPHANTHIDIN), and Keller's digitoxin reaction (above),‿and is hydrolysed by acids

$$C_{30}H_{44}O_9+H_2O=C_{23}H_{30}O_5,H_2O+C_7H_{14}O_4$$
into cymarigenin (=strophanthidin, *q.v.*) and cymarose, which is probably the methyl ether of digitoxose (Windaus and Hermanns Ber. 1915, 48, 979), where the earlier investigations on *Apocynum* are referred to.

Bufagin $C_{18}H_{24}O_4$, from the parotid gland of the Central-American toad *Bufo aqua*, has also been obtained crystalline and pure (Abel and Macht, J. Pharm. exp. Therap. 1912, 3, 319). It is not a glucoside. For *bufotalin* from European toads, *see* Wieland and Weil (Ber. 1913, 46, 3315).

Convallamarin $C_{23}H_{44}O_{12}$ and *convallarin* $C_{34}H_{62}O_{11}$ are crystalline glucosides from *Convallaria majalis* (Linn.) (Lily of the Valley), which plant was deleted from the U.S.P. in 1916 (Walz, Jahrb. f. Chem. 1858, 518).

‍ *a-Antiarin* $C_{27}H_{42}O_{10},4H_2O$ and *β-antiarin* are crystalline glucosides from the latex of *Antiaris toxicaria*, the Upas tree of Java (Kiliani, Ber. 1910, 43, 3574). Other crystalline glucosides with digitalis action are *thevetin* $C_{54}H_{84}O_{24}$, from the seeds of *Thevetia neriifolia* (Juss.), crystallising readily (de' Vrij, Pharm. J. 1881, 457 ; Warden, *ibid.* 1881, 417), and *echujin*

$(C_8H_9O_2)n$, from the latex of *Adenium Bœhmianum* (Schinz), a South-West African arrow poison (Boehm, Arch. exp. Path. Pharm. 1899, 26, 165). The latter substance has an activity intermediate between that of digitoxin and strophanthin.

Tanghinin $C_{27}H_{46}O_8$, m.p. 182°, from the fruits of *Tanghinia venenifera* (Madagascar), is crystalline, hardly soluble in water, readily in alcohol and in ether, and is not a glucoside (Arnaud Compt rend. 1889, 108, 1255). *Adonin* $C_{24}H_{40}O_9$, from *Adonis amurensis* (Reg. et Radd.) (Tahara, Ber. 1891, 24, 2579), *adonidin* from *A. vernalis* (Linn.) (Cervello, Arch. exp. Path. Pharm. 1882, 15, 235), and *oleandrin* from *Nerium oleander* (Linn.) (Schmiedeberg, *l.c.*) are amorphous. Many of the above substances are used as arrow poisons. The N.O. *Apocynaceæ* seems to be especially rich in substances with a digitalis-like action (*Apocynum, Strophanthus, Thevetia, Adenium, Nerium oleander*). Windaus and Hermanns (Ber. 1915, 48, 981) have suggested that there is a more or less close chemical relationship between many of the above substances The non-sugar portion of the glucosides (' genin ') seems to be derived from a cholesterol-like complex by various degrees of oxidation ; the sugars are peculiar and sometimes identical or closely related, and often contain less oxygen than carbohydrates. The genins are less active than the glucosides (*v. k*-strophanthin and Straub, Biochem. Zeitsch. 1916, 75, 132). G. B.

DIGITALON *v.* DIGITALIS.

DIGITOXIN *v.* DIGITALIS.

DIHEPTYLACETIC ACID $(C_7H_{15})_2CH\cdot COOH$ is obtained by treating diheptylacetoacetic ester with potassium hydroxide (Jourdan, Annalen, 200, 116) ; m.p. 26°-27°.

DIHYDROXYTARTARIC ACID

$$CO_2H\cdot C(OH)_2\cdot C(OH)_2\cdot CO_2H$$
is made by the action of a mixture of fuming sulphuric acid and nitric acid upon dry tartaric at 20°, cooling with ice and neutralising with sodium carbonate when the sparingly soluble sodium salt separates out. Used in making

tartrazine : *v.* PYRAZOLONE COLOURING MATTERS and KETONES.

DI-IODOFORM *v.* SYNTHETIC DRUGS.

DIKA-BREAD. An edible cake made by the natives of Sierra Leone and the Gaboon from the fruit of the mango tree, indigenous to most tropical climates. The fruit resembles chocolate in appearance, and contains a large quantity of fatty matter. It has occasionally ripened under hot-house cultivation in this country.

DIKA FAT GROUP. Under this name may be comprised several fats which are characterised by high saponification values, like the fats of the Cocoa Nut Oil group, but which differ from them by the absence of volatile fatty acids. The high saponification value indicates a preponderant proportion of lauric acid. These fats are further characterised by low iodine values. The most prominent of this group are · (1) **Dika fat**, obtained from the seed-kernels of various kinds of *Irvingia* : *I. gabonensis* (Baill), *I. Barteri* (Hook, fl.), indigenous to West Africa. The seeds yield about 65 p.c. of a yellowish-white fat, which the natives separate by expressing the kernels after boiling with water. The fat melts at about 30°, and has an iodine value of about 31. (2) **Tangkallak fat**, obtained from the fruits of *Lepidadenia Wightiana* (Nees : Bl.), *Cylicodaphne sebifera* (Bl), *Tetranthera calophylla* (Miquel), *Tetranthera laurifolia* (Jacq.), *Litsea Sebifera* (Pers.), *Sebifera glutinosa* (Lour) (3) **Irvingia butter. Cochin-China wax,** or **Cáy-cáy fat**, the fat obtained from *Irvingia Oliveri* (Pierre), *Irvingia malayana* (Oliv.), *Irvingia Harmandiana* (Pierre), *Buchanania fastigiata* (H Baillon). The Cáy-cáy tree—' candle tree '—is a tropical tree indigenous to Cochin China and Cambodia. Large quantities of the fat are used by the natives as candles. The freshly prepared fat is employed for edible purposes. (4) **Kusu oil**, contained in the fruit of the camphor-yielding tree, *Cinnamomum camphora* (Nees), *Lauraceæ*. From its chemical characteristics, the conclusion may be drawn that it consists of pure laurin with a few per cent. of olein.   J. L.

DIKETONES *v.* KETONES.

DIKETOSUCCINIC ACID *v.* KETONES

DILATOMETER. A term originally used to denote an apparatus for measuring the thermal expansion of liquids. Subsequently given by Silbermann to an instrument for determining the strength of aqueous alcohol.

DILITURIC ACID, *nitrobarbituric acid, nitromalonylurea,* $CO\underset{NH\cdot CO}{\overset{NH\cdot CO}{<}}CH\cdot NO_2, 3H_2O$, obtained by treating alloxantin first with hydrochloric acid and subsequently with nitric acid (Schlieper, Annalen, 56, 24); by warming hydurilic acid with nitric acid (Baeyer, *ibid.* 127, 211); by nitrating barbituric acid with fuming nitric acid (Baeyer, *ibid.* 130, 140); by oxidising violuric acid (nitrosobarbituric acid) (Ceresole, Ber. 16, 1134); or by oxidising with nitric acid the compound $C_{16}H_{28}O_{11}N_{12}S_2$ obtained by condensing *iso*dialuric acid with thiocarbamide (*v.* Vogel, Annalen, 315, 259; Bartling, *ibid.* 339, 27).

Dilituric acid crystallises in colourless quadratic prisms or plates, is sparingly soluble in cold, more readily so in hot water, is sparingly soluble in alcohol and insoluble in ether. It

forms chloropicrin when warmed with bleaching powder, is reduced by hydriodic acid to *uramil (aminobarbituric acid)*, and suffers partial reduction when heated with glycerol, yielding *violuric acid*. Dilituric acid is tribasic, but most of the salts are acidic, and contain only one equivalent of the metal; they are sparingly soluble in water, and are not generally decomposed by mineral acids. The *ammonium salt*

$$C_4H_2(NH_4)O_5N_3$$

the *sodium salt* $C_4H_2NaO_5N_3, 4H_2O$, *potassium salt* $C_4H_2KO_5N_3$, *calcium salt*

$$Ca(C_4H_2O_5N_3)_2, 4H_2O$$
the *barium compound* $BaCl(C_4H_3O_5N_3), H_2O$, *ferrous salt* $Fe(C_4H_2O_5N_3)_2, 8H_2O$, and the *silver salt* $C_4H_2AgO_5N_3, 2H_2O$, are colourless; the *ferric salt* $Fe(C_4H_2O_5N_3)_3, 6H_2O$ is bright yellow, the *copper salt* $Cu(C_4H_2O_5N_3), H_2O$ is greenish, the *dipotassium salt* $C_4HK_2O_5N_3$ is bright-yellow (Schlieper, *l.c.*), and the *truargentic salt* $C_4Ag_3O_5N_3$ is lemon-yellow (Baeyer, Annalen, 130, 140). According to Holleman (Rec. trav. chim. 1897, 16, 162), dilituric acid and its homologues are aliphatic nitro- compounds in which the *iso-* form (*cf.* Hantzsch and Schultze, Ber. 1896, 29, 699, 2251; Hantzsch and Veit, *ibid.* 1899, 32, 607) is the stable modification. The aqueous solution of dilituric acid is faintly yellow and decomposes carbonates; the molecular conductivity for 1 gram-molecule dissolved in *v* litres of water is 323·4 (*v*=32), 341·4 (*v*=512), (μ_∞ should be 356); the acid is therefore almost completely dissociated in aqueous solution; the addition of one equivalent of a base does not appreciably change the colour of the solution, but on adding a second equivalent, the solution assumes the deep-yellow colour characteristic of the aqueous solutions of the salts of this acid. Assuming that the formula $CO\underset{NH\cdot CO}{\overset{N=C(OH)}{<}}\rangle C\cdot N\cdot OH$ represents the constitution of the acid, Holleman states that the anion

$$CO\underset{NH\cdot CO}{\overset{N=C(O-)}{<}}\rangle C\cdot N\cdot OH$$
is colourless and slowly hydrolyses into the yellow anion $CO\underset{NH\cdot CO}{\overset{N=C(O-)}{<}}\rangle C\cdot N\cdot O-$.
Methyldilituric acid, 1 - *methyl* - 5 - *nitrobarbituric acid* $CO\underset{NH\cdot CO}{\overset{NMe\cdot CO}{<}}CH\cdot NO_2, 1\cdot5H_2O$, prepared by oxidising methylvioluric acid with concentrated nitric acid (Andreasch, Monatsh. 1900, 21, 281), crystallises from aqueous solution, and the anhydrous acid is colourless; it melts and decomposes at 143°, is readily soluble in hot water, less so in cold water, alcohol, or acetone, and sparingly soluble in ether. The aqueous solution of the acid is intensely yellow, and decomposes carbonates; the aqueous solutions of the salts are also yellow, but the solid salts are colourless or pale-yellow and sparingly soluble; the *potassium salt* $C_5H_4KO_5N_3$, the *sodium salt* $C_5H_4NaO_5N_3, H_2O$, the *ammonium salt* $C_5H_4(NH_4)O_5N_3$, are colourless; the *barium salt* $(C_5H_4O_5N_3)_2Ba, H_2O$, the

cadmium salt ($C_5H_4N_3O_5)_2Cd,2H_2O$, are pale-yellow ; the *strontium salt* ($C_5H_4O_5N_3)_2Sr,3H_2O$ is colourless, but becomes yellow on losing its water of crystallisation. Methyldilituric acid is stable with bases ; it reacts readily with chlorine to form *methylchlordilituric acid*

$$CO{<}^{NMe \cdot CO}_{NH \cdot CO}{>}CCl(NO_2)$$
m p. 121° ; the corresponding bromo- compound melts and decomposes at 138°-139°.

Dimethyldilituric acid, 1:3 - *dimethyl* - 5 - *nitro-barbituric acid* $CO{<}^{NMe \cdot CO}_{NMe \cdot CO}{>}CH \cdot NO_2$

obtained by oxidising dimethylvioluric acid with concentrated nitric acid (Techow, Ber. 27, 3085 ; Andreasch, Monatsh. 16, 26) ; forms colourless microscopic crystals from acetone ; dissolves in 5·98 parts of water at 14°, is sparingly soluble in alcohol, melts at 152° and changes into dimethylalloxan (Holleman, Rec. trav. chim. 16, 162), and is reduced by hydriodic acid to dimethyluramil.

Dimethyldiliuric acid is intensely yellow in aqueous solution, and this is due to the presence of the coloured anion of the *isonitro-* form $CO{<}^{NMe \cdot CO}_{NMe \cdot CO}{>}C{:}NO \cdot OH$, for on adding con centrated nitric acid, the colour almost entirely disappears ; further, the molecular conductivity of the acid for 1 gram-molecule dissolved in v litres of water is 313·3 (v=32), and 337·6 (v=1024), (μ_∞ should be 352), so that in each solution the acid is almost completely ionised (Holleman, Rec. trav. chim. 16, 162). The salts of dimethyldiliuric acid are coloured, the *sodium salt* $C_6H_7NaO_5N_3,H_2O$ is yellow, the *potassium salt* $C_6H_7KO_5N_3$ is greenish-yellow, the *magnesium salt* ($C_6H_6O_5N_3)_2Mg,4H_2O$ is yellowish-green, the *calcium salt* ($C_6H_6O_5N_3)_2Ca$ is bluish-green, the *strontium salt* ($C_6H_6O_5N_3)_2Sr$ is pale-green, the *barium salt*

$$(C_6H_6O_5N_3)_2Ba,2H_2O$$
is rose-red, and the *silver salt* $C_6H_6AgO_5N_3$ is greyish-violet (Andreash, *l.c.*, and Monatsh. 21, 295).

Dimethylchlordilituric acid

$$CO{<}^{NMe \cdot CO}_{NMe \cdot CO}{>}CCl(NO_2)$$
prepared by passing chlorine into an aqueous solution of dimethyldilituric acid ; melts and decomposes at 150° ; the corresponding *bromo-derivative* melts partially at 152° (Andreasch, *l.c.*). Dimethyldilituric acid is readily decomposed by the action of bases forming water, carbon dioxide, and dimethylnitromalonamide.

DILL FRUIT. *Anethi fructus,* B.P. The dried ripe fruit of *Peucedanum graveolens* (Benth. and Hook.).

DILL OIL v. OILS, ESSENTIAL.

DIMETHYLALLOXAN v. ALLOXAN.

p-**DIMETHYLAMINOBENZOPHENONE** v. KETONES

DIMETHYLAMINONAPHTHAPHENAZINE v. AZINES.

DIMETHYLANILINE $<\!\!\!>\!N(CH_3)_2$.
Made by heating a mixture of aniline and methyl alcohol containing sulphuric acid in an autoclave. For details of mode of manufacture,

see Walter, Chem. Zeit. 1910, 34, 641, *et seq.* ; and Cain's Intermediate Products for Dyes. Instead of sulphuric acid iodine may be employed (Knoll & Co., D. R. P. 250236). Or a mixture of aniline and milk of lime and methyl chloride may be heated under pressure (Grandmougin, Rev. prod. chim. 1917, 20, 68).

Dimethylaniline boils at 192·6°/738 mm. ; m.p. 2·07° ; sp.gr. 0·96 at 15° (*see* AMINES).

DIMETHYLDIAMINODI - o - TOLYLME-THANE

$$CH_3 \cdot NH{<}^{CH_3}{>}CH_2{<}^{CH_3}{>}NH \cdot CH_3$$
Obtained by treating methyl-*o*-toluidine, or a mixture of mono- and dimethyl-*o*-toluidine with formaldehyde (40 p.c. solution) and hydrogen chloride, diluting with water, adding sodium and steam distilling to expel the excess of the methyl-*o*-toluidine. On cooling the base crystallises, and may be purified by crystallisation from alcohol (Bad. Anil. and Soda Fabrik, D. R. P. 67478) ; m.p. 87° ; b.p. 255°/9 mm.

DIMETHYLDIAMINOTOLUPHENAZINE v. AZINES.

2 : 2'-DIMETHYL-1 : 1'-DIANTHRAQUIN-ONYL
Obtained by diazotising 1-amino-2-methyl-anthraquinone dissolved in sulphuric acid, pouring the product on ice, separating the diazonium sulphate, and treating it with acetic anhydride and copper powder. The precipitate thus formed is mixed with water to remove acetic anhydride, and with dilute nitric acid to free it from copper. Can also be prepared by treating 1-chloromethylanthraquinone with copper powder (Bad. Anilin and Soda Fabrik. D. R. P. 180157) ; m.p. 366°-367°. Used in making Indanthrene Golden yellow. v. Pyranthrene, art. INDANTHRENE.

DIMETHYLETHYL ACETIC ACID v. CA-PROIC ACID.

DIMETHYLGLYOXIME (*βγ-dioximinobutane*) $CH_3 \cdot C : N \cdot OH$
                          | , was originally obtained by
$CH_3 \cdot C \cdot N \cdot OH$
Schramm, in 1883, by acting upon methyl-oximino-ethyl ketone with aqueous hydroxyl-amine hydrochloride (Ber. 16, 180). It is readily prepared in quantity by the following method (Gandurin, J. pr. Chem. 1908, 77, [ii.] 414) :—

850 c.c. of commercial methyl ethyl ketone are mixed with 30 c.c. of hydrochloric acid of sp.gr. 1·19, and 1 litre of amyl nitrite is allowed to run in slowly with vigorous stirring. This takes 1½ hours, and the temperature should be maintained between 40°-50°. When the reaction is over, 800 grams of ice are added, followed by 378 grams of sodium hydroxide in 800 c.c. of water, and the mixture is shaken for half an

hour. After standing, the layer of amyl alcohol is removed, and the aqueous liquid twice extracted with ether. 100 c.c. of the alkaline liquid are treated with the calculated amount of hydroxylamine hydrochloride, and the dimethylglyoxime produced is collected and weighed. If the original volume of the alkaline liquid is v c.c., a grams the weight of dimethylglyoxime obtained from the 100 c.c. of liquid, then the amount of hydroxylamine hydrochloride in grams required for the remaining liquid is equal to $656(v-100)a/109500$. This weight of hydroxylamine hydrochloride is dissolved in a little water, added to the alkaline liquid, and the whole warmed on the water-bath for an hour. The liquid is acidified with acetic acid, and the dimethylglyoxime, which separates, is filtered, washed, and dried. This product is sufficiently pure, but it may, if desired, be recrystallised from alcohol. Yield, 650–700 grams.

(For details, *see* Adams and Kamm, J. Amer. Chem. Soc. 1918, 40, 1281.)

(For other methods of preparation, *v* Biltz, Zeitsch. anal. Chem. 1909, 48, 164 ; Tschugaeff, Ber. 1905, 38, 2520.)

Properties.—Dimethylglyoxime forms colourless, glistening needles, and is insoluble in water, but soluble in alcohol. It melts at 245°–246° (Meyer-Jacobsen, I. (ii.) 826, 1913). Its dibenzoyl derivative forms rhombic plates, melting at 223° (Diels and Stern, Ber. 1907, 40, 1629).

On oxidation with potassium ferricyanide or nitrogen peroxide it yields furoxane (Scholl, Ber. 1890, 23, 3498) ; this is reduced to the dioxime again when treated with zinc and acetic acid (Rimini, Gazz. chim. ital. 1895, 25, [ii.] 266). When heated with aqueous ammonia at 170°–180° it yields the anhydride dimethylfurazan (Wolff, Ber. 1895, 28, 69).

Application in Analysis.—Dimethylglyoxime is now an important analytical reagent, owing to its property of forming a bright scarlet insoluble nickel derivative. It thus becomes possible to estimate nickel simply and accurately, in the presence of iron, aluminium, chromium, cobalt, zinc, or manganese, all of which form soluble derivatives. In addition, an excellent qualitative test for nickel in the presence of cobalt is supplied. For the latter purpose, a pinch of the oxime is added to the solution containing excess of ammonia or sodium acetate, and the liquid boiled. A scarlet precipitate is obtained even when there is present only one part of nickel in two million parts of solution (Tschugaeff, Ber. 1905, 38, 2520 ; Compt. rend. 1907, 145, 679 ; Kraut, Zeitsch. angew. Chem. 1906, 19, 1793). 0·1 milligram of nickel can be detected in the presence of 5000 times as much cobalt.

For the quantitative estimation of nickel, the acid solution is heated nearly to boiling ; a slight excess of 1 p.c. alcoholic dimethylglyoxime is added, then a small excess of either ammonia or sodium acetate. The precipitate is filtered while hot on to a Gooch crucible, washed with hot water, and dried at 110°–120°. Its formula is $(CH_3 \cdot C:NO)_2Ni + (CH_3 \cdot C:NOH)_2$, and it contains 20·31 p.c. of nickel ; it has no definite melting-point, but sublimes at 250°. Ammonium salts do not interfere ; if the acetate method is employed, the original solution should be nearly neutralised with ammonia before

adding the oxime and acetate (Brunck, Zeitsch. angew. Chem. 1907, 20, 1844). As the precipitate of nickel glyoxime is very voluminous, it is advisable to work with solutions containing not more than about 0·1 gram nickel, owing to the difficulty of filtration, and again in order to avoid waste of material, the cobalt, if present, should not exceed 0·1 gram, otherwise a large excess of ammonium hydroxide and dimethylglyoxime is necessary in order to prevent its precipitation.

By either of the above methods, cobalt and zinc may be separated from nickel ; but about twice the theoretical amount of reagent is necessary. Manganese, of course, can only be separated by the acetate method. Iron, aluminium, and chromium may be separated by the ammonia method, if tartaric acid be previously added (and, in addition, ammonium chloride in the case of chromium). Iron may also be separated in acetic acid solution, provided it is in the ferrous state (Brunck, Zeitsch. angew. Chem. 1907, 20, 1845 ; Prettner, Chem. Zeit. 1909, 33, 396, 411 ; Ivanicki, Chem. Zeit. Rep. 1908, 32, 644 ; Rhead, Analyst, 1910, 35, 97 ; *v. also* ANALYSIS).

The oxime is sufficiently expensive to make its recovery desirable. This may be effected by dissolving the nickel derivative in aqueous potassium cyanide and acidifying with acetic acid. The precipitated dimethylglyoxime is purified by recrystallisation from hot alcohol, after decolourisation with charcoal (*v.* KETONES).

DIMETHYLMALONIC ACID *v.* GLUTARIC ACID.

DIMETHYLOXALIC ACID *v.* HYDROXYBUTYRIC ACIDS.

αα-**DIMETHYLPROPIONIC ACID** *v.* VALERIC ACID.

DIMETHYLPYRROLE *v.* BONE OIL.

DIMETHYLSAFRANINES *v.* AZINES.

DIMETHYLTRIAZINE, *Diazoaminomethane* *v.* DIAZO- COMPOUNDS.

DINAPHTHAZINES *v.* AZINES.

DINITROANTHRAQUINONES.

1 : 5-Dinitroanthraquinone (m.p. 330°)
is made, together with the 1 : 8 isomeride, by adding sodium nitrate to anthraquinone dissolved in sulphuric acid. By extraction with alcohol or acetone the 1 : 8-dinitroanthraquine (m.p. 312°)
is removed.

Used in the manufacture of anthracene blues. *See* ALIZARIN AND ALLIED COLOURING MATTERS.

DINITROBENZENEDIAZO-OXIDE *v.* DIAZO-COMPOUNDS.

DINITROBENZENES *v.* BENZENE AND ITS HOMOLOGUES.

2 : 4-**DINITRO-4'-HYDROXYDIPHENYLAMINE**
Made by boiling together in water containing chalk a mixture of 4-chloro-1 : 3 dinitrobenzene and *p*-aminophenol in molecular proportions ; m.p. 190°. Used in the manufacture of sulphide dyes (*q.v.*).

DINITRONAPHTHALENES *v.* NAPHTHALENE.

DINITROPHENOLS *v.* NITROPHENOLS AND THEIR HOMOLOGUES.

DINITROSTILBENEDISULPONHIC ACID

$$NO_2\!\!<\!\!\diagdown>\!\!CH:CH\!\!<\!\!\diagdown>\!\!NO_2$$
$$SO_3H \qquad SO_3H$$
Obtained by warming a solution of sodium *p*-nitrotoluene sulphonate containing sodium hydroxide with sodium hypochlorite when sodium dinitrostilbenedisulphonate separates on cooling. The free acid is obtained by treating the sodium salt with hydrochloric acid. Pale yellow needles.

DINITROTOLUENES *v.* BENZENE AND ITS HOMOLOGUES, NITRATION OF.

DIOCTYLMALONIC ACID

$$(C_8H_{17})_2C(CO_2H)_2$$
Prepared from diethylmalonic ester, sodium methoxide and octyl iodide, and subsequent decomposition of the ester thus formed with caustic potash (Conrad and Bischoff, Annalen, 204, 163) ; m.p. 75°.

DIOFORM. Trade name for *symm.* 1·2-*di*-
chlorethylene (acetylene dichloride) $\begin{Vmatrix} CHCl \\ CHCl \end{Vmatrix}$
(*q.v.*). Suggested as an anæsthetic.

DIOGEN. Trade name for sodium amino-naphthol-disulphonate.

DIOGENAL. Trade name for dibromo-propyl diethylbarbituric acid.

DIONINE. Ethyl morphine hydrochloride, *v.* OPIUM and SYNTHETIC DRUGS.

DIOPSIDE. A double salt meta-silicate of calcium and magnesium in which a part of the magnesium is usually replaced isomorphously by an equivalent amount of ferrous oxide, the formula being Ca(Mg,Fe)(SiO₃)₂. It is a member of the monoclinic series of the pyroxene group, and is of importance as a rock-forming mineral ; while occasionally, when transparent and of a rich bottle-green colour, it is employed as a gem-stone. The depth of colour, sp gr. (3·2–3·3), and other physical characters vary with the percentage of iron present, which in material of gem quality, such as the crystals from Ala in Piedmont, and the Zillerthal in the Tyrol, amounts to about 3–4 p.c. FeO. The hardness is 6.   L. J. S.

DIOPTASE. Hydrous silicate of copper, H_2CuSiO_4, crystallising in the rhombohedral system with parallel-faced hemihedrism. The water is expelled only at a red heat, and the formula has consequently been variously interpreted as an acid ortho-silicate, or as a basic meta-silicate. F. Zambonini (1908) concludes from dehydration experiments that the formula is $CuSiO_3 \cdot H_2O$, with the water held in solid solution in the meta-silicate. The mineral is of a characteristic emerald-green colour (hence the name emerald-copper ; Ger., Kupfer-Schmaragd), and transparent crystals have occasionally been cut as gem-stones. For this purpose, however, the hardness (H.=5) is rather low ; sp.gr. 3·3. The best crystals are found on the limestone hill of Altyn-Tübe in the Kirghiz Steppes, Siberia, and in the copper mines near Mindouli in the French Congo.

An allied mineral, *plancheite* (of A. Lacroix, 1908,=*shattuckite* of W. T. Schaller, 1915), occurs as blue, fibrous concretions associated with dioptase in the French Congo. This has the composition $2CuSiO_3 \cdot H_2O$, representing a partly dehydrated dioptase.   L. J. S.

DIORITE. An igneous rock composed essentially of plagioclase felspar (oligoclase to labradorite) and hornblende, and with a coarse- to medium-grained crystalline-granular texture. It belongs, with granite, to the series of plutonic rocks, and · is of intermediate composition (SiO_2, 52–60 p c.), falling between syenite and gabbro. Its volcanic equivalent is andesite. Other minerals may also be present as essential constituents of the rock, and accordingly the following varieties are distinguished : hornblende-diorite (diorite proper), augite-diorite, enstatite-diorite, mica-diorite (the mica here being biotite), quartz-mica-diorite, quartz-diorite (or tonalite). The colour is usually dark grey or greenish-black, and for this reason the rock is included under the general term 'greenstone.' The sp gr. ranges from 2 8 to 3·1 ; the porosity is low, 0·25 p.c. ; and the crushing strength 1640 to 1830 tons per square foot. Under I is given Brögger's average of sixteen analyses of typical diorites ; analysis II. is of diorite from Strathspey, Scotland ; III. of quartz-diorite from Spanish Peak, Plumas Co., California (including BaO 0 04, CO₂ 0 20, P_2O_5 0·25, SO_3 0·03) ; IV. hornblende-augite-diorite from Inchnadamph, Sutherlandshire (including CO_2 0 54).

	I.	II.	III.	IV.
SiO_2	56 52	53·22	59·68	52·47
TiO_2	0·25	—	0·65	—
Al_2O_3	16·31	16 84	17·09	12·15
Fe_2O_3	4·28	—	2·85	3·47
FeO	5 92	9·27	2·75	5·23
CaO	6·94	8 53	6·62	9·71
MgO	4·32	6·48	3·54	9·94
K_2O	1·44	1·39	1·81	2·26
Na_2O	3 43	3·54	3 87	2·81
H_2O	1·03	0·95	1·15	1·62
	100·34	100·22	100·03	100·20

Diorites are of wide distribution and are very common in association with granitic rocks in the southern uplands and highlands of Scotland. They are extensively quarried for road-metal and paving-setts in the Channel Islands, Guernsey, Jersey, and Alderney, and at Brazil Wood near Mount Sorrel in Leicestershire. Owing to the difficulty of working the rock and its dull colour, it is not much used as a building stone, except locally. Certain coarse-grained varieties are, however, polished for ornamental purposes. For example, a variety from Corsica, known as napoleonite, corsite, or ball-diorite, shows a spheroidal structure with alternating concentric layers of light felspar and dark hornblende.   L. J. S.

DIOSCORINE $C_{13}H_{19}O_2N$, greenish-yellow plates, m.p. 43·5°, occurs in *Dioscorea hirsuta* (Blume) tubers of Japan. Bitter and poisonous (Gorter, Rec. trav. chim. 1911, 30, 161). Has an action like picrotoxin.

DIOSPHENOL, *Buchu camphor v.* BUCHU.

DIOXINE. Gambine H. 1-nitroso-2 : 7-dihydroxynaphthalene, *v.* QUINONEOXIME DYES.

DIOXOREA. A genus of plants of the Dioxoreaceous order, the tubers of which are known as yams, and are largely eaten in the West Indies and other tropical countries. *D. batatas* (Decne.) is the plant producing tubers known as 'sweet-potatoes,' which are cooked and eaten as a substitute for potatoes.

DIOXYGEN. Trade name for a 3 p.c. solution of hydrogen peroxide.

DIPHENAL, *Diaminohydroxydiphenol,* used as a photographic developer.

DIPHENAZINE *v.* AZINES.

o-**DIPHENETIDINE** *v.* DIPHENYL.

DIPHENYL. This hydrocarbon, which has the molecular formula $C_{12}H_{10}$, is structurally composed of two benzene nuclei joined together by a bond linking two carbon atoms, one in each ring. The carbon atoms are numbered for the purposes of nomenclature in the following way :—
Although of minor importance, diphenyl is nevertheless the parent substance of a large number of important bases which have found application in the preparation of the so-called substantive cotton dyes, that is to say, of colouring matters which will affix themselves to the vegetable fibres without the aid of a mordant. These bases are, however, not derived directly from the hydrocarbon, but are prepared by an indirect method which will be described later.

Diphenyl was originally obtained by Fittig (Annalen, 121, 363) from an ethereal solution of bromobenzene by the action of metallic sodium

$$C_6H_5Br + BrC_6H_5 + 2Na \rightarrow C_6H_5-C_6H_5 + 2NaBr$$

but it is more conveniently prepared by the method discovered by Berthelot (Ann. Chim. Phys. [4] 9, 453 ; [4] 12, 185), who obtained it by passing the vapour of benzene through a red-hot tube

$$C_6H_5H + HC_6H_5 \rightarrow C_6H_5-C_6H_5 + H_2$$

The following procedure is recommended (Schultz, Ber. 9, 547 ; Hubner, Annalen, 209, 339 ; Smith and Lewcock, Chem. Soc. Trans. 1912, 101, 1453 ; [apparatus] La Coste and Sorger, (Annalen 230, 5). The vapour from a quantity of benzene (free from thiophen), contained in a large flask heated on the water-bath, or produced by dropping the liquid into a copper flask heated to 150°, is allowed to pass through an iron tube, filled with pumice, which is heated to about 720° in a combustion furnace ; the lower end of the iron tube is attached to a condenser and receiver, in which the products are collected. When all the benzene has distilled over, the distillate is again placed in the flask, and the vapour passed anew through the red-hot tube, or the process may be made continuous. The ultimate product is then fractionally distilled, and the portion boiling between 250° and 260°, which solidifies on cooling, is purified by recrystallisation from alcohol. The yield is about 50–60 p.c. The pyrogenic preparation can also be effected by means of an incandescent filament of carbon, platinum, or nickel (Löb, Zeitsch. Elektrochem. 1902, 8, 777). Diphenyl separates from alcohol as large, lustrous laminæ which melt at 70·5°. It boils at 254° (corr.), and is insoluble in water. The

hydrocarbon, when oxidised by chromic acid passes into benzoic acid.

Bennett and Turner (Chem. Soc. Trans. 1914, 105, 1057) found that chromic chloride reacted quantitatively with magnesium phenyl bromide to form diphenyl. Krizewsky and Turner (Chem. Soc. Trans. 1919, 115, 559) have observed that anhydrous cupric chloride behaves similarly, yields of about 85 p.c. of the theoretical amount of diphenyl being thus obtained.

Derivatives of Diphenyl and their Orientation.—The more important derivatives of diphenyl are not prepared directly from the hydrocarbon, but from certain nitro- derivatives of benzene in a manner to be described later. The hydrocarbon yields, however, halogen, nitro- and sulphonic acid derivatives analogous to those prepared from benzene, substitution taking place in either one or both rings according to the conditions of the experiment. The method of orientation adopted for these compounds may be briefly described as follows (Schultz, Annalen, 174, 201 ; Schmidt and Schultz, *ibid.* 207, 320). When diphenyl is treated with bromine, it yields a monobromodiphenyl, a substance which, on oxidation, is converted into *p*-bromobenzoic acid, thus :
It follows, therefore, that in bromodiphenyl the bromine atom must have entered the *para*-position with respect to the linking carbon atom. When bromodiphenyl is treated with nitric acid, it is converted into a monobromo-mononitrodiphenyl, a substance which, on oxidation, yields a mixture of *p*-bromobenzoic acid and *p*-nitrobenzoic acid. It is therefore apparent that the formula of this bromonitro-derivative must be :
The same compound is also obtained from dinitrodiphenyl (m.p. 198°) and then replacing the amino- group by bromine by means of the diazo- reaction. Hence dinitrodiphenyl and its reduction product are di-*para*- derivatives. Since, however, nitroaminodiphenyl, on reduction, furnishes the diamino- derivative, benzidine, the latter is also a di-*para*- compound, or 4 : 4'-diaminodiphenyl, the preparation of which is described later.

The transformation of the simplest aromatic hydrocarbon benzene into diphenyl by the action of heat has already been mentioned. This transformation can, however, be effected much more readily by the oxidation of certain derivatives of benzene, and especially those which, like the phenols, have a reactive hydrogen in the *para*- position with respect to the substituting group. Thus phenol itself and also resorcin readily pass into derivatives of diphenyl when fused with potash (Barth, Annalen, 156, 95). With hydroquinone, the transformation is still more readily effected and the action of the mildest oxidising agents is sufficient for the purpose (Nietzki and Bernard, Ber. 31, 1334).

The primary bases of the benzene series, such as aniline, do not lend themselves to the production of derivatives of diphenyl, but the tertiary bases readily do so ; thus dimethylaniline yields tetramethylbenzidine when oxidised (Michler and Pattinson, Ber. 14, 2162 and 2164)

It has also been found that certain azo-derivatives of benzene can be transformed by oxidation into tetrazo- derivatives of diphenyl, and in this way Congo red can be formed by treating benzeneazonaphthionic acid with manganese dioxide and sulphuric acid :

$$C_6H_5N=N—C_{10}H_5(NH_2)SO_3H$$
$$+O$$
$$C_6H_5N=N—C_{10}H_5(NH_2)SO_3H$$
$$\rightarrow \begin{vmatrix} C_6H_4—N=N—C_{10}H_5(NH_2)SO_3H \\ C_6H_4—N=N—C_{10}H_5(NH_2)SO_3H \end{vmatrix} +H_2O$$
Derivatives of diphenyl can also be prepared from certain diazonium salts of the benzene series. Thus Kuhling has shown (Ber. 28, 41 ; 29, 165) that when an isodiazo- salt is treated with an aromatic hydrocarbon in the presence of an acid chloride, the following reaction ensues :—

$$NO_2·C_6H_4N_2OK +C_6H_6+CH_3COCl$$
$$\rightarrow NO_2C_6H_4—C_6H_5+N_2+ KCl+CH_3CO_2H$$
This reaction has been simplified by Bamberger (Ber. 28, 403 ; 29, 272 and 465), who uses free isodiazobenzene hydroxide, and shows that it passes, in the presence of benzene, without any condensing agent, into a derivative of diphenyl. Many derivatives of diphenyl can also be formed by the method of Ullmann, in which halogen derivatives of benzene are treated with finely divided copper (Ber. 43, 2682 ; Annalen, 1904, 332, 38).

Benzidine and the 'Benzidine Rearrangement.'—The benzidine rearrangement, which has been widely applied to the preparation of a large number of important bases used in the production of the substantive cotton dyes, is the name given to the change which an aromatic hydrazo- compound undergoes when treated with acids or certain acid reagents. The change is effected by the wandering of the hydrogen atom which is in the para- position in each ring on to the nitrogen atom attached to that ring ; at the same time, the link between the nitrogen atoms is broken, and the two aromatic nuclei are joined together. It is apparent, therefore, that only those hydrazo- derivatives of benzene which have their para- position free will undergo this transformation.

Hydrazobenzene. Benzidine.
The history of the discovery of this rearrangement is briefly as follows : Zinin (J. pr. Chem. 36, 93), in the first instance, showed that azobenzene $C_6H_5—N=N—C_6H_5$, when treated with alcoholic ammonium sulphide, passed into a crystalline compound which, when dissolved in alcohol and boiled with sulphuric acid, gave the sparingly soluble sulphate of a base This base he called benzidine.

It soon became apparent that the substance responsible for the formation of benzidine must be an intermediate product formed by the action of the reducing agent on azobenzene. This view was confirmed experimentally by A. W. Hofmann (Jahresbericht, 1863, 424), who prepared the intermediate product, hydrazobenzene, and found that it passed with remarkable ease into benzidine when treated with mineral acids.

Finally, Fittig (Annalen, 124, 280) showed that benzidine was identical with the base formed by the reduction of 4-4'-dinitrodiphenyl, and hence established the constitution of the base as 4-4'-diaminodiphenyl.

Manufacture of Benzidine.—A jacketed iron pan fitted with an agitator, reflux condenser, &c., is charged with 100 kilos. of nitrobenzene and 50 kilos. of alcohol. This mixture is heated to boiling, and 150–160 kilos. of zinc dust are added. The stirring must be very efficient during the next operation, which requires 5–6 hours, of adding gradually a mixture of 100 kilos. of alcohol and 40 kilos. of sodium hydroxide solution (36°–40°B.). The reaction is vigorous and is regulated by the rate of addition of the alkali and, if necessary, by cooling. When all the alkali has been added the mixture is stirred until it is of a uniformly grey colour, and to obtain this more zinc may have to be introduced. The alcohol is then distilled off by means of steam, and the residue is thrown on a fine sieve which retains the hydrazobenzene and allows the zinc dust, zinc oxide, &c., to pass through. Another method of working up consists in diluting the reduction mixture with water, carefully neutralising with hydrochloric acid, and filtering off the hydrazobenzene.

The latter is transformed into benzidine by mixing it with ice and acidifying with concentrated hydrochloric acid. After some time water is added and steam introduced so as to dissolve the benzidine hydrochloride, the solution is filtered, and the benzidine sulphate precipitated by adding sodium sulphate solution. This is filtered off, washed, and the base obtained by boiling with sodium hydroxide solution, cooling, collecting, and distilling in a vacuum still. The yield is about 80 p.c. of the theoretical.

The above process can also be carried out without the use of alcohol, or solvent naphtha can be employed instead.

The electrolytic reduction of nitrobenzene to hydrazobenzene is the subject of a number of patents, but it would not appear that this method is yet applied on the large scale (cf. Löb, Ber. 1900, 33, 2329).

The production of benzidine from azobenzene is easily effected by an electrolytic method with titanium salts or vanadium trioxide used as catalysts. The azobenzene is suspended in 30 p.c. sulphuric acid containing 10 p.c. titanous sulphate ; a lead cathode is used with a current of 3–4 amp. per square dcm. at 3–4 volts (D.'R. PP. 168273 and 172654).

The presence of small quantities of hydriodic acid facilitates the reduction of azobenzene to benzidine by means of sulphurous acid (D. R. P. 172569).

Benzidine, when pure, forms colourless lustrous laminæ, which melt at 127·5°–128° ; it boils at 400°–401° (740 mm.). The base is characterised as a para- derivative by the formation of quinone when it is oxidised by manganese dioxide and sulphuric acid. It can be identified by a number of colour reactions : chlorine, bromine, potassium permanganate, potassium ferricyanide, and chromic acid, producing characteristic shades. The most characteristic salts of benzidine are the sulphate $C_{12}H_{12}N_2,H_2SO_4$, and the chromate $C_{12}H_{12}N_2,H_2CrO_4$. Both salts are sparingly soluble in alcohol and in water.

When treated with nitrous acid, benzidine hydrochloride is transformed into a tetrazonium salt of diphenyl

$$C_6H_4N_2Cl$$
$$|$$
$$C_6H_4N_2Cl$$

which reacts readily with the usual second components of the azo- colouring matters, forming azo- compounds, the solutions of which possess the property of dyeing the vegetable fibres without the aid of a mordant. The number of colouring matters of this kind prepared from benzidine is largely increased owing to the insoluble character of the diazonium salt

$$C_6H_4N_2X$$
$$|$$
$$C_6H_4N_2Cl$$

in which one molecule of a second component, XH, has combined with the tetrazonium salt derived from benzidine. These diazonium salts, when combined with some other second component, YH, yield mixed azo- colouring matters of the formula

$$C_6H_4N_2X$$
$$|$$
$$C_6H_4N_2Y$$

Benzidine in the presence of hydrogen peroxide is used as a test for blood, with which it gives a blue colouration. The test solution is made by taking 10 drops of a concentrated solution of benzidine in glacial acetic acid, and adding 2 c.c. of a 3 p.c solution of H_2O_2. Sensitiveness—1 part in 200,000. (Utz, Chem. Zeit. **1907**, 31, 737; Schumm, Pharm. Zeit. 1907, 52, 604; McWeeney, Sci Proc. Roy. Dubl. Soc. 1909, 12, 216; Bordas, Compt. rend. 1910, 150, 562; Gigli, Boll. chim. farm. 1910, 49, 955; *cf.* O. and R. Adler, Zeitsch. physiol. Chem. 1904, 41, 59.)

Homologues and Derivatives of Benzidine used in the Preparation of the Substantive Cotton Dyes. —Although a great many of the derivatives of benzidine yield azo- colouring matters which are substantive to the vegetable fibres, yet this property is largely dependent on the position of the groups substituting the hydrogen atoms of the diphenyl molecule. Thus it has been found that when the substituting groups are in the meta- position to the coupling bond, as in

o-Tolidine.

o-Dianisidine.
the azo- colours formed are substantive to cotton. If, however, groups are in the ortho-position, as in

Benzidine-*m*-disulphonic acid.

Diaminodiphenic acid.
the property of the azo- colours of dyeing unmordanted vegetable fibre is lost. The ortho-derivatives nevertheless yield substantive cotton dyes if ring formation takes place between the substituting groups in those positions ; thus :

Diaminocarbazole.

Benzidine sulphone.
yield azo- dyes substantive to cotton.

Benzidine-o-disulphonic acid is prepared by heating benzidine sulphate with 2 parts of sulphuric acid for 36-48 hours at 210° (Ber. 1889, 22, 2464 ; Eng. Pat. 1074, 1884 ; D. R. P. 27954).

o-*Dichlorobenzidine* is prepared from *o*-chloronitrobenzene, and is also produced by chlorinating diacetylbenzidine (Eng. Pat. 25725, 1896 ; Fr. Pat. 265155 ; D. R. P. 94410 ; U.S. Pat. 625174).' It melts at 133°.

m-*Nitrobenzidine*, obtained by treating a solution of benzidine in sulphuric acid with one equivalent of nitric acid or potassium nitrate (Tauber, Ber. 1890, 23, 796 ; Eng. Pat. 13475, 1892 ; Fr. Pat. 223176 ; D R. P. 72867 ; U.S. Pat. 493583), melts at 143° ; when two equivalents of the nitrating agent are used, m-*dinitrobenzidine*, m.p 214°, is produced. Mononitration of diacetylbenzidine or phthalylbenzidine, and subsequent hydrolysis of the product, furnishes o-*nitrobenzidine*, m p. 190° (Koller, Ber. 1904, 37, 2883 ; Fr. Pat. 203468), whilst two different o-*dinitrobenzidines*, m.p. 275° and 233°, are obtained by the dinitration of diacetylbenzidine and diphthalylbenzidine respectively (Trans. Chem. Soc. 1912, 101, 2298).

The following compounds, prepared from the corresponding nitro- derivatives of benzene, are of importance :—

o-*Toluidine*, 4 - 4' - diamino - 3 - 3' - dimethyl diphenyl $NH_2 \cdot C_6H_3(CH_3)-C_6H_3(CH_3)NH_2$ from o-nitrotoluene, forms glistening plates, melting at 129°. It is sparingly soluble in water, but readily soluble in alcohol and in ether. The sulphate is sparingly soluble in water.

o-*Dianisidine*, 4-4'-diamino-3-3'-dimethoxy-diphenyl $NH_2 \cdot C_6H_3(OCH_3)-C_6H_3(OCH_3)NH_2$, from o-nitroanisole, forms colourless leaflets, melting at 135°. (For its manufacture, *see* Jansen, Zeitsch. Farb. Ind. 1913, 12, 247.)

o-*Diphenetidine*, 4-4'-diamino-3-3'-diethoxy-diphenyl $NH_2 \cdot C_6H_3(OC_2H_5)-C_6H_3(OC_2H_5)NH_2$, from o-nitrophenetole, forms needles or leaflets melting at 117°.   J. F. T.

DIPHENYLAMINE was first obtained by Hofmann, in 1864, by distilling aniline blue (Annalen, 132, 163), and in small quantity by distilling rosaniline and leucaniline. De Laire, Girard, and Chapoteaut discovered an easier method of preparing it by heating aniline with the hydrochloride at 210°–240° (Zeitsch. Chem. 1866, 438 ; Compt. rend. 63, 91)

$$C_6H_5NH_2 + C_6H_5NH_2HCl = NH(C_6H_5)_2 + NH_4Cl$$

This reaction is greatly facilitated by the use of certain catalysts. It may also be obtained by heating phenol with the double compound of

aniline and zinc chloride at 250°–260° (Merz and Weith, Ber. 13, 1298, 1880) :

$$C_6H_5NH_2+C_6H_5OH=(C_6H_5)_2NH+H_2O$$
and by heating aniline and diazoaminobenzene to 150° till the evolution of nitrogen ceases. In this last reaction, ortho- and para- aminodiphenyl are formed at the same time (Hirsch, D. R. P. 62309). Diphenylamine has also been prepared by the action of aniline on bromobenzene in presence of cuprous iodide (Goldberg, D. R. P. 187870, 1906). Aniline, when heated with ferric chloride, finely divided copper, and iodine, is converted into diphenylamine. Other catalysts can also be used (Rogers and de Nemours, U S. Pat. 1314538).

Manufacture —Aniline (1 mol.) is heated with aniline hydrochloride (1 mol.) for 30–35 hours in an autoclave at 220°–230°. The product is extracted with hot dilute hydrochloric acid which dissolves the aniline hydrochloride and converts the diphenylamine into the free base, forming an oil which solidifies on cooling. The cake of diphenylamine is washed and then distilled alone or in a current of steam. Yield, 60–70 p.c. of the aniline employed. It is used in the manufacture of diphenylamine blue, diphenylamine orange, and aurantia (*v. infra*).

Properties —Monoclinic laminæ ; m.p. 54° ; b.p. 310° ; almost insoluble in water, soluble in alcohol, benzene, and ether. It is feebly basic, and the salts are hydrolysed by an excess of water.

Reactions.—The hydrogen of the imino- group is replaceable by alkyl or acyl radicals (Bösekon, Rec trav. chim. 1912, 31, 350). With methyl iodide it gives a methyl derivative ; with benzyl chloride, a benzyl derivative With formic or oxalic acid it yields formyldiphenylamine, m.p. 74° ; with acetic acid or the acid chloride, an acetyl derivative, m p. 103° ; and with benzoyl chloride, a benzoyl derivative, m.p. 180°. When heated with zinc chloride, the acyl derivatives lose water and form acridine derivatives. Formyldiphenylamine gives acridine

$$C_6H_5\diagdown \overset{N}{\underset{CHO}{|}} \diagup C_6H_5 = C_6H_4 \diagdown \overset{N}{\underset{CH}{|}} \diagup C_6H_4 + H_4O$$
The acetyl compound yields methylacridine (Bernthsen and Bender, Ber. 1883, 16, 767). Diphenylamine also gives acridine by heating with chloroform and zinc chloride or aluminium chloride

$$(C_6H_5)_2NH + CHCl_3 = C_6H_4 \diagdown \overset{N}{\underset{CH}{|}} \diagup C_6H_4 + 3HCl$$
(O. Fischer and Körner, Ber. 1886, 17, 101). With excess of oxalic acid, diphenylamine is converted into diphenylamine blue

$$3(C_6H_5)_2NH + CO_2 = C\diagdown \overset{C_6H_4 \cdot NH \cdot C_6H_5}{\underset{C_6H_4\!-\!N C_6H_5}{\overset{|}{\underset{}{\diagup}}} C_6H_4 \cdot NH \cdot C_6H_5} + 2H_2O$$
Carbon tetrachloride reacts like oxalic acid, and gives the same blue colour. With sulphur, thiodiphenylamine, the parent substance of methylene blue, is produced :

$$(C_6H_5)_2NH + 2S = C_6H_4 \diagdown \overset{NH}{\underset{S}{}} \diagup C_6H_4 + H_2S$$
(Bernthsen, Ber. 1883, 16, 2897). When the vapour of diphenylamine is passed through a red-hot tube, carbazole is formed :

$$C(C_6H_5)_2NH = \overset{C_6H_4}{\underset{C_6H_4}{|}} \diagup NH + H_2$$
(Graebe, Annalen, 167, 127) ; and the latter is also obtained from thiodiphenylamine and copper powder (Goske, Ber. 1887, 20, 233).

Tests.—A solution of diphenylamine in conc. sulphuric acid gives a deep indigo-blue colour with nitric, nitrous or chloric acid (Ber. 1912, 45, 2641 ; 1913, 46, 2286 ; Chem. Zeit. 1912, 26, 1239 ; Bull Soc. Chim 1914, (14), 15, 186. The commercial product is a pale-yellow solid, melting not much below 54° ; it should contain no oil, possess no unpleasant odour, nor turn brown on exposure to air.

Derivatives.—By passing chlorine into a solution of diphenylamine in acetic acid, a tetrachlorodiphenylamine is formed. 4- chloro-2·6 dinitrodiphenylamine has been prepared (Ullmann and Shrirang, Ber. 1911, 44, 3730. Bromine in alcoholic solution produces a tetrabromodiphenylamine ; in acetic acid, a hexabromo- derivative ; and at a high temperature in presence of iodine, an octo- and deca-bromo-compound. Diiododiphenylamine is formed by the action of iodine in alcoholic solution in presence of mercuric oxide. Bromine derivatives of nitrodiphenylamine are also known (H. and P. Ryan, Proc. Roy Irish Acad 1919, 34, 218). By nitration in acetic acid solution, a tetranitro- derivative is formed, whilst direct nitration yields a hexanitro- compound, crystallising in yellow prisms, and melting at 238°. The latter has strongly acid characters, and gives an ammonium salt which is used as a yellow dye known as *aurantia* (q v.). Nitrosodiphenylamine is obtained by acting upon the base with amyl nitrite.

Alkyl Derivatives —Methyldiphenylamine is obtained by heating together diphenylamine (100 parts) conc. hydrochloric acid (68 parts), and methyl-alcohol (24 parts) for 10 hours to 250° in an autoclave (Girard, Bull. Soc. chim. [ii.] 23, 2). It is a liquid ; b.p. 282°. The ethyl derivative is obtained in a similar way ; b.p. 293°. The amyl derivative boils at 330°–340°. Benzyl chloride produces a benzyl derivative which is used in the preparation of viridine and alkali green.

Amino- Derivatives.—2-Chloro-5-nitrobenzenesulphonic acid combines with *p*-phenylenediamine to form 4-nitro-4-aminodiphenylamine sulphonic acid

$$NO_2\diagup\!\!\diagdown\!\!-NH-\diagup\!\!\diagdown\!\!\overset{SO_3H}{}NH_2$$
which, on reduction, gives *p*-diaminodiphenylamine sulphonic acid (Baeyer & Co., D. R. P. 86250, 1894 ; Farb. vorm. Meister, Lucius and Brüning, D. R. P. 265197, 1914). Similar derivatives are obtained by the action of *p*-aminophenol, aminophenol sulphonic acid, and *p*-aminosalicylic acid. The sulphonic acid group may be removed by heating with dilute acids under pressure (Meister, Lucius, and Brüning, D. R. P. 112180, 1899). Paraphenylenediamine and phenol in presence of copper salts and a solution of hypochlorite are oxidised to *p*-amino-*p*-hydroxydiphenylamine (Aktien Gesell. D. R. P. 204596, 1907). Aminohydroxydiphenylamine is also obtained by the electrolytic reduction of *m*-nitrodiphenylamine (Piccard and Lassen, J. Amer. Chem. Soc. 1918, 40, 1079). Diphenylamine derivatives prepared by the action,

of primary aromatic bases such as *p*-phenylene-diamine, *p*-aminophenol, and aminosalicylic acid on (1.3.4)-dinitrochlorobenzene, (1.3.4.6)-dinitrodichlorobenzene, and (1.4.3)-nitrochlorobenzene sulphonic acid, are used in the preparation of sulphide colours, of which the most important is dinitroxydiphenylamine

$$C_6H_3(NO_2)_2NH \cdot C_6H_4(OH)$$
obtained from *p*-aminophenol and dinitrochlorobenzene. Phenoxydinitrodiphenylamine is obtained from 1 3 dichloro 4·6 dinitrobenzene, potassium phenate and aniline (Borsche, Ber. 1917, 50, 1339).

Diphenylaminedicarboxylic acid is obtained by the action of anthranilic acid on *o*-chlorobenzoic acid in presence of finely divided copper. Other amino-acids behave similarly (Meister, Lucius, and Brüning, D. R P. 148179, 1902; Purgotti, Gazetta, 1914, 44, i, 386)

Diphenylamine combines with formaldehyde, and the product forms an additive compound with sodium bisulphite

$[(C_6H_5)_2N]_2 + HSO_3Na$
$\quad = (C_6H_5)_2N \cdot CH_2 \cdot SO_3Na + (C_6H_5)_2NH$
(Bad. Anilin-Sod. Fab. D. R P 158718, 1904) For nitro- derivatives, *see* Borsche and Rantschelf, Annalen, 1911, 379, 152; B Linke, J. prakt. DIPHENYLAMINE ORANGE *v.* AZO- COLOURING MATTERS.

DIPHENYLBISDIAZONIUM CHLORIDE *v.* DIAZO- COMPOUNDS.

DIPHENYL BROWN, -CATECHINE, -CHRYSOIENES, -CITRONINE, -FAST BLACK, -FAST YELLOW, -GREEN, -ORANGE, -RED *v.* AZO-COLOURING MATTERS.

DIPHENYL-DIMETHYLOLID
The dilactone of dihydroxy-diphenyl dicarboxylic acid, is the mother substance of a small series of colouring matters, of which but one natural representative, ellagic acid, is as yet known to exist. The methylolid grouping —CO—O— present in the compounds has a feebler chromophoric character than the carbonyl itself, and on this account the dyeing properties of the members of this class are inferior as regards strength to those of the benzophenone, flavone, and allied dyestuffs. That the diphenyl linkage here exerts an influence is certain, for gallotannin containing as it does digalloyl nuclei :

$(OH)_3C_6H_2$—CO—O—$C_6H_2(OH)_2$—CO—O—

dyes only with iron and titanium mordants, and again such an effect is clearly seen by a comparison of benzophenone and fluorenone :
for whereas the former is colourless, the latter possesses a strong yellow tint.

Though diphenyl-dimethylol is at present unknown, diphenyl-methylolid :
needles, melting at 92·5°, has been prepared by various methods, and of these that of Richter (J. pr. Chem. [2] 28, 294), who obtained it by the action of phosphorus oxychloride on ethyl salicylate :
is the simplest.

Colouring matters derived from diphenyl-methylolid itself do not appear to exist in nature, though certain of them can be readily prepared by the action of alkali on diphenyl dimethylolid compounds, in which case hydrolysis followed by the elimination of a carboxyl group occurs :
By a more drastic action of the alkali, hydroxy-diphenyl derivatives are produced :
Interesting is the fact pointed out by Graebe (Ber. 1903, 36, 214) that by distillation with zinc-dust diphenylmethylolid yields fluorene :
in addition to diphenyl and methyldiphenyl. Formerly the production of the first-named hydrocarbon from ellagic acid proved a stumbling-block in attempts to obtain a clear conception of its constitution. A. G. P.

DIPHENYLENEMETHANE *v.* FLUORENE.

DIPHENYLHYDRAZINE *v.* HYDRAZINES.

DIPHENYLHYDRAZONES *v.* HYDRAZONES.

DIPHENYLKETONE *v.* BENZOPHENONE and KETONES.

DIPHENYLMETHANE was first obtained by Jena, in 1870 (Annalen, 155, 86), by the dry distillation of barium diphenylacetate

$$[(C_6H_5)_2CH \cdot COO]_2Ba$$
According to Zincke (Annalen, 159, 374), it is produced by the action of finely divided copper, iron, or zinc or their chlorides, on a mixture of benzyl chloride and benzene or by heating benzoylbenzoic acid with soda-lime. Friedel and Crafts (Bull. Soc. chim. [ii.] 41, 324) and Schwartz (Ber. 1881, 14, 1526) obtained it by the action of benzene on methylene chloride in presence of aluminium chloride ; E. & O. Fischer (Annalen, 194, 253), as by-product in the formation of triphenylmethane from chloroform and benzene in presence of aluminium chloride ; the Friedel-Crafts reaction applied to aromatic

alcohols in presence of benzene (Huston and Friedemann, J. Amer. Chem. Soc. 1916, 38, 25); and Hirst and Cohen (Chem. Soc. Trans. 1895, 67, 826), by the action of the aluminium-mercury couple on a mixture of benzyl chloride and benzene. It is also formed by the reduction of benzophenone (Zincke, Thörner, Ber. 1877, 10, 1473; Staedel, Annalen, 194, 307; Graebe, Ber. 1874, 7, 1624), and by the action of phosphorus pentoxide on benzyl ethyl ether (v. Meyer, J. prakt. chem. 1910, ii. 82, 538). But the methods which have found a technical application in the production of diphenylmethane derivatives, as well as of the parent hydrocarbon, are those of (1) Meyer and Würster, which consists in heating a mixture of benzyl alcohol, benzene and conc. sulphuric acid (Ber. 1873, 6, 693), and of (2) Baeyer, in which benzene, formaldehyde, or methylal are shaken together in presence of conc. sulphuric acid (Ber. 1873, 6, 221).

$$CH_2O + 2C_6H_6 = CH_2(C_6H_6)_2 + H_2O$$
Properties.—Diphenylmethane crystallises in long, colourless, prismatic needles, possesses a fragrant smell, melts at 26°-27°, and distils without decomposition at 261°-262°. It dissolves easily in alcohol, ether, and chloroform.

Reactions.—On oxidation with chromic acid, it yields benzophenone. On passing the vapour through a red-hot tube, it is converted into o-diphenylenemethane. On heating it with sulphur to 250°, it gives tetraphenylethylene, and on prolonged chlorination with iodine chloride at 350° it breaks up into hexachlorobenzene and carbon tetrachloride (Ruoff, Ber. 1876, 9, 1485).

Nitro- Derivatives.—On nitration, diphenylmethane yields two dinitro- derivatives, one of which melts at 183°, and the second, which is the chief product, at 118°. Other dinitro- derivatives are obtained from nitrobenzyl chloride, benzene and aluminium chloride, nitrobenzyl alcohol, benzene and sulphuric acid or nitrobenzene, formaldehyde and sulphuric acid, in a similar manner to the parent hydrocarbon. Also nitrohydroxy- derivatives can be prepared by condensing nitrophenols and their ethers with formaldehyde and conc. sulphuric acid (D. R. P. 72490). The prolonged action of nitric and sulphuric acids gives rise to a tetranitro- derivative.

Amino- Derivatives.—The only substances possessing at the present time an industrial value are the amino- derivatives of diphenylmethane. They may be obtained by the reduction of the nitro- derivatives by tin and hydrochloric acid; but the more common method is to effect condensation between the aromatic base and formaldehyde, a general process for which a number of patents have been granted in recent years. Thus, by heating aniline, aniline hydrochloride and formaldehyde, 40 p.c., to 100°, 4,4'-diaminodiphenylmethane is produced (D. R. PP. 53937 and 55565). The reaction appears to occur in two stages, for on heating aniline, formaldehyde, and a strong alcoholic solution of potassium hydroxide, the following change takes place :—

$$CH_2O + 2C_6H_5NH_2 = C_6H_5NH\cdot CH_2\cdot NH\cdot C_6H_5 + H_2O$$
and the latter when heated with aniline and its hydrochloride passes into the diphenylmethane

derivative. A tetramethyldiamino- compound is obtained in a similar manner from dimethylaniline and formaldehyde in acid solution. Similarly, a diphenyldiamino- derivative

$$C_6H_5NH\ C_6H_4\cdot CH_2\cdot C_6H_4NH\cdot C_6H_5$$

has been prepared from diphenylamine and formaldehyde (D. R. P. 58072), a tetramethyldiaminodihydroxy- derivative

$$(CH_3)_2N(OH)C_6H_3\cdot CH_2\cdot C_6H_3(OH)N(CH_3)_2$$
from dimethyl-m-amino phenol (D. R. PP. 63081 and 67001), and a diethoxydiaminodiphenylmethane $NH_2(C_2H_5O)C_6H_3\cdot CH_2\cdot C_6H_3(OC_2H_5)NH_2$ from o-phenetidine and formaldehyde in presence of hydrochloric acid (D. R. PP. 70402, 72490, 73951, 73946).

Other methods for obtaining 4,4'-diaminodiphenylmethane are (1) the action of p-aminobenzyl alcohol on aniline hydrochloride in aqueous solution (D. R. P. 96762), and (2) heating p-aminobenzylaniline with hydrochloric acid (D. R. P. 107718)

$$NH_2C_6H_4\cdot CH_2\cdot NHC_6H_5$$
$$= NH_2C_6H_4\cdot CH_2\cdot C_6H_4NH_2$$
The 4·4 diaminodiphenylmethane has been prepared from p-aminobenzylaniline by heating with aniline and similar aromatic bases

$$NH_2C_6H_4\cdot CH_2NH\cdot C_6H_5 + C_6H_5NH_2$$
$$= NH_2\cdot C_6H_4\cdot CH_2\ C_6H_4\cdot NH_2 + C_6H_5NH_2$$
(v. Braun and Kruber, Ber. 1913, 46, 3952).

For diaminoditolylmethane see Farb. vorm. Meister, Lucius and Brüning, D. R. P. 252916, 1913.

A 1 1' dichloro 2.2' diamino diphenylmethane is described by Duval, Compt. rend. 1912, 154, 780, and by Meyer, Ber. 1914, 47, 1161, who prepared it from formaldehyde and o-chloraniline.

A tetrahydroxy- derivative was obtained by Ghosh and Watson (Chem. Soc. Trans. 1917, 111, 824) from quinol and formaldehyde.

Aryl derivatives of diphenylmethane, prepared by the Grignard reaction, are described by Boudroux, Compt. rend. 1915, 161, 131.

Sulphonic acids of diphenylmethane have been obtained by Wedekind and Schenk, Ber. 1911, 44, 198, and Staudinger and Pfenninger, Ber. 1916, 49, 1941.

Diphenylmethane mono-, and dicarboxylic acids have been prepared by Mitter, Ber. 1912, 45, 1207, by the action of oxalyl chloride in presence of aluminium chloride on diphenylmethane.   J. B. C.

DIPHENYLMETHYLAMINE. *Methyldiphenylamine v.* DIPHENYLAMINE.

DISALOL. Trade name for phenyl salicylsalicylate.

DISAZO- and TETRAZO- COLOURING MATTERS. The terms 'disazo' and 'tetrazo' are both used to indicate the presence of two azo- groups ($\cdot$N:N$\cdot$) in the molecule of a colouring matter, but at the same time they indicate the mode of preparation of such dyestuffs rather than, strictly speaking, their constitution. Tetrazo- colouring matters may be regarded as a special division of the disazo-colouring matters, as will be seen from the following classification.

Primary disazo-colouring matters are obtained by the action of two molecules of a diazo- compound (derived either from two molecules of an amine or from two different amines) on one molecule of an amine (e.g. m-phenylenediamine, m-tolylenediamine), a phenol (e.g. phenol, resorcinol, a dihydroxynaphthalene) or an aminophenol (e.g. aminonaphtholsulphonic acids). The position taken up by the diazo- groups may be illustrated by the commonest cases (see also Azo- colouring matters). m-Phenylenediamine : The azo- groups occupy the two positions para- with respect to the two amino- groups. When one of these para- positions is occupied, as in m-tolylenediamine, the second azo- group enters the ortho- position with respect to the second amino- group ; thus :

$$CH_3 \underset{NH_2 \quad N_2}{\overset{N_2-}{\underset{\qquad}{\bigcirc}} NH_2^{\cdot}}$$
Phenol, a-naphthol. The para- and ortho-positions with respect to the hydroxy- group are occupied.

Resorcinol. Two isomeric disazo- dyestuffs may be formed. When the combination is effected in alkali hydroxide solution, the symmetrical compound (I.) is obtained, but when

$$\underset{I.}{HO\overset{N_2-}{\underset{\bigcirc}{\bigcirc}}OH} \qquad \underset{II.}{HO\overset{N_2-}{\underset{\bigcirc}{\bigcirc}}OH}$$
$$-N_2 \qquad \qquad N_2- \qquad \qquad N_2-$$
the reaction takes place in the presence of sodium acetate or sodium carbonate, the unsymmetrical compound (II.) is produced.

Dihydroxynaphthalene. Here the azo- groups enter the usual position with respect to the hydroxy- groups, as would be expected if these groups represented two independent naphthols (cf. Azo- colouring matters).

Aminonaphtholsulphonic acids. In this case also, the compound may be regarded both as an independent naphthylamine and as a naphthol ; one molecule of the diazo- compound is combined in acid solution, when the position taken up by the azo- group is the same as if the substance were a naphthylamine, and the second molecule is combined in alkaline solution as if the substance were a naphthol.

Secondary disazo- colouring matters are obtained by the action of a diazoazo- compound on an amine or phenol ; their general formula is $X \cdot N_2 \cdot Y \cdot N_2 \cdot Z$, the essential difference being that Y does not contain primary class auxochrome groups (NH_2 or OH).

Tetrazo- colouring matters are produced from diamines, both amino- groups of which are diazotised (i.e. the diamine is tetrazotised) and combined with two molecules of the same or different components (amines or phenols). These are mostly derived from benzidine, tolidine, dianisidine, &c. ; some, however, are prepared from p-phenylenediamine, and in this case direct tetrazotisation cannot conveniently be effected, but the monoacetyl compound is first diazotised and combined, the acetyl- group being then eliminated and the free amino- group is diazotised and combined with the second molecule of a component.[1] When the first combination has been effected with an amine (in practice nearly always a naphthalene derivative), and in consequence a diamino- compound is produced on saponification, treatment with one molecule of nitrous acid leads to the diazotisation of the benzenoid amino- group, that attached to the naphthalene ring not being attacked.

For the sake of completeness, it is necessary here to describe those dyestuffs which contain three or more azo- groups.

Trisazo- colouring matters are obtained in the following ways. (1) Combination of three molecules of a diazo- compound with a phenol. This method is of only theoretical importance, and has hitherto been applied only to the cases of phenol (Wallach and Fischer, Ber. 1882, 15, 2814 ; Grandmougin and Freimann, ibid. 1907, 40, 2662 ; J. pr. Chem. 1908, [ii.] 78, 384 ; Heller and Nötzel, ibid. 1907, [ii.] 76, 58 ; Heller, ibid. 77, 189), phloroglucinol (A. G. Perkin, Chem. Soc. Trans. 1897, 71, 1154), and resorcinol (Orndorff and Ray, Ber. 1907, 40, 3212 ; Amer. Chem. J. 1910, 44, 1). (2) Combination of one molecule of a diazoazo- and a diazo- compound with a phenol, amine, or aminophenol. The diazoazo- compound may be produced, for example, by diazotising an aminoazo- compound such as p-sulphobenzeneazo-a-naphthylamine, or the intermediate product, obtained by combining a tetrazotised diamine (benzidine, &c.) with one molecule only of a component (such as salicylic acid, &c.), may be used, or the formation of the diazoazo-compound may be left to the last stage of the operation, for example, a tetrazotised diamine (benzidine) may be combined with one molecule of an aminonaphthol (H acid) in acid solution, a diazo-compound (diazobenzene) now added in alkaline solution and the diazodisazo-compound coupled with a component (m-phenylenediamine or phenol) (Eric direct black GX and Eric direct green DT). (3) Combination of a diazotised tetrazo- colouring matter (which must, of course, contain a diazotisable-amino- group) with a phenol or amine, either in substance or on the fibre. (4) Combination of a triamine (e.g. magenta), having each amino- group diazotised, with three molecules of a component.

Tetrakisazo- colouring matters, containing four azo- groups, are obtained (1) by the combination of two molecules of a diazoazo- compound with a phenol or amine (e.g. Anthracene acid brown B, v. Azo- colouring matters) ; (2) by combining two molecules of a diazo- compound with one of a tetrazo- colouring matter (e.g. Benzo brown G) ; (3) by combining a tetrazo- compound, with two molecules of a monoazo-colouring matter (e.g. Hessian brown BBN) ;

[1] An alternative method is first to combine diazotised p-nitroaniline with the component, then to reduce the nitro- group with sodium sulphide, and diazotise the amino- group thus formed.

(4) by tetrazotising a tetrazo- colouring matter (containing two diazotisable amino- groups) and combining with two molecules of a component (*e.g.* Dianil black PR) ; (5) by diazotising a tris-azo-colouring matter (containing one diazotisable amino- group) and combining with a phenol or amine either in substance or on the fibre.

Colouring matters, containing more than four azo- groups, can be prepared, but, generally speaking, their tinctorial power is little or no greater than those described above.   J. C. C.

DISINFECTANTS. A disinfectant is an agent that will kill lower organisms which act injuriously on the higher forms of life. Although most disinfectants are also antiseptics and deodorants, a clear difference between the three classes lies primarily in their uses and objects. Disinfectants are germicides : antiseptics may only retard or inhibit the growths. It is not essential for a disinfectant to effect absolute sterility : in practical disinfection, there is nearly always a residue of highly resistant and non-pathogenic organisms. To destroy these involves great additional time and cost, and may even be disadvantageous when they act as natural scavengers in removing objectionable organic matter and antagonising dangerous forms. The choice of an agent will obviously depend on considerations of safety, convenience, and economy in use

INORGANIC SUBSTANCES.

Ordinary oxygen acts slowly by the aid of aërobic organisms. Its activity is slightly increased by compression ; it becomes exceedingly energetic when converted into **Ozone.** Since ozone is decomposed by heat and absorbed by most metals and by otherwise inert organic matter, the chief conditions for success and economy in working are (1) avoidance of sparking ; (2) keeping the gas and the apparatus cool ; (3) straining the air, and also partially drying when it is desired to prevent the formation of oxides of nitrogen ; (4) parts in contact with ozone must be made of, or lined with, unoxidisable materials ; (5) the grosser organic impurities, as well as sulphuretted hydrogen and ferrous iron, should be removed before disinfection. The use of ozone on the large scale for purifying water is now well known, and the principal types of apparatus have been described by Don (Inst. Mechan. Engineers, Jan. and Feb. 1909 ; *see* also S. Rideal, J. R. San. Inst. 30, 1, 1909 ; Rideal found at St. Maur Waterworks, Paris, that with the sand-filtered (Marne) river water, containing a fluctuating number of bacteria, 28-320 per c.c , with a mean frequency of *coli* organisms of 1 per 100 c.c. (in more than one-third of the tests it was 1 in 40 c.c.), ozone in the proportion of about 0·6 gram per cubic metre of water (6 lbs. per million gallons) destroyed all bacteria except an average of 1 per c.c. of innocuous spore-bearing organisms of the *subtilis* type. The ozonised air was applied in a De Frise tower at the rate of about 40 p.c. of the volume of water treated, and contained 1·4–1·8 grams of ozone per cubic metre (determined at frequent intervals by neutral potassium iodide). An advantage of ozone is that in disinfecting it adds no mineral matter to the water, and it has been fully proved that where water is not too contaminated

with organic matter, sulphuretted hydrogen, or ferrous iron, ozone will destroy all pathogenic organisms at a reasonable cost. In the dry state, like chlorine, it has very little action on micro-organisms, and therefore does not act powerfully on bacilli in air. 8 grams per cubic metre of air in a room ordinarily closed accomplish disinfection in 3 hours. Its use as an adjunct to ventilation has often been proposed, but its irritant action on the lungs prohibits its use in these quantities. It is most active when moist. Ozonised air, under pressure, has been used successfully for destroying moulds and bacteria in brewers' foul casks, and has been introduced into wort in the latter part of the fermentation ' to destroy noxious germs ' (Eng. Pat. 22355, 1898) Will and Beyersdorfer (Zeit. ges Brauw. 1912, xxxv. 73) showed that air containing 0·6–0·7 gram of ozone per cubic metre destroyed organisms inimicable to the brewery. On account of its rapid consumption by oxidisable substances, it can only be effective in disinfecting the *surfaces* of organic solids. At the Pittsburg Homœopathic Hospital, ozone, besides purifying the water supply, is used for sterilising instruments, bandages, &c., and for dressing wounds and ulcers. In cold storage it would probably be useful for destroying injurious organisms and odours, thereby possibly lessening the amount of refrigeration required. Many attempts have been made to utilise it for disinfecting, combined with bleaching, textiles, feathers, and other surface-contaminated articles, and have been only limited by questions of expense.

Patent 4153 of 1902, for ' fixing ozone in liquids,' states that pure acetaldehyde dissolves 2823 times its volume of ozone ; that 10 p.c. solutions of acetaldehyde in water dissolve 536, in alcohol 748, in ether 859 volumes of ozone ; that these solutions are very stable, and have been successfully used in surgery.

Hydrogen peroxide. The first experiments (Ber. 15, 1585) showed that this was a bactericide which, in the dilute state, appeared inert to enzymes such as diastase,[1] ptyalin, pepsin, and pancreatin ; did not injure foods ; and is also innocuous and non-corrosive. These properties suggested its use for killing pathogenic organisms, and those that cause change in articles of diet, especially milk (Renard), and also as an internal disinfectant. Altchoefer (Centr. Bakt. 1890, viii. 129) and most later observers give 1 per 100 of H_2O_2 as required to destroy pathogenic organisms in 24 hours. In 1903 S. Rideal found that in milk raised to 50°, then treated with 0 6 gram of H_2O_2 per litre, and the heat maintained at 52°–55° for 8 hours, pathogenic organisms and even the spores of *B. anthracis* and *subtilis* were killed, the milk was not physically altered, and kept for over a month unchanged in the closed receptacles (Budde's patent 10903, 1903). Similar results have been obtained by Lewin and others, by Hewlett (Lancet, Jan. 27, 1906), and Reichel (Zeit. f. Hyg. 1908, lxi. 49). So that hydrogen peroxide aids pasteurisation, and enables it to be efficient at a lower temperature. The solution is

---

[1] The enzyme *catalase* (present in malt, yeast, milk, and many organic liquids) and hydrogen peroxide mutually decompose one another (Van Laer, J. Soc. Chem. Ind. 1906, 489 ; 1909. 950) ; but the above statement remains practically true. (*See also ibid.* 1909, 1267.)

frequently used as a spray, gargle, or dressing, and has had a wide application for war service in dealing with gas gangrene infected wounds (*see* reports by Capt. M. Page, R.A.M.S., Lancet, Sept. 1914; Col. Makins, *ibid.* August, 1914). Peroxide of hydrogen is present in 'Sanitas' (*q.v.*). 'Perhydrol' is a 30 p.c. or 100 volume solution of H_2O_2. The use of peroxide of hydrogen in medicine depends partly on its bactericidal action. Registered names of solutions are 'Dioxogen' (3 p.c.), 'Hydrozone,' 'Glycozone' and 'Pyrozone' (dental practice); and 'Peroxols' are mixtures of H_2O_2 with various disinfectants. Peroxides of sodium, magnesium ('Hopogan'), zinc ('Ektogan' or 'Dermogen') and mercury, generate oxygen or H_2O_2, and have analogous use. Hydrogen peroxide is more stable in ether than in water; 'ozonic ether' is an ethereal solution containing about 1·2 p.c. of H_2O_2, which has been used in whooping-cough and scarlet fever. 'Perhydrit' or 'Hyperol' dressings, containing H_2O_2, urea, and a trace of citric acid, have recently been introduced.

Foregger and Philipp (J. Soc. Chem. Ind. 1906, 298) treat at length on the applications of peroxides, and suggest calcium peroxide ('Bicalzit') instead of H_2O_2 for sterilising milk, as more lasting in effect. For water sterilising, tablets of magnesium peroxide and citric acid are made; Park found that 0·1 gram of this peroxide killed upwards of 2 million typhoid organisms in 150 c.c. of water in 30 minutes, and 0·2 gram gave the same result in 1 minute. Although Cronor (Zeit f Hyg 1908, lvii. 487) obtained sterility in water with the use of 0·7–1·0 gram MgO_2 per litre, more recent investigations by Young and Sherwood (J. Ind. Eng. Chem. 1911, 3, 495) have indicated that over five times this quantity must be used to ensure sterility. Patents for similar uses of H_2O_2 and other peroxides are very numerous.

Nitric acid and oxides of nitrogen. The corrosive action of nitric acid limits its value as an active disinfectant J. C Smith used it with success in 1780 for fumigation in a violent outbreak of *typhus* fever in the British fleet (Vallin, Désinfectants, 1882, 265). Disinfection of rooms by nitrogen peroxide was carried out during the siege of Paris ; 48 hours were occupied, and the cost was very high. Severe bronchitis and several deaths from poisoning have resulted from breathing this gas, and nitric disinfection has been replaced by safer methods, except in the local destruction of bacteria as in laboratories.

Sulphur. Dusting with sulphur is used for killing insects and fungi on plants, as sulphurous acid is gradually formed. The use of sulphur internally is due to its forming sulphuretted hydrogen in the system, and thereby destroying or enfeebling micro-organisms and higher parasites. A solution containing calcium polysulphides, made by boiling milk of lime with sulphur, has been extensively used as an insecticide (*see* Agric. Bull. 319 and 320, New York, 1909).

Sulphur dioxide disinfection is still a subject of controversy, but certain of the unfavourable results adduced have been due to faulty application. Spores are not generally killed by it, and the dry gas has very little effect on micro-organisms, but it destroys all vermin, and therefore is of special value in combating insect-borne

diseases. As to its effect on the lungs, about 5 p.c. in the air has produced fatal results, but $\frac{1}{2}$ p.c. can be tolerated for some time, and a larger amount with the protection of a wet towel alkalised with washing soda. 1 lb. of sulphur burnt in a room of 1000 cubic feet produces theoretically an air-content of 1·15 p.c. SO_2, and requires 0·56 lb. of water to turn it into sulphurous acid. Such an amount of moistening is, however, not necessary, on account of the natural moisture of the air. Prescriptions as to the proper quantity of SO_2 have varied greatly, partly because in some cases it has been considered sufficient to destroy only a special organism. Klein, Houston, and Gordon (Report, Med. Off. L.C.C. 1902) found that with $3\frac{1}{4}$ lbs. S per 1000 cubic feet in 24 hours, *B. typhosus*, *diphtheriæ*, *pyocyaneus*, and *Staph. p. aureus* were killed, but not anthrax spores nor *B. tuberculosis* in dried sputum. In America, 5 lbs. per 1000 cub. feet have been found sufficient to kill all spore-bearing organisms after 16 hours' exposure (Rosenau) S. Rideal's results with the liquefied gas were as follows. Silk threads and paper slips infected with *B. coli* and *Staph. p. aureus* were sterilised after 24 hours' exposure in a sealed room of 1500 cub. feet, into which 20 ozs. of SO_2 were passed. *Subtilis* spores were not killed. With 10 ozs., the threads were again sterilised, but the paper slips were not. When shallow pans of water were exposed in the room to supply moisture, the SO_2 content of the air was actually *lowered* after the 24 hours (through absorption by the water), from 0·5 p.c. present in the previous experiment to 0·2 p.c., and the organisms were still living. Therefore moisture should only be supplied by washing or lightly spraying the surfaces. In chemical disinfection, it is generally recommended that walls should be previously stripped and fabrics spread out on lines; but spreading the infection must be carefully avoided. The room must be sealed by obvious means, and, observing this condition, heating is advantageous. Liquid SO_2 in canisters is more convenient than burning sulphur, and avoids risk of fire : one pound of the liquid $= 5\frac{1}{2}$ cub. feet of the gas. SO_2 has the disadvantage that it attacks metals and organic substances from the production of sulphuric acid : a good deal is also absorbed by plaster. It has little penetrating power, and therefore bedding and thick articles must be removed and sterilised by heat. The 'Clayton method' of disinfection is much used for the holds of ships, and has been favourably reported on by Wade and Eyre for the Local Government Board (Rep. 232, 1906; and Med. Off. Rep. 1903-4, 330). Sulphur is burnt in a special apparatus, and the gases, consisting of air, SO_2, and a visible cloud of sulphuric acid, are forced in till the SO_2 reaches about 10 p.c. of the air in the infected space. (For experience of its use, *see* Rev. d'Hyg. Oct. 1902; N.S.W. Agric. Gaz. 1900 and 1901).

• Sulphurous acid is used beneficially as a germicidal spray or wash in various parasitic affections (*e.g.* diphtheria), also internally in cholera and gastric fermentation, for rectal injections, and other allied objects. 'Thiocamf' is a liquid obtained by the action of the gas on camphor. It can be preserved without pressure in well-closed vessels, and on exposure to air a 6-oz. bottle should evolve about 20 litres of SO_2.

Sulphurous acid and bisulphites are widely used for checking fermentations and preserving food. Lehmann states that an amount equivalent to 0·004 p.c. of SO$_2$ may be allowed without injury to health. The Report of the British Departmental Committee on Preservatives, 1901, 26, leaves the matter open. Some commercial preparations are 'Meat preserve crystals,' 'Freeze-em,' and 'Hawke's anti-ferment.' For objections to the use of sulphites in food, *see* Thresh and Porter, Preservatives, 1906, 70–77; also an article by Durham in the J. of Hygiene, April, 1909. The latter recommends the fixing of a maximum legal limit, not exceeding 0·01 p.c. of 'total sulphur dioxide,' with a declaration of the amount, but less than 0·001 or 0·002 p.c. might be simply declared as a 'trace.'

Sulphuric acid, like acids generally, is antiseptic, and in some cases disinfectant. 0·05 p c. (which is a palatable strength) is fatal to *Sp. choleræ* in 15 minutes. Stutzer found that this strength disinfected iron pipes, cleaning out rust and sediment without sensibly attacking the metal. With 0·04 p.c. Ivanhoff destroyed cholera organisms in Berlin sewage, and with 0·08 p.c. in that from Potsdam. In the laboratory it was found that 0·035 p.c. kills *B typhosus* in 30 minutes, and 0·07 p.c. in 15 minutes, in impure water infected ordinarily with typhoid, but with very heavy infections the latter strength requires 45 minutes. He recommended 0·09 p.c. as having advantages over heat sterilisation for dealing with the drainage from hospitals and other infected areas : the acidity would speedily be neutralised on mixing with the bulk of the sewage (Brit. Assoc. 1901).

Sodium bisulphate has been introduced by one of the writers and Dr. Parkes, as a means of sterilising drinking water for armies in the field and travellers. 15 grains of NaHSO$_4$ to a pint of water in 15 minutes destroys *B. typhosus* and *enteritidis*, *Spirillum choleræ*, and internal parasitic worms. In effervescent tabloids, yielding a slightly acid solution, it was used with success in the South African, Russo-Japanese, and the European wars.

Persulphates give off oxygen when moist, and are useful as hand disinfectants (Lancet, 1905, ii. 1106).

Carbon disulphide, if it were not for its other properties, would be a valuable disinfectant and preservative. As well as its alkaline compounds, the xanthates, it has been found useful against fungi, and insect parasites such as the vine phylloxera. Ckeandi Bey's lamp burns it safely for generating SO$_2$.

Boric acid is not a disinfectant, but has a power of restraining bacteria which act injuriously in foods. Rideal and Foulerton found that 1 in 2000 of a boric mixture, containing 3 parts of H$_3$BO$_3$ and 1 part of crystallised borax, keeps milk sweet for 24 hours without appreciable effect on digestion. The British Departmental Committee already referred to, recommend that the only preservatives allowed to be used in cream, butter, and margarine be boric acid, or mixtures of boric acid and borax, not exceeding 0·25 p.c. of H$_3$BO$_3$ for cream, and 0·5 p.c. for butter and margarine. Later, as this quantity appeared insufficient in the cream trade, an official report by Hamill advised that 0·4 p.c. H$_3$BO$_3$ should be allowed in cream from

May to October inclusive (Food Report 10, L.G.B. 1909). Soluble borates are used as a larvicide in manure heaps. It has no action on the crops as they are rendered insoluble (Cook and Wilson, J. Agric. Research, 1917, 10, 591).

The Halogens, chlorine, bromine, and iodine, act as disinfectants in several ways : (1) they can combine with H$_2$ and liberate O$_2$ in water ; (2) they can combine directly with organic matters, or replace the hydrogen in them, precipitating albuminous substances and rendering them imputrescible, killing organisms by combining with and coagulating protoplasm, removing their food or rendering it unsuitable, acting toward them as irritants or direct poisons, also producing substances which have that effect.

Chlorine and the hypochlorites, like other oxidisers, are consumed by otherwise inert organic and inorganic matters present, but in ordinary disinfection leave behind them as substitution compounds which maintain germicidal power—the chloramines, hydrazine, and the chloroproteids (Rideal, J. R. San. Inst. 31, 2, 1910). This paper shows that in dilute solution of hypochlorites the Rideal-Walker coefficient of 2·18 for 1 p c. of available Cl is increased to 6·36 by the addition of an equivalent of ammonia, remains near this level for 24 hours, and even after 72 hours has an enhanced value. Therefore, since the coefficient of chlorine itself averages 220 units, that of ammonia less than 0·7, and ammonium chloride *nil*, that of the chief product, *chloramine* NH$_2$Cl, must be over 600 units ; hence this substance, but for its instability, would probably be the most valuable of disinfectants. It has a pungent odour, hitherto often mistaken for chlorine or hypochlorous acid, and gives the blue reaction with KI and starch. With excess of ammonia, as in sewages, it gradually disappears, forming a salt of *hydrazine,* which still has a germicidal value (R. W. coefficient of the base at least 24). The action of chlorine on nitrogenous compounds gives compound chloramines, many of which are insoluble ; they have a tendency to become fixed on cellulose, and in this way attack the envelopes of organisms.[1]

Various substituted chloramines have been introduced by H. D. Dakin for use as sterilisers and disinfectants. Amongst the more important may be mentioned chloramine-T, *p*-toluene sodium sulphochloramide, *p*-sulphodichloraminobenzoic acid, and dichloramine T (B.M.S. Aug. 1917). The former, under the title Halozene, has been used for water sterilisation on a small scale.

The addition of ammonia solutions to bleaching powder solutions preparatory to the sterilisation of water has effected a considerable economy in the quantity of materials used in the public water supply at Toronto, Canada.

The chloramine is about five times as strong as the corresponding molecular concentrations of sodium hypochlorite.

· The bromamines of the benzene series, the naphthaline chloramines and the protein chloramines, are all strong germicides, but suffer from lack of stability in solution.

Chloride of lime, or 'calx chlorinata ' (about 33 p.c. available chlorine), has some advantages

[1] Also see Cross Bevan and Bacon, Chem. Soc. Trans. 1910, 244.

from being a solid, but is quickly deliquesced and decomposed by air, takes some time to dissolve, and gives a quantity of insoluble waste. Klein found that 1 p.c. of bleaching powder only killed less resistant organisms in 24 hours. There is, in many respects, a preference for the sodium solutions: chlorinated soda or 'Eau de Labarraque' (often called 'Eau de Javel,' which was originally the potash salt), contains about 2·5 p.c. av. Cl; 'Chloros,' 10 p.c. av. Cl; 'Antiformin' is a solution of caustic soda and hypochlorite used in breweries. Electrolytic preparations are 'Oxychloride,' up to 11·5 p.c. av. Cl, and 'Hermite fluid,' used successfully at Poplar. In the latter solution magnesia is employed as an adjunct in the electrolysis: it contains free hypochlorous acid: av. Cl 4·2 to 4·8 p.c. The effective strength for local disinfection is 0·35 p.c. av. Cl, which kills nonsaatring organisms in 5 to 10 minutes, and anthrax and enteritidis spores in 1½ hours. Chloride of lime has the objection that it leaves the surface for a long time damp from the presence of calcium chloride. The same salt imparts its bitter taste, and increases the hardness, when chloride of lime is applied to the purification of drinking water, while the soda preparations tend to soften the water and are not sensible in the flavour. In trials at Guildford in 1904 (J. R. San. Inst. xxvi. 891) with electrolytic hypochlorite in the proportion of 0·75 to 1·0 part per million of av. Cl, one of the writers found that water containing an average of 90 organisms per c c. was practically sterilised, while after standing 1½ hours the odour and taste were normal, and there was no need for further treatment. Candy's patent, 4212, 1906, removes excess of av. Cl by filtration through coke, Thresh's, 3023, 1909, by treatment with metallic iron. Other methods of removal are suggested: (1) by the addition of ferrous salts, subsequently removing the ferric salt formed by a 'Permutit' filter; (2) by the addition of gaseous sulphur dioxide; (3) by the addition of sodium bisulphite. After the Maidstone typhoid epidemic, 1897, the infected reservoir, mains, and pipes, were sterilised with 1 p.c. solution of chloride of lime during 48 hours: no corrosion of the iron was observed. During a similar outbreak at Lincoln, in 1905, the water supply was sterilised by sodium hypochlorite (av. Cl, 1 per million) with most satisfactory results. In 1910 Toronto treated its water supply with 0·14 part per million of av. Cl as chloride of lime. Since June, 1909, the writers have been applying 'Chloros' in the proportion of 1 to 2 parts av. Cl per million to 100,000 gallons daily of the drinking water of a town in the north of England: the liquid is made practically sterile, coli is absent from 75 to 85 c.c., and there is no effect on the taste. At Cambridge, in 1910, a portion of the supply (lower chalk) was treated with one in 4 to 8 millions of av. Cl as chloride of lime, and Houston found that this minute quantity destroyed 66 to 98 p.c. of the bacteria, and coli, which was always present before, was afterwards absent in 500 c.c. This water, however, contained hardly any organic matter. In America, treatment of the entire water supply of Jersey City (about 40 million gallons per day, from the Rockaway river) with chloride of lime, has been adopted since the beginning of

1909: the proportion used is now 0·2 part per million of av. Cl, and the daily examination shows that coli is absent from 10 c.c. of the treated water. In England, the 'De-Chlor' system was applied at Reading to the prefiltered river water in 1910. Since the war chlorine treatment has been adopted for the London supply (11th Annual Report, M.W.B.).

Recently an impulse has been given to the sterilisation of water by means of gaseous chlorine injected by means of suitable dosing apparatus, owing to the convenience of handling and transporting chlorine in the liquid state contained in steel cylinders of 100 lbs. capacity. Injection into the water may be direct through a diffuser, as in the Wallace and Tieman apparatus, or indirect through the addition of a minor volume of more concentrated chlorine water to the bulk volume, as in the Electrobleach and Patterson plants. NH₃ does not seem to enhance the germicidal value in the absence of alkaline bases.

With sewage, of course, a larger dose is required, and the first experiments at Nice, Brest, and Worthing, in 1894, with the Hermite fluid, showed that, as with ozone and other disinfectants, the agent should be applied, not to a raw liquid (except in special cases), but as a 'finisher' to one that was partially purified. In 1898, using an electrolytic brine (Woolf's 'Electrozone') for purifying an effluent at Maidenhead, one of the writers found that with three parts per million of av. Cl, and a contact of 5 minutes, the bacteria were reduced to 10 per 50 c c, and that 17 parts per million killed all the organisms in 15 minutes. His long series of trials at Guildford commenced in 1904, using 'Oxychloride,' and proved that with 2·5 parts per million of av. Cl, tertiary effluents could be practically sterilised, but that the raw sewage and septic effluents required 30 to 70 parts; the contact period was 4½ hours (J. R. San. Inst. xxvi. 7, 1905). The oxygen consumed from permanganate in 5 minutes in the cold, as measuring the H₂S and other easily oxidisable substances, was a guide to the amount of the agent used, and in the earlier experiments it was found that when the av. Cl added was 1·7 times this figure, the availability of the chlorine was sufficiently prolonged to ensure the desired sterilising effect, and the subsequent experiments frequently yielded excellent results with an amount equal to this oxygen figure, that is, one to one. (See further, Rideal, Trans. Farad. Soc. iv. 3, 1909.) An important point shown was that the necessary factor of safety could be ascertained by simply testing with KI and starch, and noticing the persistence after 4½ hours of the blue colour, due in this case, as has been mentioned, not to chlorine, but to chloramines. Schumacher (1905), at Hamburg, found that with raw sewage sufficient sterilisation is attained if after 4 or 6 hours the test shows a reaction equal to 19 and 17 parts of million of av. Cl respectively. Investigations on sewage filter effluents with chloride of lime were continued in America by Phelps and Carpenter (U.S. Technological Quarterly, Dec. 1906), who remark that the use of electrolytic chlorine manufactured on the spot would, in the larger works, considerably reduce the cost, and is cheaper than sand filtration. Kellerman, Pratt, and Kimberley (U.S. Dept. of Agric.

Bull. 115, Oct. 1907) conclude that with a hypochlorite, disinfection costs less than with copper sulphate. Later American experiments at several centres have proved that 2 to 5 parts per million of av. Cl destroy 95 to 98 p.c. of the bacteria in 2 hours, and that 3 parts are sufficient for the trickling filter effluents tried (Mass. Inst. Technol. 5, 1909 ; 6, 1910).

The Royal Commission on Sewage obtained results at Guildford which were in agreement with those of the writer (Appendix iv. 1910, 87 ; also ibid. 84-171, and Rep. 1908, 195-201).

Sod. hypochlorite solutions are the best means of sterilising swimming baths ; they remove from the surfaces growths of algæ and fungi which harbour dangerous organisms. (Also see Rideal and Orchard, J. San. Inst. 556, 1906.)

'Ferrochlore' (Duyck) is the name of a treatment with 8 parts per million of ferric chloride and 0·5 part of chloride of lime, which at the same time clarifies water and liberates hypochlorous acid.[1]

Hypochlorous acid has been employed as an antiseptic for wounds by Dakin, Daufresne, and Lorraine Smith, and is also known as 'Eupad' and 'Eusol.' In these solutions hypochlorous acid is obtained by double decomposition of bleaching powder with sodium carbonate, with the addition of boric acid or sodium bicarbonate. The presence of sodium borate or sodium carbonate in the resulting solutions when freed from the precipitated calcium carbonate ensures the stability of the solution owing to the 'buffer' action of the easily hydrolysable salt.

Chlorine peroxide, obtained from potassium chlorate and sulphuric acid, has been successfully employed in the Howatson-Bergé process at Brussels, Ostend, and Lectoure (South France), for sterilising (previously clarified) polluted waters. The writer found that 20 parts of ClO_2 per million did not kill B. typhosus in a vigorous pure culture in 2 hours, but that 50 parts killed it in half an hour. (See also Reychler, Bull. Soc. chim. [3] xxv. 13 ; Chem. News, 1901, 316)

On a large scale, chlorine and ozone are both in successful use at present for sterilising water. The latter seems preferable for drinking supplies, the former is suitable for effluents. From questions of efficiency as well as cost, both require that the liquid should be previously clarified, and as free from organic matter as possible, that is, they are finishers.

Time as in all disinfections, is an important factor ; in an effort to get the work done quickly, it is sometimes forgotten that a longer time is advantageous, and economises the re-agent. For rapid sterilisation of a small quantity, as in the field, a larger proportion of reagent is required, and from questions of portability, bromine and iodine have been used instead of chlorine, but are attended by residual products having a taste and physiological effect. These, in the quantity required for dealing with the moderate pollution ordinarily met with, have been proved to be negligible, although, with heavier contamination, the amount of the halogen consumed by the organic matter before a sterilising excess is present, may become in-

jurious in its products. Cash showed that the quantities of chlorine, bromine, and iodine required for disinfection of anthrax and tubercle were nearly in the ratio of their atomic weights.

Bromine is a powerful disinfectant, but its use is obviously limited by its danger. In 1897 Altmann patented a solution of Br in KBr for sterilising water, using 40 parts per million of Br with 5 minutes' contact, and removing excess by ammonia. The solution is, however, bulky, and the use of a potassium salt has disadvantages. Braithwaite introduced 'Bromidine,' a dry mixture of sodium or potassium bromide and bromate with sodium bisulphate, which with moisture liberates bromine. Schumberg recommended free bromine in thin sealed tubes for the same purpose (Zeitsch f. Hyg. 1900, 53) in the proportion of 60 parts per million with 5 minutes' contact, removing excess by thiosulphate (Braithwaite advised 57 parts). Schöder (ibid xxxvii. 306) and others have stated that this treatment is insufficient to sterilise, and the presence of residual bromides is against the process (see also Parkes and Rideal, Trans. Epidem Soc. xx. 1901 ; Fraser, Publ. Health, Sept. 1902). It was tried in the Soudan campaign of 1898. 20 parts per million of Br sterilises typhosus (in water) in less than half an hour. It is more rapidly absorbed by organic matter than iodine.

Iodine owes many of its uses to its germicidal action, as in parasitic diseases. Grossich, in 1908 (Centr. f. Chirurg No. 4), adopted the tincture as a cutaneous disinfectant before operations, the surface being previously cleansed by a 1 p.c. solution of iodine in benzene (Bogden, ibid. Jan. 15, 1910). Instead of the tincture, Chassevant (Lancet, March 26, 1910) suggests the solution in chloroform, as it does not, like the former, cause desquamation ; its use is specially advised prior to hypodermic injections (see also Brit. Med J. Feb. 6, 1909, and Aug. 14, 1910 ; Lancet, April 16, 1910). Solutions of iodine and iodine trichloride, both as field dressings, and enclosed in friable glass compounds as emergency first-aid sterilisers, have been extensively employed during the war (see B. M. S. Jan. 2, 1915 ; Lancet, Dec. 12, 1914). During the Sikkim and Thibet expedition, iodine (in some cases as tincture) followed by sodium sulphite, was successfully employed for sterilising drinking water, and Nesfield recommends triple tablets of (A) iodide and iodate, (B) citric or tartaric acid, followed after 2 minutes' contact by (C) sodium sulphite, and states that used in this way 3·8 to 5 parts per million of free iodine sterilises the organisms of typhoid, cholera, and dysentery. One of the writers, in 1905, confirmed this result as regards distilled water infected with 20,000 per c.c. of B. typhosus, the A and B tablets used gave 4·75 parts of iodine per million.

Iodine trichloride was introduced by Von Langenbach for sterilising the hands and instruments and for other surgical uses. 50 parts per million are required to kill typhoid (in water) in 30 minutes. Iodine cyanide is said, by Kobert, to be universally destructive to lower forms of life, and is suggested for preserving biological specimens.

Organic substitution compounds of chlorine, bromine, and iodine, as a class, inhibit organisms,

---

[1] For an account of trials at Marseilles of ozone, chlorine, and ultra-violet rays, see Engineering, Jan. 27th and Feb. 3rd, 1911.

and may sometimes kill them. The germicidal power of a large number of these has been determined by Bechhold (Zeitsch. Hyg. Infect. 1909, lxiv. 113); he finds that a Br atom gives a greater power than a sulphonic group. *Chloroform* is often used to preserve perishable specimens and infusions. Farrel and Howles (J. Soc. Dyers, 1908, 24, 109) state that CCl_4 kills typhoid, and that pure $CHCl_3$ does not kill it, whilst 0·62 p.c. aqueous $CHCl_3$ kills it in less than 30 minutes.

Iodoform was formerly much employed in surgery, and a large number of other iodine compounds have been introduced into medical and surgical practice. Many of them are non-irritant, but their bactericidal power is much inferior to that of dilute solutions of the element. Fumigation of sick rooms with iodine, sometimes in conjunction with other disinfectants, by burning prepared candles or lamps, has been tried, but apart from the fact that the method is unsatisfactory, no chamber can be disinfected while occupied.

The organic iodo- compounds owe most, if not all, their germicidal power to the gradual liberation of iodine by the alkaline wound secretions. Iodoform itself gives rise to symptoms of poisoning owing to the too rapid evolution of iodine. Amongst the more important organic iodine derivatives may be mentioned hexamethylenetetramine compounds, chrysoform, iodoformin, phenol, and homologous compounds, aristol, iodothymoloform, europhen, traumatol, isophen, iodoamsol, iodocol, iodised albumen, tannin, gelatine, casein, gluten peptone lecithin, and various iodised oils have been protected under fancy names.

Fluorides, like boric acid, check bacteria, but do not kill them. As food preservatives, they are only moderately efficient, and are not innocent physiologically, as they hinder pancreatic digestion. Sodium silicofluoride ('salufer') and borofluoride ('pyricit') have been tried. Effront introduced the use of hydrofluoric acid and its acid salts for checking injurious fermentation, and J. Brand (Zeitsch. f. Brauw. 1904, xxvii. 115) states that 0·5 to 1 p.c. solution of acid ammonium fluoride is largely used for disinfecting rubber hose in breweries (*see also* Hehner, Analyst, 1902, 173; Richmond, Dep. Comm. on Preservatives, appendix xxxi.; Thresh and Porter, Preservatives, 1906, 87). Hydrofluosilicic acid is the active constituent of 'Montanin' (obtained from by-products in the pottery industries), and 'Keramyl' (about 25 p.c. H_2SiF_6) (J. Soc. Chem. Ind. 1904, 34; 1909, 904). Frank (Wasser u. Alwasser) recommended the use of aluminum silicofluoride for water sterilisation. They are stated to have no injurious action on health (Public Health, Oct. 1908).

Carbonic acid seems to have a certain amount of disinfectant action, since 'aërated' beverages have been shown to be in many cases sterilised, and CO_2 under pressure preserves food (*cf.* J. Soc. Chem. Ind. 1907, 1290).

Cyanogen and hydrocyanic acid are more destructive to insects than to lower organisms. Fumigation of fruit trees with HCN is extensively practised in America, and is considered better than spraying. For greenhouses, zinc capsules containing sodium cyanide are made; they are placed in dilute sulphuric acid,

and while the zinc dissolves the operator has time to retire.

Acids. An acid medium is unfavourable to the growth of most bacteria, and acids generally possess considerable disinfectant power. Kitasato found that the growth of *B. typhosus* in nutrient broth or gelatine was entirely prevented by the following percentages of different acids: 0·08 H_2SO_4; 0·2 HCl or HNO_3; 0·28 SO_2; 0·3 to 0·4 phosphoric, acetic, carbolic, formic, oxalic, or lactic; 0·476 tartaric, citric, and malic; 1·66 tannic; and 2·7 boric. One of the writers has shown that in infected waters, 0·035 p.c of H_2SO_4 kills typhosus in 30 minutes, that in terms of acidity nitro-hydrochloric was slightly more active, and that with tartaric and citric at least three times the amount of acidity was required (Epidemiological Society, Jan. 1901). But like other disinfectants, the activity of dilute acid solutions is considerably modified by the presence of added matters; for instance, in 1 p.c. peptone broth, *Sp. cholerœ* is killed by 0·01 p.c. hydrochloric acid in half an hour, but in 2 p.c. peptone broth, 0·04 p.c. HCl is required.

Paul, Kronig, and Sawey (Pharm. J. 1900) conclude that the germicidal activity of acids generally, depends upon the degree of ionisation in solution, exceptions being HF, HNO_3 and trichloracetic, which exercise specific toxic influences. In normal solutions, the three latter killed anthrax spores exposed on garnets in 24 hours, while H_2SO_4, HCl, HBr and $HClO_3$ were less active. Working with more dilute acid solutions, Winslow and Lochridge (Mass. Inst. Tech 1906) have compared the effect on *B. coli* and *typhosus* in tap water and in a 1 p.c. peptone water. With upwards of 10,000 organisms per c.c., sterilisation was obtained by the following percentages of each acid after 40 minutes' contact :—

	B. typhous		*B. coli*	
	Tap water	1 p.c. peptone water	Tap water	1 p.c. peptone water
Hydrochloric acid	0·018	0·174	0·045	0·368
Sulphuric ,,	0·022	0·188	0·081	0·530
Acetic ,,	—	—	0·561	0·836
Benzoic ,,	0·069	0·292	0·242	0·555

In agreement with the results of other workers, larger amounts of each acid are required to disinfect in the presence of peptone; with the organic acids, benzoic and acetic, this diminished activity is not so pronounced. Winslow and Lochridge find that the disinfectant power of the acids is not proportional to their strength in terms of normality, but, in the case of the mineral acids, hydrochloric and sulphuric, to the degree of ionisation of the solution, 99 to 100 p.c. reduction of *B. coli* or *typhosus* being effected with either acid at the same concentration of dissociated hydrogen. The evidence tends to show that the alteration in ionisation in a dilute acid solution brought about by the presence of otherwise inert substances in solution, as, for example, neutral salts of the acid, accounts for the variation in germicidal activity. In practical disinfection, the subject is often rendered still more complex by a further interference—the absorptive effect on solids in suspension. Therefore the acidity, as found by titration, does not give the germicidal value of an acid solution unless these disturbing factors are considered.

Metallic derivatives. Warm alkaline leys are the most ancient of disinfectants : potassium and sodium hydroxides are sterilisers in the proportion of not less than 2 to 5 p.c., their carbonates in 5 to 10 p.c. At 60° a contact of 5 minutes ensures the death of most organisms (Zeitsch. f. Hyg. 1903, 349), hence ordinary soaps have a slight disinfectant value. Strong brine is preservative, but not disinfectant, and the practice, formerly frequent, of washing out milk cans and other utensils with it, is not a safe one. Lode shows (Chem. Zentr. 1902, i. 1122) that 50 p.c. salt solution does not kill the spores of common moulds.

Lime, as quicklime, is fatal to bacteria when it comes in contact with them in an almost dry condition, and has been much used where there is a considerable space and bulk of material to be dealt with. It is not safe, however, to trust entirely to the old method of burying infected bodies in lime, as, on disinterring, the live spores may again be diffused, unless a long period has elapsed. The disinfecting power of milk of lime and whitewash has been much overrated ; as to milk of lime, Liborius stated (Zeitsch. f. Hyg. ii. 25) that in the proportion of 74 parts per million of CaO, it destroyed typhoid bacilli, and that 246 parts per million were required for cholera organisms, while 2 p.c. of dry lime was needed for cholera discharges ; with in each case ' a few hours' ' contact. When lime is added to sewage, a great number of bacteria are carried down, but are not killed, and the supernatant liquid is not sterilised. Dr. Houston (7th and 8th Reports of the Metropolitan Water Board, 1911 and 1912) found that 0·02 p.c. of quicklime effectively destroyed *B. coli* in raw Thames water in from 5 to 24 hours. *Zinc chloride,* ' Burnett's fluid,' formerly in high repute as a disinfectant, is not reliable in its effect, and ranks below copper sulphate and mercuric chloride. The sulphate has still less energy (R. W. coeff. 0·09).

Aluminium chloride, ' chloralum,' was classed by Miquel between zinc chloride and copper sulphate. *Iron salts,* especially ferrous sulphate, were at one time in vogue for sanitation, but are ineffective.

Permanganates and manganates were first introduced as Condy's red and green fluids. Like oxidisers generally, they are largely consumed by otherwise inert matters before attacking organisms, and as complete disinfection cannot be ensured unless an excess of reagent remains, evidenced by a pink colour, which is not always easily visible owing to the brown oxide of manganese produced, their use may be very costly and its execution frequently imperfect. The writer carried out experiments in street-watering of two similar areas of ordinary soiled asphalt roadway : (*a*) with water alone ; (*b*) with permanganate solution 1 in 5000 (six times the amount then customary), and examined the liquid from the surface. The permanganate was almost immediately decolourised. Sample (*b*) was nearly inodorous, on keeping became much less foul than (*a*), and the reduction in the number of organisms was 96 p.c., but the survivors included a large proportion of the dangerous forms (Rideal's Sewage, 1906, 117). For polluted water Rosenau recommends adding permanganate drop by drop till the pink colour

persists for 24 hours. ' Pinking ' of wells was many years ago adopted by Hankin in India as a precaution against cholera. Permanganates, used in various ways, are still being patented, chiefly for water purification.

Chromic acid, although a powerful oxidiser and instantly coagulating albumen, is excluded by its cost and poisonous and corrosive nature from the list of useful disinfectants or of preservatives.

Arsenic, like cyanogen, has more effect on higher than on lower forms of life, and is the basis of valuable insecticides, such as the sheep-dip solutions of arsenious oxide or sulphide in soda, frequently associated with tar products and nicotine. *See* Chemist and Druggist, June 11, 1904 ; Rep. Dept. Comm. B. of Agric., leading to the Sheep-Dip Act of 1903 ; and Quibell, J. Soc. Chem. Ind. 1907, 1266. The copper compounds, ' *Paris green* ' (aceto-arsenite) and others, are used for spraying or dusting trees, combining the actions of arsenic and copper Several organic arsenic compounds have been introduced as medicinal parasiticides (*see* Lancet, Brit. Med. J., &c., 1910 and onwards).

Arsenicals and similar organic metallic compounds are frequently selectively germicidal. Salvarsan, *p-p*-dihydrosia, *m-m*-diamino arsenobenzene has a strong antiseptic action on anthrax, erysipelas, and glanders, as well as syphilis. The selective action is more pronounced in serum (Zeitsch. f. Hyg. u. Infeht. Krankh. 1914, 77).

Among the more important arsenicals may be mentioned :—

Salvarsan.
Cacodylic acid and its salts
Atoxyl sodium aminophenylarsenate.
Asyphil mercury aminophenylarsenate.
Arrhenal methyl disodium arsenate.
Arsacetin *p*-acetyl aminophenyl sodium arsenate.
Soamin sodium arsanilate.
Neosalvarsan sodium 3·3-diamino-4 4'-dihydroxy arsenobenzene methanal sulphoxylate.

Some metals in the free state are antagonistic to germs. Dievert states (Compt. rend. 136, 707) that agitation with granulated zinc kills *B. typhosus* and *coli* in a few hours, and Baeyer's method of treating polluted waters with zinc-dust, charcoal, and lime causes, according to Margosches (Leipz. Monats. Textilind. 1901, vi.), practical sterilisation. Rankin (Proc. Roy. Soc. 1910, B, 82, 78) shows that clean strips of Al, Zn, or Cu, in air-free water, do not reduce the number of *coli*, whilst when air is bubbled through there is a great reduction after 1 hour. Except with Cu, peroxide of hydrogen was produced, but the amounts of this and of the metal dissolved were too small to account for the germicidal effect, which is ascribed to the metal and oxygen together. *Metallic iron* has long been used for purifying water, as in Anderson's process (J. Soc. Arts. Feb. 14, 1896) ; in this case, galvanic action and the oxides formed come largely into play, but Frankland proved that the metal itself was, to a certain extent, bactericidal. Old Hindoo writings direct water to be kept in vessels of *copper* ; among modern observers,

Nageli, Galeotti, and Israel and Klingman hold that there is formed a colloidal solution which renders the water toxic to many algæ and bacteria. In 1904 the U.S. Dept. of Agriculture reported that 1 sq. cm. of bright copper per 100 c.c. of water was sufficient to exterminate *Uroglena* and some forms of *Spirogyra*, and Kraemer showed that the same treatment destroyed colon and typhoid bacilli in 4 hours, whilst colloidal copper was quickly fatal to these organisms. For household purification, he commended the use of strips of copper, about $3\frac{1}{2}$ sq. inch to each quart (2 sq. cm. to 100 c.c.), immersed in the water for 6 to 8 hours. In a similar way, Rideal and Baines (J. San. Inst. 1904, 594) obtained sterilisation of *typhosus*, *coli*, and *S. py. aureus* in less than 24 hours. Bassett Smith (J. Prev. Med. July, 1904) found that in a bright copper vessel, *B. typhosus* was still living at 12 hours, but was dead at 24, and that of ordinary water organisms, 1020 per c.c. at first, only 8 per c.c (none of them liquefying) were left after 24 hours He concluded that clean iron or zinc was nearly equal to copper in first effect, but soon lost the power by oxidation.

Copper salts have a distinctly poisonous action on lower organisms, and are now used in many places to retard algæ development early in their seasonal growth in water reservoirs. Kroncke considered *cuprous chloride* to be the most active of the salts : he treated Elbe water, containing 40 to 50 thousand organisms per c.c., with 50 parts per million of Cu_2Cl_2 and 20 parts of ferrous sulphate, allowed 6 hours' contact, then agitated with 10 parts of lime. After settling and filtration through sand, the water was sterilised, clear, and colourless, and free from iron and copper. Schumberg (Chem. Zentr. 1900, ii. 203) corroborated the sterility at the end of 6 hours. The efficiency of soluble cupric salts is generally dependent on their percentage of copper (Green, Zeitsch. f. Hyg. 1893, 495 ; Rideal and Baines, l.c.), but the sulphate is commonly used as most convenient. For disinfecting sewage effluents (and inferentially for reservoirs), American investigations conclude that copper sulphate 'is not so efficient as chlorine compounds, is more seriously affected by carbonates, and is much more expensive' (U.S. Geol. Survey, Water Supply Paper 229, 1909, 32 ; also see Bull. U.S. Dept. of Agric. No. 100, 1906).

Disinfection of excreta and morbid products, even with considerable quantities of copper salts (e.g. 5 to 10 p.c. of the sulphate), is not reliable. For killing agricultural parasites, their use is well known, including that of the sulphate for soaking seeds and against potato blight, also verdigris (acetate), 'Paris green' (arsenite), copper-lime-sugar and copper-soap washes for trees, and 'Bordeaux mixture' (copper sulphate and lime). The last named was introduced in the former way, but has been since extended to other crops. In reference to the general practice of employing the metallic compound in the precipitated or solid form, instead of in solution, the main points stated are (1) that, in the former way, it is not liable to injure the plant or contaminate its tissues ; (2) that the copper should remain as an external coating, because the spores germinate on the surface ; (3) that uncertainty of composition

and inequality of application are overcome by certain precautions and definite prescriptions. See British Board of Agriculture leaflets 23 and 225 ; the latter (May, 1909) gives a method of preparing and using Bordeaux mixture : 'for a 3 p.c. solution, 3 lb. copper sulphate and 2 lb. freshly burnt quicklime to 10 gallons of water.' See also J. Soc. Chem. Ind. 1896, 332 ; 1907, 1291 ; Compt. rend. 1911, 152, 532. Chuard (ibid. 1910, 150, 839), estimating that 12,000 tons of copper are thus consumed annually in France, expresses anxiety as to the result of its accumulation in the surface soil, and with a view to reducing the quantity states that a half p.c. aqueous mixture of the oxychloride is as adhesive and effective as the usual 2 p.c. paste of the sulphate. Cupric sulphate impregnation for preserving or 'kyanising' timber has been superseded by creosote oils, since the former washed out of the wood. 'Microsol,' sold as a soluble disinfectant for stables and drains, contained 75 p.c. of copper sulphate with sulphocarbolate and some free sulphur dioxide.

Mercury.—Mercuric chloride, 'corrosive sublimate,' has long been recognised as one of the most powerful of disinfectants, and a 1 per 1000 solution was the earliest standard for comparisons. Apart from cost, points limiting its utility to special purposes are : (1) the poisonous effect on higher animals and plants ; (2) its precipitation by so large a number of substances, such as hard water, alkalis, and numerous salts, metals, sulphides, and many organic bodies, causing its action to be liable to great variations and inconveniences. It will often form a pellicle over organisms without killing them, and it is inapplicable to the disinfection of sputum, excreta, and the like, from its producing a coagulum which prevents further penetration. Sodium or ammonium chloride is sometimes added to increase the stability of the aqueous solution, but considerably diminishes the germicidal power. The Local Government Board recommended for disinfecting purposes : $HgCl_2 \frac{1}{2}$ oz., HCl 1 fluid oz., aniline blue 5 grs. (a colouring for safety), water 3 gallons (1 in 962).

Kronig and Paul in 1897 showed that mercury salts followed a general rule that the germicidal power depends on the metallic ion, and is in proportion to the degree of ionisation, so that a 1 in 500 solution of $HgCl_2$ is much less than twice as active as 1 in 1000 : moreover, the chloride is more active (in equivalent solutions) than the bromide, and 4 times more active than the cyanide, which is almost non-ionised. Solutions of the *oxycyanide* are used in surgery, are distinctly *alkaline*, and only slightly precipitate albumen ; a strength of 1 in 1500 is antiseptic, does not really attack instruments, and is not irritant. *Mercuric iodide*, dissolved in potassium iodide, is a powerful disinfectant, and is made up as 'iodic hydrarg.' It is less affected by albuminoids and less irritant than the chloride, and is incorporated in a disinfectant soap. *Mercury-zinc cyanide*, 'Lister's antiseptic,' has the disadvantage of being of variable composition. A great number of organic mercurial compounds, introduced into medicine and surgery, trace their main effect to an antiseptic or germicidal action. '$Sublamin,$' mercuric-ethylenediamine sulphate (43 p.c. Hg), is easily

soluble in water, is much less irritant than mercuric chloride, does not coagulate albuminous solutions nor precipitate soap, and is a valuable hand-disinfectant. 'Proteotyl' contains about 96 p.c. water, 1 p.c. salicylic acid, 0·2 p.c. mercury, and about 3 p.c. gelatin.

Sodium hydriodic mercurobenzoate was carefully investigated as a disinfectant by Schroller and Schranth (Zeitsch. f. Hyg. u. Infect. Kranh. 1911). They found that the germicidal powers could be enhanced by the introduction of halogens, methyl, methoid, or a second hydroidic mercury group into the nucleus, whilst a corresponding depression was caused by sulphonation or the introduction of an amino grouping, sodium oxymercury ortho-nitrophenolate. 'Mercurophen' is said to have a carbolic acid coefficient by the R.W. method of over 10,000, to be less toxic than mercuric chloride, and to exert less than one-quarter of the precipitating power which this salt has on blood serum (S. Schamberg, J. Amer. Med. Assoc. 1917).

Silver nitrate stands next to mercuric chloride in germicidal power, and has similar limitations in its use, with the additional one of being precipitated by chlorides. The writer found that 1 in 1000 killed *B. coli* and *S. py. aureus* in 24 hours, but a small quantity of chloride or organic matter prevented the effect. Among other silver salts are the citrate, 'Itrol,' recommended as a non-irritant antiseptic dusting for wounds (Pharm. Zentr. 38, 460); 'Actol,' the lactate, for antiseptic injections: 'Tachiol' silver fluoride, easily soluble, and a powerful non-toxic bactericide specially useful for the urinary tract (1 in 1000 to 1 in 5000 is suggested by Paterno and Cigolani for sterilising water in a concentration of 1 in 400,000. Chiefly with the object of avoiding irritant action, incompatibility with chlorides, and coagulation of albuminoids, a large number of organic preparations of silver have been introduced, such as 'argentamino' (ethylenediamine-silver-phosphate), and the proteid compounds 'argonine' (casein), 'argyrol' (gluten), 'largin' (albumen), and 'protargol' (protein). A report to the British Med. Assoc. in 1906 gives the time in minutes required to kill *S. py. aureus* by the preparations used as: silver nitrate (½ to 2 p.c.), 2 to 5; protargol (2 to 4 p.c.), 3 to 5; largin (10 p.c.), 2 to 5; argonine (5 p.c.), 3 to 6; whilst argyrol and 'collargol' (colloidal silver, J. Soc. Chem. Ind. 1903, 315) had very little bactericidal power (Lancet, 1907, i. 675). Many of these are destructive to gonococci and to ophthalmic disease organisms.

Osmic acid was found by Koch and Kleih to be powerfully bactericidal; it is very poisonous and a strong oxidiser. The former stated that an extremely dilute solution of *potassium auricyanide*, 1 part $Au(CN)_3$ in 2 millions, checked the growth of *B. tuberculosis*.

Chick and Martin (J. of Hyg. 1908, 634) observe that for spores, metallic salts rank highest as germicides; with mercuric chloride, the reduction of efficiency caused by blood srum is much greater than with phenol.

ORGANIC COMPOUNDS.

Compounds related to the alcohols. It has long been known that 'wood spirit,' crude

methyl alcohol, in a dilution as low as about 5 p.c., can kill insects and most micro-organisms, and preserve perishable organic materials owing to the tar products that it naturally contains. The alcohols, by themselves, are only efficient in a very much higher strength by coagulating albumen and (when absolute) by withdrawing water. Wirgin (Zeitsch. Hyg. 1904, 46, 149) has tested methyl, ethyl, butyl, and amyl alcohols with anthrax spores, and *S. py. aureus*, and concludes that the disinfecting power is low, that it increases with the molecular weight, and that there is scarcely any action on dry spores. It has been suggested to add alcohol vapour in steam disinfection, but Seige (Chem. Zentr. 1902, 1, 130) finds no advantage. Hand-disinfection with alcohol is not reliable (Goenner; Harrington, Boston M. J. May 21, 1903), although Hansen found that epidermal bacteria, *e.q.* eczema, are, when moist, destroyed in one minute by absolute, and in most cases by 50-60 p.c. alcohol (Centr. Bakt. 1907, 466). This statement is supported by A. Zabludowski (Deut. Med. Wochenschrift, 1911, 405), who advised the addition of 5 p.c. of tannic acid. Sterility of the hands could be obtained by 2 minutes' immersion. *Glycerol* in strong solutions (25 p.c. and upwards), is antiseptic, but in weaker ones it rather promotes the growth of bacteria. *Allyl isothiocyanate*, mustard oil, has figured in a number of patents, and is capable of killing many organisms, but not economically.

Formaldehyde is found in commerce as the 40 p.c. solution 'formalin' or 'formol'; it is antiseptic and germicidal, and is official in the German, Austrian, Belgian, United States, and Japanese pharmacopœias. Formalin, diluted 10 times, is used for embalming and for preserving bodies for dissection and museum specimens, but for antisepsis generally, a much weaker solution is efficient. The Board of Agriculture (Dec. 1906) found that fruit of all kinds immersed for 10 minutes in a solution of 3 pints formalin to 10 gallons water (=1¼ p.c. CH_2O), then allowed to drain and dry, keeps 10 to 21 days longer than when untreated; and that one lot of liquid can be used for a number of batches. S. Rideal and Dr. Foulerton have proved that 1 in 50,000 of formaldehyde (=1 in 20,000 of formalin) suffices to keep milk sweet for 24 hours, even in warm weather, without injury to health (Pub. Health, May, 1899; Lancet, 1899, 1427, 1571). Apparently because experiments with larger doses showed effects on nutrition, the British Dept. Committee on Preservatives, in 1901, recommended 'that the use of formaldehyde or formalin or preparations thereof in foods or drinks be absolutely prohibited.' And yet its agency in the preservation of food is as ancient as that of salt. The disinfectant and preservative power of wood-smoke is in part due to formaldehyde, which is present on the surface of smoked provisions,[1] and was found by Trillat in amounts varying from $\frac{1}{10000}$ to $\frac{1}{100000}$ of the weight of the substance consumed, in smoke from wood and cellulose. In tobacco smoke, he found 0·05 to 0·12 p.c., and in soot from house chimneys, 0·28 to 0·35 p.c.

[1] Petrier finds $\frac{1}{10000}$ to $\frac{1}{100000}$ in bacon, ham, sausages, and herrings; remarks that a strict regulation against formaldehyde would forbid these foods; and contends that a limit should be fixed instead of prohibition.

as paraformaldehyde. Typhoid and cholera organisms were killed by products from the combustion of 2 grams of sugar passed into a 12 litre vessel, and by burning 4 kilos. of sugar in a room of 100 cub. metres ' even very resistant organisms were destroyed.' (Rouguier has made this the basis of Fr. Pat. 360476, 1905.) With straw, the best results were obtained by burning it in a heap of alternate dry and wet layers : using 18 kilos. of straw in a room of 140 cub. metres (4944 cub. feet), *B. coli* and *diphtheriæ* were destroyed after contact with the smoke for 12 hours ; the room temperature rose to 35°, and up to 2 grams of formaldehyde were generated per kilo. of straw (Compt. rend. 138, 1613 ; 139, 742 ; 140, 797 ; 141, 215 ; 150, 339).

H. Will (Zeitsch. Brauw. 1905, 28, 330, 347) gives formalin a very high place among brewery disinfectants. He notices, like other observers (Kingzett, Slater and Rideal, Lancet, April 21, 1894), that it is more powerful against bacteria than against yeasts and mould fungi. Limits recorded as preventing development are : sarcinæ and bacteria, 0·003 to 0·031 p.c ; yeasts, 0·007 to 0·062 p.c. ; moulds, 0·031 to 0·125 p.c.

Advantages in formaldehyde disinfection are : (1) that it can be easily applied in the state of gas or vapour for fumigation ; in the liquid condition as spray, wash, dipping, or in higher dilutions as an antiseptic, or in the solid form as its polymers, compounds, or mixtures ; (2) that unlike mercuric chloride and many other agents, it is not thrown out of action by albuminous matter or by most chemicals ; (3) that it is effective in strengths which are not irritant or poisonous, and does not injure fabrics or metals. At quarantine stations, large quantities of bulbs, roots, nuts, fruits, &c., coming from plague or cholera-infected regions are disinfected by immersion in a 5 p.c. solution of formalin, which does not injure the food value and much retards decay. In the Linley process, meat is treated with formaldehyde vapour, ' 1 oz. formalin per cub. foot of space in the chamber,' the gas after a time removed by a fan, and the meat frozen for shipment. Buchanan and Schryver (L.G.B. Food Report, No. 9) state that the gas commonly penetrates for about 20 mm. under a thin layer of connective tissue, that the amount absorbed often reaches 1 in 3500, that it is reduced or removed by boiling or roasting, but that grilling seems to make it penetrate further.

In surgery, formaldehyde and its preparations have been of wide service. Amongst the more important may be mentioned the following formaldehyde and formaldehyde ammonia (hexamethylene tetramine) compounds :—

	With formaldehyde	With hexamethylene tetramine
Inorganic compounds	Glyceroborate or boroform	Triborate or borovertin
	Aluminium silicate or dreiaform	Dichromate or chromoform
		Acid phosphate or hexanitrine
Aliphatic derivatives	Iodoform or eteaiodoform	Dibromodiiodo chrysoform
	Acetamide or formicin	Sodium acetate or cystopurin
		Iodoform iodoformin

	With formaldehyde	With hexamethylene tetramine
Aromatic derivatives	Phenol Resorcinol Guaiacol Thymol Cresols and potash or tysoform Tar and pitch	Resorcinol Guaiacol Salicylates Salicyl-sulphonates
Carbohydrates	Lactose Dextrin Milk sugars	Milk sugar
Miscellaneous	Starches Casein Gelatin Terpenes Tannins	Silver albumin Camphorate Tannins

Geronzi found that the addition of 5 p.c. of sodium carbonate to the 5 p.c. formalin which he successfully used for obstinate ear disease increased the tolerance and enhanced the germicidal power (Arch. Ital. di Otologia, 1903).

Formaldehyde antiseptic powders for dressing are ' Amyloform ' (starch) ; ' Proteol ' (casein) ; ' Steriform ' and ' Sterisol ' (lactose) ; ' Glutol ' (gelatin). These, especially the last, when moistened as in a wound, slowly regenerate formaldehyde. Formalised gelatine is now largely used with success instead of surgical collodions. *Formamint tablets*, ' for infectious diseases and as a prophylactic,' are said to contain 0·01 gram of CH_2O in each, combined with milk sugar (Eng. Pat. 2672, 1906 ; Pharm. J. 1907, ii 838). M. Jones states that with *B. diphtheriæ* the R.W. coefficient is only 0·01 as against 0·30 for cyllin pastiles.

Paraform, paraformaldehyde, trioxymethylene, or ' triformal,' is a solid polymer, only slightly soluble in cold water, and dissociated into CH_2O gas on heating. It was introduced as an internal antiseptic and for disinfecting instruments, and said to be as active as β-naphthol, but its chief use is for evolving formaldehyde either alone or in mixture, for which a large number of methods have been proposed, many of them patented. Mixtures with Na, Ba, or Sr peroxide, when brought into contact with water, yield formaldehyde and hydrogen peroxide : it is stated that ' Autan ' contains 1 part of paraform to 2 of BaO_2 (Lancet, 1908, i. 139), and that 50 grams mixed with water kills all organisms in a cubic metre of air bubbled through it (Fr. Pat. 366605, 1906).

Room disinfection with formaldehyde cannot be economically effected by simply evaporating the solution ; under ordinary circumstances, only a portion of the substance is volatilised, the remainder polymerising and remaining behind as a solid, while reliable disinfection requires a definite large volume of gas to be produced in a short time. For this object, very numerous methods and apparatus have been devised, which may be grouped as follows:—

A. Direct production of CH_2O gas, by passing methyl alcohol vapour and air over hot surfaces of platinum (Hofmann) or partly oxidised copper (Loew). The various lamps on this principle have had the faults, among others, that the oxidation is incomplete and inconstant. Kenwood found that 1½ litres of methyl alcohol were required to disinfect a room of 2000 cub. feet.

B. Heating the solution (formalin) under pressure was used by Trillat, calcium chloride being added to raise the boiling-point. In his *autoclave*, 1 lb formalin was required for 1500 cub. feet. By this method, Kenwood obtained sterilisation of diphtheria swabs, and S. Rideal with various articles infected with *B. typhosus*, *diphtheriæ, coli*, *S. py. aureus*, and anthrax spores, found that in 24 hours all were sterilised, whilst fabrics, furniture, metals, and leather were not injured. (*See also* J. R. San Inst 1903, 508.)

C. Formalin, mixed with glycerol, is distilled at nearly the ordinary pressure, as in the Trenner-Lee, Lentz, and Lingner apparatus. The latter, according to the Russian National Health Society's Journ. 1900, was mainly instrumental in extinguishing the plague at Astrachan, in 1899. Klein (report of 1902), by 3 hours' exposure in a sealed room with the Lingner generator, sterilised anthrax spores and tubercular sputum. Houston and Newman also report favourably (Practitioner, Sept. 1902)

An important point to notice is that in method (B), the CH_2O is chiefly liberated at the beginning of the operation, in (C) at the end, mixed in the latter case with steam and glycerol spray, which deposits as a film on the surfaces, and assists in the penetration and disinfectant action.

D. Formaldehyde has also been used in conjunction with acetone (Eng. Pat. 10398, 1908), SO_2 (Fr. Pat. 379998, 1906), alcohol, and some fatty acids.

E. Evolution by mixing with other chemicals. Dehydrating agents disengage very little CH_2O gas from formalin, since most of it polymerises. With quicklime, S. Rideal has only obtained 8 p.c. of the theoretical yield (*cf.* Eng. Pat. 8259, 1899; Fr. Pat. 323041, 1902; and U.S. Pat. 790468, 1905). Carteret observes (Compt. rend. 1908, 146, 819) that 1 part formaldehyde and 2 parts bleaching powder added to 3 parts water evolve 70 p.c. of the theoretical yield (D. R. P. 217204 of 1908). Potassium permanganate behaves similarly, generating great heat; U.S. Pat. 885223 relates to a mixture of this kind. Major Munson (Trans. Inter. Congress Hygiene, Washington, 1913, 756) has obtained 86 p.c. of the formalin vaporised, and S. Rideal (Blackpool Congress, 1914) used a paper bag for sterilising clothes, using 40 grams permanganate to 100 c.c. formalin. The action of peroxides has been already mentioned.

F. The simplest process is heating paraform by a small flame (avoiding ignition), when it melts and is resolved into CH_2O. The 'Alformant,' or Schering lamp, uses 1-gram tablets placed in a perforated cup, and it is directed to use 10 tablets per 1000 cub. feet with 6 hours' exposure. S. Rideal found that this quantity killed *B. coli, typhosus, diphtheriæ*, and *S. py. aureus* in 20-24 hours, and that double the quantity in the same time killed *moist*, but not always *dry* anthrax spores. He recommended spraying with $\frac{1}{2}$ p.c. solution of formalin before using the lamp, as the gas is evolved with insufficient moisture. The latter defect is remedied in the 'hydroformant' lamp, in which 12 ozs. of water in an annular vessel is simultaneously evaporated. Rosenau considers this method of generating CH_2O useful for the disinfection of closets and small enclosures of

less than 100 cub. feet, with not less than 12 and preferably 24 hours' exposure, and not less than 2 ozs. of paraform per 100 cub. feet (about 2 grams per cub. metre). Klein, Houston, and Gordon (London County Council, 1902) record that with 23 grams of paraform per 1000 cub. feet, *B. typhosus, diphtheriæ, pyocyaneus*, and *S. py. aureus* were killed in 5 hours, but not anthrax spores nor (with certainty) *tuberculosis* in sputum. It will be noticed that the time is not even that given in the directions issued with the lamp, and the humidity and temperature of the room are not stated. Allan, Newman, and Cribb had previously obtained generally satisfactory results with 10 grams paraform per 1000 cub. feet, under moist conditions (Brit. Med. J. Aug. 13, 1898). Kenwood's experiments pointed to an average of 25 grams per 1000 cub. feet being necessary. Werner and Bonhoff (Berl. Klin. Woch. 1904) find that tubercular sputum is certainly disinfected by 5 grams per cub. metre (141 grams per 1000 cub. feet) acting for 7 hours, which is double the quantity Flugge first recommended. In Breslau a large number of formaldehyde disinfections are carried out for scarlet fever and measles, and the disease has in no case recurred in the same room.

Spraying with the solution should be the invariable practice except with the large CH_2O generators, which are capable of filling the room also with steam and spray. When spraying is used alone, there is a danger of not penetrating into crevices, and the solution must be of higher strength; Dr Mackenzie's extensive experience in the disinfection of houses and hospital wards, proved that 1 p.c. CH_2O (4 ozs. formalin per gallon) is attended with success; he adds 5 ozs. glycerol per gallon of formalin to prevent too-rapid drying. Thresh and Sowden in 3 to 4 hours sterilised *diphtheria, typhosus, cholera, pyoq. aureus*, and *prodigiosus* with $\frac{1}{2}$ p.c. CH_2O, but *pyocyaneus* (on whitewash) only with 2 p.c.; they, therefore, recommend the latter strength.

Where the space has to be occupied soon afterwards, any residual formaldehyde can be neutralised by volatilising ammonia. The product, under the name of *Urotropine*, is a serviceable antiseptic in cystic affections, and is administered to typhoid 'carriers' to destroy the bacilli of the disease in the urine. Urotropine is the basis of a large number of antiseptic preparations (*see* above).

Disinfection of excreta is attained by mixing with 3 to 5 p.c. of formalin and keeping in a closed vessel for at least an hour. Rosenau states that faeces are rendered sterile at the end of 10 minutes by an equal volume of a 4 p.c. solution of formalin. Houston prescribes 1 to 2 pints (according to bulk) of 5 p.c. formalin, acting for at least an hour (Practitioner, Sept. 1902).

Formaldehyde, as an insecticide, is much inferior to SO_2, although Brough (J. Mass. B. of H. March, 1898, 51) observed, in his disinfections with the former gas, that all the flies were invariably killed, and generally the bed-bugs. It is an excellent deodorant.

No acidity is produced by continuous spraying or distillation of formaldehyde, therefore it is not readily converted into formic acid in this way.

Formic acid.—We have discussed the germi-cidal action of acids generally in an earlier section of this article. Formic acid has this power to a considerable extent, and is a strong antiseptic. Kitasato's results, as summarised by Horrocks, gave acetic acid a slightly higher activity in nutrient media, stating that with *B. typhosus* the amounts p.c. in cases of (1) growth, (2) growth restrained, (3) no growth, were respectively : formic acid, 0·22, 0 278, and 0·356 ; acetic acid, 0·2, 0·225, and 0 3 ; with *Sp. choleræ*, formic, 0·11, 0 167, 0·22 ; acetic, 0·1, 0·153, 0·2. But very different results are ob-tained in water and most organic solutions The writer has found that *typhosus* is killed by 0 5 p.c. of formic acid in less than 15 minutes, and by 0·1 p.c. in about 30 minutes ; and in 1907 he made the R.W. typhosus coefficient of formic acid many times higher than that of acetic. He also found the preservative action to be higher : with vegetable substances, 1 p.c. of formic acid was equal in effect to 5 p.c. of acetic (time of trial, 2 months). Raw fish were mounted in 0·53 p.c. formic, in 5 p.c. acetic, and in 0 3 p c boric, acids, heated for 20 minutes to 80°, and the jar closed with cotton wool ; in a week, the last was brownish, disintegrated, and uneatable, though not distinctly putrid ; while the first two kept sweet and of natural characters for 3 months. Experiments with bread-pulp infected with a mixed mould-growth proved that 0 1 p.c. of formic acid entirely inhibits the growth for several days, even under the most favour-able conditions of culture. But in the de-struction of the spores, formic acid is less effective than formaldehyde. Lebbin (Chem. Zeit. 1906, 30, 1009) effectively preserved different classes of foods by 0 15 p c of formic acid, and others have proved that in the quan-tities mentioned above it is physiologically harmless ; the taste is more pleasant than acetic acid, and the odour is not noticeable. B. H. Smith (J. Amer. Chem. Soc 1907, 1236) preserved vegetables with formic, with salicylic and with benzoic acid, in unprotected jars. Under conditions in which the untreated samples became sour and mouldy in 2 days, 0·1 p c. formic acid preserved them for 7 days, 0·3 p.c. for 12 to 18 days, 0·5 p.c. for 25 days, 0 7 p.c and 1 p.c. for 45 to over 85 days, and 2 p c. for over 85 days. He states that 0·1 p c of benzoic acid kept his sample for 85 days, whilst with the same quantity of salicylic acid it was sour in 9 days. In ordinary preserving practice, as we have seen, the articles would have remained good for the longer time with the smaller quan-tities of formic acid, which, even if it must be applied in a somewhat higher proportion, is from physiological and physical reasons pre-ferable to salicylic or benzoic. The chief formic acid preservatives used in commerce, mainly for fruit preparations, are 'Werderol' and 'Fructol' (10–14 p.c. formic acid, '1–1½ p.c. of the liquid to be added'); and 'Alacet' (made synthetically from CO and NaOH at the Nitritfabrik, Köpenick, about 50 to 60 p.c. formic acid, 'use 0·3 p.c. of the liquid'). The result in the three cases would be about 0·14–0·18 p.c. of the acid. In an investigation of these articles by Croner and Seligmann (Zeitsch. f. Hyg. 1907, 56, 387), they find that inhibition of moulds, yeasts, and acid-forming organisms

begins at 0·15 p.c. formic acid, that sterilisation is effected in 24 hours by 0·2 p.c., and in 10 to 30 minutes by 1 p.c.

Only the free acid is active against organisms, although the salts do not favour the growths as do the alkaline acetates. Sodium formate helps the solubility of many antiseptics without lessening their power, therefore figures as an adjunct in a number of patents.

Acetic acid is one of the most anciently used of preservatives ; 'aromatic vinegar,' a more or less concentrated acid containing essential oils, had a partially-justified reputation against in-fection. The writers find that *B. coli* is killed by 5 p.c. HA in 5 minutes, by 2·5 p.c. in 15 minutes, while with 0·5 and 0·1 p.c. it is alive after 40 minutes. *Pyroligneous acid*, or crude wood vinegar, owes its antiseptic power chiefly to the presence of creosote and formaldehyde.

Acetyl peroxide and benzoyl-acetyl peroxide are stated by Freer and Novy (Amer. Chem. J. 1902, 27, [3] 161) to be strongly germicidal, since solutions corresponding to 0·037–0 074 p.c. of the former, or 0 056–0·112 p.c. of the latter, =0·005–0·01 p.c. of active oxygen, destroyed within a minute all known disease-producing bacteria, and even spores of *B. mesentericus*, which are not killed by 5 p.c. phenol ; whilst H_2O_2 solution containing 0·05 p.c. of active O was without action on many bacteria even in 60 minutes. Benzoyl peroxide had no oxidising action, and was without effect on bacteria. A solution of acetyl peroxide was introduced under the name 'acetozone,' but the title is now applied to a more convenient and stable mixture of the benzoyl-acetyl compound with infusorial earth, said to be useful in typhoid, dysentery, and cholera (Lancet, 1904, ii. 1160 ; Brit. Med. J. 1907, i. 634).

Propionic acid has been tested comparatively by Duggan (Amer. Chem. J. 7, 62) with the highly resistant *B subtilis*. He gives as the strengths necessary for killing : formic acid, 7 p.c. ; acetic acid, 9 p c. ; propionic acid, 12 p c. (numbers proportional to the molecular weights). According to A. C. Jordan (Prac-titioner, Sept. 1902, 297), 0·1 p c. of *butyric acid* in broth tubes infected with vigorous *B. coli* or *typhosus* caused them to remain sterile ; *S. pyog. aureus* required 0 2 p c. *Valeric acid* is a feeble antiseptic, but has been introduced along with a little creosote, as an internal antiseptic called 'geosote.'

Oleic acid, the fats, 'Lanolin,' &c., have but slight antiseptic power in themselves, but when applied to the skin may prevent infection by the exclusion of germs. Reichenbach (Zeitsch. f. Hyg. u. Infect. 1908, 59, 296) showed that the alkali salts of the palmitates had the strongest bactericidal action of the soaps investigated. The potassium salts of the saturated fatty acids are comparatively strong bactericides, but those of the unsaturated acids, with the exception of elaidic, are not. Vicario, however, observed that the fatty matters some-times already contain germs, and Baldas (Giorn. R S. Ital. d' Igiene, Feb. 1901) proved that *B. coli* and *typhosus*, *S. pyog. aureus* and *albus*, retained their virulence in oils for 2 months ; therefore ointment bases require to be sterilised by heating to 100°, or preferably to 120°, as various bacilli survive in oil far

longer than in aqueous solution. In fatty media antiseptics and disinfectants, as a rule, are much less active than in water, hence the ineffectiveness of carbolised oil as shown by Koch and Breslauer. Lanoline and cold cream contain water, so can enable agents in aqueous solution to come in contact with micro-organisms Some metallic oleates are parasiticide : cupric oleate in ringworm and favus (Lancet, 1907, i. 510) ; mercuric oleate for pediculi ; zinc oleate is said to cure chronic eczema.

Vegetable acids have the general power of inhibiting bacteria which prefer a neutral to an acid medium, but their effect is much less than that of mineral acids, and their solutions quickly become mouldy in warm weather. Citric acid was formerly recommended for sterilising water : Dr. Christmas in 1892 stated that cholera organisms were killed by 0·08 p.c. and typhoid by 0·10 p.c. Kitasato's figures for tartaric, citric, and malic acids added to neutral media containing *typhosus* are in p.c.'s : growth, 0·338 ; growth restrained, 0·384 ; no growth, 0·476. Succinic acid is slightly antiseptic. ' Alphogen ' or ' Alphozone,' succinyl peroxide, is said to be a powerful germicide (Lancet, 1905, i. 367).

Aromatic acids.—The introduction of —COOH groups or aliphatic acid radicals into the benzene ring yields acids of relatively low antiseptic power, increasing with the molecular weight of the entering acid.

Benzoic acid is strongly antiseptic in solution and vapour, and to a rather less degree in its soluble salts. It dissolves in about 400 parts of cold water, and the saturated solution kills *B. typhosus* in a few minutes. When molecular proportions, *i.e.* sodium benzoate 0·026 p.c., potassium benzoate 0·029 p.c., benzoic acid 0·022 p.c., are separately mixed with milk, the writer observes that all retard the souring, the acid more than its salts, but the effect comes to an end sooner than with inorganic salts like the fluorides, since benzoic acid is itself decomposed by some organisms (Analyst, 1907, 32). Not being poisonous, it has been much used as a food preservative, particularly in countries where salicylic acid was forbidden. Following a report of the Referee Board of the U.S. Board of Agric. that doses of benzoates under 0·5 gram per day were not injurious to health, and that even 4 grams per day did not act as a poison, the U.S. Board, in Pamphlet 104, 1909, have announced that they will make no objection to the use of sodium benzoate in food, provided it is plainly labelled on each package, both as to presence and quantity. The taste and odour are difficult to mask. It has long been used as an antiseptic in surgery, *e.g.* in ' Friar's Balsam ' (tinct. benzoini co). *Benzoic aldehyde* is official in the U.S. Pharmacopœia, and in the form of commercial oil of bitter almonds owes its parasiticide power in ointments mainly to the hydrocyanic acid it contains, which, of course, necessitates care in use. *Benzoyl-sulphonic-imide*, ' Saccharin ', or ' Gluside,' has some preservative power, and has been given internally to stop decomposition of urine in cystitis, but its use for sweetening is less on account of this power than because it is itself unfermentable.

Salicylic acid.—The saturated aqueous solu-

tion contains 1 in 500 : tested with *typhosus*, *pyog.*, *aureus*, and *anthrax*, Westcott found that in 3 hours only the former was killed. As a food preservative, it is about equal to benzoic, their relative activities varying under different circumstances. Its physiological effect is more distinct than that of boric or formic acid or formaldehyde in the small quantities required, but there is no clear evidence that it causes injury to adults if the amount is limited. The British Depart. Committee's suggested restriction is that it ' be not used in a greater proportion than 1 grain per pint in liquid food and 1 grain per lb. in solid food,' or 0·0114 and 0·014 p.c. respectively, which practically would amount to a prohibition, since moulds and ferments are only reliably inhibited by 0·1 p.c., the amount commonly employed, though often exceeded. Addition of the acid to foods is forbidden in France, Austria, and some other countries. Traces are present in a large number of fruits (Analyst, 1903, 149). Dr. Linga G. Anderson used extensively a saline gelatined salicylic acid paste containing 2 p c of the acid as a wound dressing with satisfactory results. Compounded with an equal weight of boric acid it is also used as a first dressing under the name of Borsul. ' Salol ' is phenyl salicylate, an internal antiseptic which is decomposed in the duodenum into phenol and salicylic acid. According to Lowenthal, when mixed with pancreatic juice, it rapidly kills *Sp. choleræ* (Compt. rend. 107, 1169). ' Salophen,' *p*-aminophenyl acetyl salicylate, is said to have a rather stronger antiseptic power (Practitioner, March, 1907). A large number of derivatives of salicylic acid have been introduced, and many of them patented.

Cinnamic acid, at 2 p.c., prevents the growth of bacteria, and at 4 p.c. destroys them. It is contained in Peru and storax balsams, which are parasiticide in skin diseases. Fr. Pat. 371091 preserves butter by enclosing it in a wrapper impregnated with cinnamic acid, which ' prevents butyric fermentation.' *Acetyl-o-coumaric acid*, ' Tylmarin,' is another internal antiseptic, said to have a R.W. coefficient of 4·5. The use of halogen substituted hydrosic acids, especially 6-chlor-3-hydroxy-*p*-toluic acid, has been suggested for disinfectant purposes (J. Soc. Chem. Ind. 1914, 33, 807).

Tannin is antiseptic to proteids through its property of forming with them insoluble compounds such as leather, but none of the tannin extracts have even the power to preserve their own solutions.

Phenols and phenoloids. The introduction of aliphatic side chains into the nucleus of phenol raises the germicidal activity ; the *o-* and *p-* positions for the entering groups have a greater influence than the *m*. Morgan and Cooper found the following C.A. coefficients for three cresols, *o*=2·1, *p*=2·4, *m*=2·0. Whilst trimethol trimethyl methoxy phenol is said to have a R.W. coefficient of 40 when properly emulsified.

For general purposes of disinfection, ' coaltar ' fluids, having as their chief active constituents bodies allied to phenols, are most extensively employed. They are usually dark syrupy liquids smelling of coal tar, and may be roughly divided into two classes : (1) those

which on the addition of water form a more or less clear dilution; and (2) preparations miscible with water but producing an emulsion. The former usually consist of saponified tar-acids: the *liquor cresoli saponatus*, Ph. G., consisting of equal parts of potash soap and crude cresol heated together, is of this nature. In the manufacture of these fluids, potash soap, glycerol, alcohol, and other agents are employed to aid the solubility in water. With the second group, the mostly insoluble, active ingredients are emulsified by the aid of soda, soaps, resin, neutral oils, or gelatin.

Polyhydric phenols and naphthols. The antiseptic powers of the di- and trihydroxybenzenes are less than those of phenol.

Resorcinol, m-dihydroxybenzene, is a powerful medicinal antiseptic, and a 1 p.c. solution kills most organisms. Andeer's lotion' contains 40 grains in 1 oz. water. 'Anusol' is a bismuth iodo-resorcin sulphonate. *Quinol* or hydroquinone, *p*-dihydroxybenzene, is said to be a stronger antiseptic than the last, and has been suggested for typhoid in doses of 3 to 8 grains. The ortho- compound, *catechol* or pyrocatechin, is also antiseptic. Duggan finds (Amer. Chem. J. 7, 62) that the amounts of the three isomerides required for preventing development of *B. subtilis* in broth are: ortho- 20, meta- 25, para- 30; phenol being 20 and pyrogallol 15. Morgan and Cooper (8th Int. Cong. App. Chem. 1912, viii. cl.) give the following figures for the carbolic acid coefficients: ortho- =0·48, meta- =0·29, para- =1·1.

Pyrogallol, tri-hydroxybenzene, is antiseptic, and a 3 p.c. solution kills most bacteria, particularly aerobes, but it stains, is unstable, and very poisonous.

Guaiacol (methyl-catechol) and *creosol* (methyl-guaiacol) are the active ingredients in wood creosotes, and have been widely useful as antiseptics and parasiticides, especially in tuberculosis. Guaiacol has an antiseptic power (but not bactericidal—*see* Table) 2½ times that of phenol, and a ½ to 1 p.c. solution destroys *B. tuberculosis* in 2 hours (Marfori, Ann. di Chim. 12, 3). A one in 150 solution of (Morson's) creosote kills *pyog. aureus* and *typhosus* in 3 hours (Westcott). 'Little's Soluble Phenyle' contains wood creosote, and Corfield's experiments give it a high value for wounds and against vermin. Kenwood and Hewlett (J. R. San. Inst. 1906, 13) make its R.W. coefficient 1·2.

Beta-naphthol is official in the British (1898) and in a number of other Pharmacopœias, the dose in the former being 3 to 10 grains in a cachet for internal antisepsis, especially in typhoid and in cholera as a preventative. Its solubility in water is increased by boric acid. Schneider observes that naphthols dissolved in alkaline carbonates have greater disinfectant power than alkaline naphtholates; the former solutions contain naphthol in the free state. He states that staphylococci and typhoid are killed in a short time by 0·5 to 1·0 p.c. of β-naphthol alkaline carbonate solution (Zeitsch. Hyg. 1906, 52, 534).

Ointments containing 10 to 15 p.c. are efficient in scabies and psoriasis. 'Betol,' β-naphthol salicylate, is less soluble than naphthol, and is now seldom used. 'Alphol' is its analogue from α-naphthol, and is very similar.

A number of easily soluble compounds have been introduced, such as the β-naphthol sulphonates, 'Asaprol' or 'Abrastol' (calcium), and 'Alumnol' (aluminium). Helbing states that an aqueous solution of the latter, 1 in 250, prevents all growth of gonococci, pus cocci, and allied bacteria. Bechold (Zeitsch. angew. Chem. 1909, xxii. 2033) finds the odourless and non-poisonous halogen-substituted naphthols more powerful than any disinfectant except HgCl₂, and that tribromonaphthol kills staphylococci in dilutions of 1 in 250,000.

Dihydroxynaphthalene. The 2·3- substituted compound has a relatively high germicidal activity, with a C.A. coefficient of 4·4. The 2·7- derivative has a coefficient of 2·8.

Amidobenzene derivatives. The introduction of $-NH_2$ groups into the ring produces substitutes of low germicidal activity.

Aniline is open to the same objection as the nitro- derivatives; it has a carbolic acid coefficient of 0·57, whilst *o*-toluidine, the next homologue, has a coefficient of 1·00, and *m*-toluidine one of 1·30.

The dyestuffs. A number of aniline dyes are germicidal, owing to their power of penetrating and combining with living tissue. This action is very variable, but it is stated that 1 p.c. prevents development of organisms, whilst 1 in 500 to 4000 retards their growth.

The investigation of the parasiticidal powers of the dyestuffs was conducted by Ehrlich and his pupils in their search for compounds containing strongly developed parasitotropic groupings, but only with feeble organotropic groupings. It was found that tetrazo colours derived from naphthalene-3·6-disulphonic acid, basic dyes of the triphenylmethane series, and certain azocolours were equally effective. Symmetrical colours were found to be less organotropic than unsymmetrical ones.

Methyl violet or 'pyoktanin,' gentian violet, certain auramines, safranine, methylene and toluidine blue have been used in surgery and in malaria. Malachite green, injected into the blood, kills *trypanosoma* in 48 hours (Birt. Med. J. 1904, ii. 1449, 1645; Deutsche Med. Woch. Leipzig, 1906, 21, 463). Methylene blue, with atropine and benzoic acid, according to Lclean (Lancet, May 3, 1902), was the only drug he found of use against *Bilharzia.*

Derivatives of acridine, especially acriflavine-3·6-diamino-10-methyl acridinium sulphate and proflavine-3·6-diamino acridine sulphate, have been shown to be somewhat superior to malachite green when used for wound dressing. Originally prepared for Ehrlich, their selective action on bacteria was first tested at the Middlesex Hospital, London. For wound dressing, the derivatives are made up as soaps, gelatine, or starch mucilages.

Linked benzene derivatives. Both the chemical constitutions and the germicidal activities of the higher boiling tar acid fractions are as yet unknown. The direct linkage of two phenoloid groupings or linkage through $=CH_2$, $=CHOH$, $=CHOX$ where X is an aliphatic group, in some cases elevates the germicidal powers. Linkages through $=CO$ or $=SO_2$ groupings is said to depress the coefficient.

Aromatic nitro- and *halogen substituted compounds,* such as nitro-benzene, have often been

proposed as disinfectants, but are precluded by their odours, poisonous action, and sparing solubility. Trinitrophenol, ' picric acid,' is rapidly fatal in saturated solution (about 1 p.c.) to bacteria and spores, but causes yellow stains, is irritant and very poisonous. Cotton wool, soaked in the solution, is used very successfully in the aseptic treatment of burns ; hence it is recommended by H.M. Inspector of Explosives to keep handy for this purpose. The R.W. coefficient is about 6. Potassium dinitro-ortho-cresol, ' Antinonnin,' 1 in 400, is destructive to all common injurious parasites, and does not injure plants.

Trichlorphenol has been used at Petrograd as a disinfectant. It is said to be 25 times stronger than carbolic acid.

Hydrocarbons.—Petroleum, mainly consisting of hydrocarbons of the paraffin series, has long been a well-known insecticide, and is mentioned by Marco Polo in the 13th century as used to kill acari in mange.

For protecting burns and wounds from exposure, various substitutes for ' ambrine,' consisting essentially of paraffin wax or asphalt with a fatty oil have been suggested (B.M.J. 1917, 789).

A. J. Hull introduces into these burn dressings ' scarlet red,' ' brilliant green,' ' flavine,' and dichloramine-T on account of their antiseptic action.

Naphthalene is feebly antiseptic, but is not a disinfectant It is useful by its odour to drive away domestic insects.

It has been stated that articles are disinfected by dry-cleaning with petroleum benzine, or by benzene. Farrel and Howles (J. Soc. Dyers, 1908, 24, 109, 166), however, find that acting on infected threads for 6½ hours, neither benzene (C_6H_6) nor petroleum-benzine killed *typhosus*, whereas carbon tetrachloride killed it in 30 minutes, whilst ' benzine soap,' dissolved in benzine, has no germicidal power.

Ether is used for sterilising catgut.

Essential oils and **camphors**. Perfumes, chiefly composed of terpenes and their oxidised products (*e.g.* the camphors, menthol, thymol, and eucalyptol), have a limited sanitary value. All of them are very sparingly soluble in water, but impart to it a more or less antiseptic effect Early estimates of their power have not been concordant, chiefly owing to their having been tried variously in aqueous or alcoholic solution, or in suspension. A saturated solution of *thymol* in water (0·3 p.c.) arrests fermentation and putrefaction. Peppermint (containing *menthol* and menthane) has had a high reputation, and a number of recipes for ' plague water,' have it as a basis. The use of hops in brewing partly rests on the power of the essential oil to check fermentation. ' Terebene,' made by the action of H_2SO_4 on terpentine, was once reputed as a disinfectant, but now hardly figures except as terebene soap. Among other artificial products from turpentine are *terpin hydrate* (said by Colpi to arrest the growth of tubercle bacilli in 0·25 p.c. strength), and *terpineol* (anthrax's is stated to be killed by 1 p.c., and staphylococci by 10 p.c. in 60 minutes : (H. Marx, *v. infra* ; *also* D. R. P. 207576, 1908)).

Camphor is much spoken of as a personal prophylactic, but there cannot be sufficient of

the vapour to sterilise the air. It is an ingredient in many remedies for cholera and diarrhœa, and in several ' block disinfectants ' such as ' Sanoscent,' ' Camphortar, &c. *Eucalyptus globulus* and other species which have long been famous as antimalarial, are largely planted on the Continent in marshy districts. The essential oil is decidedly germicidal, having a carbolic acid coefficient of 1·2, and has been given with some success in typhoid, and also against tape- and threadworm.

Pinol is a liquid of similar character from *Pinus pumilo*. H. Marx has investigated the action of various perfumes on anthrax and *S. pyog. aureus* (Centr. Bakt. 1903, [1] 33, 74). Kobert (Chem. Zentr. 1907, 1. 419) finds that the terpenes have, by themselves, in general only a weak antiseptic action. The proportions needed for sterilising exceed the solubility in water, and can only be reached by a spirituous solution or an emulsion.

But it has been recognised, since Schönbein pointed out the fact about 1840, that essential oils have a disinfectant power conferred on them by their slow oxidation in the presence of air and moisture, whereby ozone is produced ; that as long as air and oil are present, the ozone is continually regenerated and absorbed, forming oxidising and antiseptic products, which dissolve in the water, along with peroxide of hydrogen. This was the principle of the ' Sanitas ' patent 274, 1876.

Pyridine, quinoline. and **related bodies.** *Pyridine* is volatile, mixes freely with water, and is strongly insecticide, but has a very unpleasant odour, which has militated against its use in horticulture. Tobacco smoke, indeed, owes its powers, not to nicotine, which is almost entirely decomposed by the heat, but to the products pyridine and its homologues, which are formed. Tessmar destroyed the bacilli of cholera and pneumonia by tobacco smoke passed for 10 to 30 minutes through a tube containing infected nutrient gelatin. Wynter Blyth killed the bacillus of nasal catarrh by 1 p.c solution of pyridine and its homologues (from bone oil), or by tobacco smoke. There is proof that smokers and workers in tobacco enjoy comparative immunity from epidemics, but pyridine inhalations (*e.g.* in asthma and whooping cough) require care, as it is a cardiac depressant. The above experiments confirm the general view that disinfectant preparations containing the basic constituents of coal tar are to be preferred to those which only include the phenols.

Tobacco juice, of course, contains nicotine, and in France is sold as an insecticide under an official guarantee as to its nicotine strength. In England, a solution of the pure base in water is sometimes used as more definite. Richard's cakes for fumigation are nicotine and camphor : the writer found a sample in 1909 to contain 1·17 p.c. of nicotine and to be completely volatile at a gentle heat.

Chinosol is potassium - oxyquinoline - sul - phonate $C_9H_6NO\cdot OSO_3K$, a yellow powder easily soluble in water to an acid yellow solution, which does not stain, has only a slight aromatic odour, is permanent on keeping, is not poisonous, and does not coagulate albumen. It has been patented as a disinfectant, and more especially as an antiseptic. Klein compared its

action on *S. pyog. aureus*, *B. coli* and *anthracis* with that of carbolic acid, and reports that a solution of the latter of 1 in 20 strength is required to kill *aureus* or *coli* in 5 minutes with certainty, whereas chinosol does this in a strength of 1 in 150. Anthrax spores are not appreciably affected in 48 hours by 5 to 6 p.c. carbolic, whereas chinosol of 1 p.c. acts germicidally on them in 5 minutes. In the writer's laboratory, *B. coli* was not sensibly affected after 4 hours by 1 in 1000 chinosol, whilst 1 in 2000 of HgCl₂ produced sterility under the same conditions in 15 minutes, so that it is difficult to explain the much higher powers that some observers have found for chinosol. Thresh and Sowden state that chinosol spray of not less than 1 p.c., is a reliable disinfectant (J San. Inst. Jan. 1903). Houston did not succeed in killing *B. coli* in excréta by 1 in 75, and on linen by 1 in 62 (Practitioner, 1902, 331). On account of its acidity, it acts on iron and steel. Alkaline solutions interfere with its power: the writer showed that a soap containing 5 p.c. of chinosol was inferior to a 0 5 mercuric iodide soap F. G. Muller reports encouraging results with chinosol in leprosy (Zeitsch. Oest Apoth Ver xxxv. 858). 'Cresochin' (Pharm Centralhalle, xxxvii. 247) is said to be a neutral sulphonate of quinoline and tricresol, which is recommended for disinfecting instruments, as it does not darken the steel.

Ichthyol.—Various derivatives from sulphurated tars and fossilised fish or petroleums have been suggested for mild disinfection and the treatment of skin diseases. Ichthyol ammonium ichthyol sulphurated has been compounded with various substances, such as albumen, formaldehyde, and metals, such as silver and mercury, under a variety of names.

Quinine, which has a quinoline nucleus, probably owes its action against fevers as much to its antiseptic power as to its effect on the nervous system.

A. Raal (Pharm. Zeit. 1900, xlv. 569) asserts that strongly fluorescent bodies much increase the action of sunlight on organisms, whilst they are almost inert in the dark. A 1 in 20,000 solution of acridine killed infusoria exposed to sunshine in 6 minutes; in the dark they survived for 24 hours. Similar results were noted with quinine sulphate and with eosin. The inference is that the effect is caused by the fluorescent rays. Fluorescein has been patented as an antiseptic by Turpin, chiefly for toilet preparations (Fr. Pat 346363, 1904). The bromofluoresceins, particularly eosin, are found to have greater power. He claims a large number of other phthalein compounds as disinfectants.

Certain faults of many antiseptics and disinfectants in the free state have led to an immense number of attempts to improve them by converting them into various derivatives. Although the effort to produce new proprietary substances, has given rise to a multitude of often misleading titles, many of these preparations have been proved to have utility. The modifications may be generally classified as follows :—

1. *Metallic salts.*—Compounds with the alkalis or earths are generally less active than the free substance. Other metals have been introduced, with the object of adding their special properties,

as Al for astringency, Zn, Cu, Ag, and Hg for developing germicidal effect; but it must be remembered that a combination of this kind, though it may have some lateral advantages, is commonly weaker than either agent singly. The same remark applies to the two next groups.

2. *Substituted compounds.*—Those with iodine are exceedingly numerous, including a large number which have been improvements on iodoform when it was unduly valued. Where organic radicals (basic like methyl or ethyl, acid like acetyl or benzoyl) are introduced, the physiological properties are usually entirely altered.

3. *Esters*, sulphonic, and other colligated compounds which, while less poisonous or irritant than the parent bodies, slowly yield the latter by gradual decomposition. Several of these have proved of great value.

As already indicated, the proprietary articles of this nature bearing fancy names are very numerous. Since the Privy Council Orders of 1900 and 1902, the uncontrolled sale of liquids containing upwards of 3 p c. carbolic acid or its homologues is prohibited, and the germicidal value of the more insoluble and higher boiling-point tar acids has been recognised. The generality of commercial disinfectant fluids are now practically free from carbolic acid, and, in comparison with the latter, are non-poisonous These disinfectant preparations should not be employed to destroy resistant spores without prolonged exposure; according to the nature and amounts of active ingredients present, they are usually germicidal with non-sporulating organisms in dilutions far greater than is the case with absolute phenol However, the strength of these proprietary articles varies considerably, and beyond the requirements of germicidal value specified in contracts with various authorities, there is at present, unfortunately, no legal control over the efficiency of disinfectants as sold to the public. There are instances of so-called disinfectants which enjoyed great popularity and even were advocated by the medical profession, yet possessed little or no germ-killing power under the conditions in which they would be employed.

Since the adoption of the R.W. test, there has been a steady rise in the efficiency of commercial disinfectants

The Mechanism of Disinfection.—Krönig and Paul, in 1897, first drew attention to the relationship between germicidal action and the ionic concentration of certain germicidal ions such as mercurion, argention, hydrion, and formulated the rule that the germicidal activity of a solution was proportional to the ionic concentration of the germicidal ions. More recent work, such as that of Kitasato, Horrocks, and Winslow, on the common acids, and more especially the development of the organometallic group of disinfectants, indicated that this generalisation was by no means correct. Ehrlich and his pupils attributed to disinfectants the possession of at least two specific properties, the presence of an organotropic and a parasitotropic grouping indicating the 'affinity' of the germicide to living tissue and the parasite or bacterium respectively.

Neither of these theories will serve to

explain the phenomena observed in disinfecting with ionised and unionised solutions, with emulsions and other colloids. Bacterial suspensions must be regarded as suspensoids coated by, or containing, an emulsoid, and are to be classed as definite colloidal systems.

The reactions between agglutin and the bacteria, similar to the reactions between toxins and antitoxins, resemble in many respects either the combination of a very weak acid and a weak base, a view advanced and supported by Arrhenius (' Immunochemie '), or the usual absorption phenomena observed at colloidal surfaces. Although experimental evidence (notably that of Marsden, Nyman, and Chick, carried out at the Lister Institute) is not sufficiently accurate to distinguish between the two, yet the other general characteristics of bacterial suspensions lead us to infer that absorption is the first stage of disinfection. We can thus distinguish between the following types of action :—

(1) Absorption of cations (ionic disinfectants) with simultaneous anion absorption, which may affect the activity.

(2) Absorption of substances in solution, e.g. phenol.

(3) Mutual action between bacteria and other colloids, such as emulsions (tar acids) or suspensoids (colloidal metals). The next stage, common to all, is penetration and chemical attack by the absorbed disinfectant. It is evident that the germicidal activity of a substance after absorption is determined by its penetrative or intradiffusive powers as well as its chemical reactivity or 'parasitotropic' properties. The enhanced germicidal powers of the chloramine is doubtless due to their possession of a reactive $-NH_2$ group, but it is by no means clear that dyestuffs are germicidal on account of their possessing certain parasito-groupings or that their activity is not due to a medium diffusivity accompanied by gradual decomposition into germicidal constituents. It appears probable that more light will be shed on this somewhat complex subject by a close study of the phenomena of absorption and the mechanism of intradiffusion of substances in colloidal material rather than by the development of the concept of ionic activity or postulation of certain parasitotropic groupings or valencies endowed with exceptional and unexpected properties.

Testing of Disinfectants.—Before 1881, when Koch introduced the use of pure cultures, tests depending upon the prevention of putrefactive changes in various organic infusions were mainly employed, and to a great extent the antiseptic or preservative value was noted rather than the actual germ-killing power (*see* first edition of this dictionary). Since then, an increasingly large number of investigators have worked upon practical methods of testing. With the phenolic disinfectants, valuations were made upon the total amount of tar acids present, but the widely differing activity of these bodies, which is also modified according to their physical condition on dilution (in *solution*, tricresol has only one-third the germicidal value of that in *emulsion*), has led to the general adoption of bacteriological tests.

In the *thread* method (Koch), silk threads

are impregnated with the test organism, and exposed for a definite time to the action of the diluted agent, and then, after the removal of adhering disinfectant, sub-cultures are inoculated from the threads to determine the survival or death of the organism (*v.* Lancet, July 30, 1900 ; and J. R. San. Inst. 1907, xxviii.). In place of threads, small garnets can be employed (Krönig and Paul), stones of uniform size being coated from cultures of the organism, and added directly to the disinfectant, sterility being determined by inoculating sub-cultures at intervals (Zeitsch. angew. Chem. 1901, xiv. xv.). The chief points to be considered are (1) time ; (2) age of culture ; (3) choice of medium, reaction of same ; (4) temperature of incubation and (5) of disinfection ; (6) variation in vital resistance of same species and (7) of different species ; (8) proportion of culture to disinfectant. In order to facilitate the comparison of disinfectants, Rideal and Walker (J. R. San. Inst. 1903, 424) suggested their carbolic acid coefficient method as the basis for a standard process. In this test, which has been extensively adopted in England and abroad, the efficiency of the disinfectant is expressed in multiples of absolute phenol performing the same work. It is briefly as follows : add 5 drops of a 24 hours' blood-heat culture of the organism in broth to 5 c.c. of a particular dilution of the disinfectant in sterile distilled water ; shake and take sub-cultures with a platinum loop every $2\frac{1}{2}$ minutes up to 15 minutes ; incubate sub-cultures at $37°$ for 48 hours. Allowing 30 seconds for each operation, four different dilutions of the disinfectant with one carbolic control are tested against the same culture and under strictly comparable conditions. For example :

	Minutes $2\frac{1}{2}$	5	$7\frac{1}{2}$	10	$12\frac{1}{2}$	15
Disinfectant 1 : 500	+	–	...	--	–	–
,, 1 : 550	+	+	–	—	–	–
,, 1 : 600	+	+	+	--	--	–
,, 1 : 700	+	+	+	+	+	–
Carbolic acid 1 : 110	+	+	—	—	—	—

Carbolic acid coefficient $\frac{550}{110}=5$

This test has for many years been officially used by the War Office, Admiralty, India Office and other Government departments at home and in the Colonies. It is impossible in any one test to include the greatly varying conditions of practical disinfection, but numerous modifications of the R.W. coefficient test have been suggested, mainly with the object of testing in the presence of considerable quantities of organic matter. Sterilised sea-water, urine, sewage, starch, and gelatine emulsions, nutrient broth and milk, have been incorporated with the diluting water—also testing with organisms in their natural environment, as with *coli* in sewage, in place of pure cultures. A sedimentation test for emulsified fluids allows a 1 p.c. solution to stand 24 hours before preparing final dilutions for testing (Lancet, Sept. 19, 1908). The ' Lister test ' (C. J. Martin) is made in the presence of 3 p.c. of fæces, previously sterilised; dried, and powdered. Sims Woodhead and Ponder (J. Path. and Bact. 1909, 148) replace the inoculating loop by platinum spoons, used with a special sterilising apparatus, and extend the

time to 30 minutes. A mean coefficient is taken for two values obtained at the beginning and end of the experiment with *B. coli* and sub-culturing into McConkey's bile-salt fluid. The Lancet (Nov. 1909) has suggested, in conjunction with the above method, a chemical analysis for the valuation of emulsified fluids as follows : 10 grams of disinfectant with 100 c.c. of water and 15 grams baryta, are heated for 30 minutes at 100° under a reflux condenser, then cooled and decanted through asbestos, washing with warm baryta water ; the tar acids are extracted with ether from an aliquot portion of the filtrate, after adding calcium chloride and acidifying with HCl, dried at 38°, weighed, and their bromine absorption determined. Neutral hydrocarbon oils are extracted from the baryta residue with acetone, and the insoluble soaps and resins treated with HCl and shaken out with ether. For estimation of water, 25 grams of the sample are acidified with 10 c c. of 10 p.c. H_2SO_4 and shaken with 25 c c of white petro-leum spirit, taking the volume less 10 c c. of the aqueous layer after standing. In presence of the higher phenoloids, the weight of tar acids obtained is too low. The coefficients obtained for *B. coli* were found to be approximately one-third of the difference between the percentage of tar acids and the bromine value.

In the United States, the National Hygienic Laboratory method of L. Anderson and T. B. McClintic (1912) is now widely adopted. The method, which follows closely the R.W. in technique, differs in the following points of detail : The standard temperature of medication of 20°C., instead of 18°C., is adopted. 0·1 c c. of broth culture is added to 5 c c. of disinfectant solution instead of 5 drops. The coefficient is determined from the mean of the following two reactions :—

Weakest strength of disinfectant which kills in 2½ minutes

Weakest strength of phenol that kills in the same time

and the similar ratio for death in 15 minutes.

From time to time various modifications have been introduced in which solid media such as nutrient agar have been substituted for broth. An emulsion of an agar slope culture of an organism is made with the various disin-fectant dilutions and phenol controls, whilst the sub-culturing is either performed direct into agar slopes or spread out on agar plates, thus permitting counts to be made. Nutrient agar made up with fresh meat is certainly less inhibiting than standard broth, whilst certain advantages attend the use of plates, giving approximate data as to the number of organisms surviving after specified periods of disinfection, as against the 'end point' method of the fluid media tests. These advantages are nearly entirely negatived by the difficulty of obtaining a uniform agar streak growth emulsion for medication, and the extra labour involved in plating a number of tests.

The germicidal power expressed in terms of carbolic acid with *B. typhosus* is shown for a number of disinfectant substances in the follow-ing table ; while most of the figures are Rideal-Walker carbolic acid coefficients, some of the results have been obtained by modifications of

the original test as noted, and these are obviously not comparable with the others.

Agent	Germicidal value	Observer
Absolute alcohol	less than 0·1	F. 1905
Acetic acid	0·6	R. 1907

The extremely high values once given for mercuric chloride were due to the powerful inhibitory action of the traces carried over with the sub-cultures in the inoculations.

S. & E. R.

DISPARGEN. Trade name for a form of colloid mercury.

DISPERMIN. Trade name for piperazine.

DISSOCIATION v. CHEMICAL AFFINITY.

DISTHENE v. KYANITE.

DISTILLATION. The object of distillation is the separation of a volatile liquid from a non-volatile substance, such as pure water from sea-water, or more commonly the separation of two or more liquids of different volatility.

The apparatus required consists essentially of four parts : a still or boiler, A (Fig. 1), in which
FIG. 1.

the liquid is boiled ; an upright tube or head, B ; a condensing tube, C, sloping downwards and cooled by suitable means—a Liebig's condenser, L, through which a current of water is passed, being generally employed in the laboratory ;
FIG. 2.

lastly, a receiver, R, to collect the distilled liquid The form of apparatus shown in Fig 2 is convenient for many purposes ; the still, the head, and the condensing tube are sealed together in one piece The still is usually heated by the flame of a Bunsen burner ; for very volatile and inflammable liquids a water-bath is generally used, but the rate of distillation can be better regulated by a very small flame in contact with the bottom of the still ; the Liebig's condenser is unnecessary for liquids which boil above 160° or 170° if the condensing tube is fairly long. For many purposes, notably for distillation under reduced pressure, it is convenient to employ an electrically heated coil of platinum, German silver, or nichrome wire as the source of heat (Richards and Matthews, J. Amer. Chem. Soc. 30, 1282 ; 31, 1200; Beckmann, Zeitsch. physikal. Chem. 64, 506 ; Bailey, J. Amer. Chem Soc 33, 447 ; Rosanoff and Easley, ibid. 31, 964)

If the temperature at which the liquid boils is to be ascertained with accuracy—and this is generally the case in fractional distillation, especially in the final purification of a liquid –the following points should be attended to :—

1. The thermometer should be carefully calibrated, and it would be a great advantage if all thermometers were compared with an air thermometer, for different kinds of glass expand very differently when heated, and therefore two thermometers, constructed of different varieties of glass, will give different readings, especially at high temperatures.

2. The zero point of the thermometer should be redetermined from time to time. It is a good plan to heat the thermometer for several hours to about 300° or 360° before calibrating it ; the subsequent changes of zero point, which other-

wise might be considerable at high temperatures, are thereby greatly reduced (Crafts, Compt. rend. 95, 910 ; also several earlier papers). Thermometers treated in this manner may now be purchased.

3. All thermometers, except those which do not register temperatures higher than 60° or 70°, should contain nitrogen to prevent volatilisation of mercury in the heated stem ; if the thermometer is provided with a small bulb at the top, rise of pressure owing to compression of the gas in the thermometer is avoided.

4. The thermometer should, if possible, be so placed in the apparatus that not only the bulb but also the column of mercury in the stem is surrounded by the vapour of the boiling liquid ; otherwise the following correction, which, at the best, is somewhat uncertain, must be applied :—

N = length of column of mercury in scale degree not heated by vapour.

T = temperature of vapour (the approximate temperature directly read on the thermometer is usually sufficiently accurate).

t = mean temperature of column of mercury not heated by vapour. This temperature may be approximately ascertained by attaching a small thermometer to the other by means of thin indiarubber bands or wire, with its bulb at about the middle of the unheated column

Correction : add 0 000143(T−t)N.

The coefficient 0 00016 is usually employed, but Holtzmann pointed out that this is too high, and adopted the number 0 000135 Thorpe, however (Chem. Soc. Trans. 37, 159), has shown that the coefficient 0 000143 gives the best results.[1] The table for the correction of thermometer readings is taken from Thorpe's paper, and shown in next column.

For further information v. article on THER-MOMETERS.

5. When the amount of liquid in the bulb is very small, the vapour is liable to be superheated by the flame, and unless the bulb of the thermometer is thoroughly moistened with condensed liquid, too high a temperature will be registered. If a very little cotton wool or, for temperatures above 230°, a little fibrous asbestos be wrapped round the bulb of the thermometer, it remains thoroughly moist, and with a pure liquid the thermometer registers a perfectly constant temperature until the last trace of liquid in the bulb has disappeared (Ramsay and Young, Chem. Soc. Trans. 47, 42).

6. The barometer should always be read, and corrected to 0°, and in a long distillation or in unsettled weather it should be read frequently, for the boiling-point varies greatly with the pressure. The observed boiling-point is corrected to that under normal pressure by means of the formula $\theta = c(760-p)(273+t)$, where θ is the correction in centigrade degrees to be added to the observed boiling-point, $t°$; c is a constant ; and p is the barometric pressure. For the

[1] Rimbach (Ber. 22, 3072) has constructed tables of corrections by interpolation from experimental data up to 220° for two kinds of thermometer graduated in degrees, and up to 100° for thermometers graduated in tenths of a degree. All these thermometers were constructed of Jena glass, and from the results it would appear that the form of the thermometer, and doubtless also the nature of the glass, have a notable influence on the magnitude of the correction.

majority of liquids the value of c may be taken, without serious error, to be 0·00012 ; but for water and the alcohols it is about 0·00010, and for a few liquefied gases it is considerably higher. A table of corrections was first given by Crafts (Ber. 20, 709). The values of c for a large number of substances have been collected and

tabulated by Young (Chem. Soc. Trans. 81, 777 ; Fractional Distillation, 15).

The various parts of the simple apparatus (Figs. 1 and 2) may require modification under certain circumstances.

The still.—For larger quantities of liquid, a tin or copper vessel is preferable to glass.

The head.—The modifications of this part

of the apparatus will be considered under *Fractional distillation.*

The condenser.—For very volatile liquids, the condensing tube must be cooled by ice or a freezing mixture (pounded ice and salt or ice and concentrated hydrochloric acid, &c.). In this case, a spiral or ' worm ' tube should be used (Fig. 3). Condensation of moisture in the receiver is prevented by the drying tube a. V CONDENSERS.
FIG. 3.

The receiver.—If a liquid boils at a very high temperature, or if it suffers decomposition at the ordinary boiling-point, it may be necessary to distil it under reduced pressure. For cases of simple distillation, the apparatus shown in Fig. 4 may be employed, but if the
FIG. 4.

distillate is to be collected in separate portions, as in fractional distillation, the removal of the receiver would necessitate the admission of air into the apparatus and a fresh exhaustion after each change. This inconvenience may be obviated by the employment of stopcocks arranged in such a manner that air may be admitted into the receiver and a fresh one put in its place while the distillation bulb remains exhausted (Thörner, Ber. 9, 1868 ; F. D. Brown, Chem. Soc. Trans. 35, 554 ; L. T. Thorne, Ber. 16, 1327 (Fig. 5) ;

FIG. 5.

Lothar Meyer, *ibid.* 20, 1834 ; Wade and Merriman, Chem. Soc. Trans. 99, 984 ; Rosanoff and Easley, *l.c.* ; Rosanoff, Bacon and White, J. Amer. Chem. Soc. 36, 1806). Or, again, a series of receivers on a revolving stand placed under an exhausted bell-jar may be employed (Gorboff

and Kessler, Ber. 18, 1363; Brühl, *ibid.* 21, 3339 (Fig. 6)).

Many liquids absorb moisture from the air or are acted upon by oxygen, and in these cases special precautions must be taken, the moist air in the apparatus being expelled and replaced by dry air, carbon dioxide, nitrogen, or hydrogen;
FIG. 6.

the receivers must also be protected by drying tubes. (For example, *v.* Thorpe, Chem. Soc. Trans. 47, 120; Young, *ibid.* 59, 923.)

Theory of distillation.—Investigations of the vapour pressures of liquids have thrown much light on the subject of distillation. If a pure liquid be confined in the space above the mercury in a barometer tube, it will evaporate until the pressure of its vapour—measured directly by the depression of the mercury column—has reached a definite amount, which, for a given substance, and, if liquid be still present, depends solely on the temperature. From the readings of pressure at various temperatures we may construct a curve to illustrate the relations of temperature to pressure for a given substance, but this curve has a twofold meaning, for it represents not only the vapour pressures at definite temperatures, but also the boiling-points of the liquid under definite pressures. Thus the vapour pressure of pure water at 100° is 760 mm. of mercury at 0°; and under a pressure of 760 mm. water boils at 100°. Again, the vapour pressure of water at 0° is 4·6 mm., and if the pressure in a distillation bulb containing water be reduced to 4·6 mm., the water will boil at 0°. The truth of this general statement was conclusively proved by Regnault (Mém. de l'Academie, 21 and 26).

Regnault also investigated the behaviour of a few mixed and heterogeneous liquids, which he divided into three classes : (1) liquids which are quite or almost insoluble in each other ; (2) liquids which are miscible only within certain limits ; (3) liquids which mix in all proportions. Regnault employed both the statical and dynamical methods of investigation ; that is to say, he determined, on the one hand, the vapour pressures of the liquids at various temperatures

in the barometer tube, and, on the other hand, the boiling-points of the liquids under various pressures.

The behaviour of two liquids, A and B, when brought into contact with each other, must be affected (*a*) by the attraction of the like molecules ; those of A for each other, and those of B for each other ; and (*b*) by the mutual attraction of the molecules of A and B. If the attraction of the unlike molecules is relatively very slight, it may be expected that the liquids will be non-miscible, or nearly so, as in the case of benzene and water. If the attraction of the unlike molecules is greater, but still relatively small, miscibility within limits may be expected, as, for example, with aniline and water. In such cases there is frequently slight expansion and slight absorption of heat on admixture. Comparing together various pairs of liquids, as the mutual attraction of the unlike molecules increases relatively to that of the like molecules, the following changes may be expected ; (*a*) increasing and finally infinite miscibility ; (*b*) slight expansion, diminishing to zero, and followed by increasing contraction ; (*c*) diminishing absorption of heat, changing to increasing heat evolution These changes do not, in many cases, run strictly *pari passu*, and among liquids which are miscible in all proportions, it is not unusual to find a small amount of contraction attended by a slight absorption of heat, as, for example, when a little water is added to normal propyl alcohol, but when certain compounds, such as chlorobenzene and bromobenzene, which are chemically closely related, are mixed together, there is no appreciable change of volume or temperature. For such substances it is probable that the different molecular attractions, A for A, B for B, and A for B, are very nearly equal, and that the relation suggested by Galitzine (Wied. Ann. 41, 770 ; and by D. Berthelot, Compt. rend. 126, 1703), namely, that $a_{A\ B} = \sqrt{a_A . a_B}$, holds good, where $a_{A.B}$ represents the attraction of the unlike molecules, and a_A and a_B the respective attractions of the like molecules.

It would appear, then, that there are two very simple cases : I. that in which the liquids are non-miscible ; II. that of two infinitely miscible and closely related liquids which show no heat or volume change on admixture.

I. It was found by Regnault that when two non-miscible liquids are placed together over the mercury in a barometer tube, the observed vapour pressure is equal to the sum of the vapour pressures of the two liquids when heated separately to the same temperature. It is only necessary that both substances should be present in sufficient quantity, and that the tube should be shaken or sufficient time allowed for the evaporation of the heavier liquid. The liquids evaporate independently of each other, and Dalton's law of partial pressures is therefore applicable to the distillation of non-miscible liquids. Each vapour behaves to the other as an indifferent gas, and the boiling-point of each liquid depends on the partial pressure of its own vapour. The temperature is necessarily the same for both liquids, and the total pressure, if the distillation is carried out in the ordinary

manner, is equal to that of the atmosphere. The boiling-point is, therefore, that temperature at which the sum of the vapour pressures of the components is equal to the atmospheric pressure. For example, at 90·23° the vapour pressure of water is 530·1 mm. ; and that of chlorobenzene is 210·1 mm. ; total, 740·2 mm. ; and it was found that when chlorobenzene and water were distilled together under a barometric pressure of 740·2 mm., the temperature varied only between 90·25° and 90·35°, until there was scarcely any chlorobenzene left in the residue, when it rose rapidly to 100°. The boiling-point of a pair of non-miscible liquids is necessarily lower than that of the more volatile component, and may be far lower than that of the less volatile.

The process of distillation with steam is very frequently employed in the case of substances of high boiling-point, which are insoluble or only slightly soluble in water, such as aniline or nitrobenzene. (For the application of steam distillation to the preparation of ethereal oils, v. von Rechenberg, Theorie der Gewinnung und Trennung der ätherischen Oele durch Destillation, Schimmel & Co 1910)

The composition of the vapour—and therefore of the distillate—from two non-miscible liquids, like the vapour pressure and boiling-point, is independent of the relative amounts of the components, provided that both are present in sufficient quantity and that evaporation can take place freely. Calling the vapour densities D_A and D_B, and the vapour pressures at $t°$ p_A and p_B, there will be, in a litre of the mixed vapour, 1 litre of A at $t°$ and p_A mm., and 1 litre of B at $t°$ and p_B mm. The weights of vapour will therefore be :

$$\frac{0·0899 \times D_A \times 273 \times p_A}{(273+t) \times 760} \text{ and } \frac{0·0899 \times D_B \times 273 \times p_B}{(273+t) \times 760}$$

respectively, and the relative weights will be $\frac{D_A \times p_A}{D_B \times p_B}$ (Naumann, Ber. 10, 1421, 1819, 2014, 2099 ; Brown, Chem. Soc. Trans. 35, 547).

The vapour density of chlorobenzene is 56·2, and that of water is 9 ; and at 90 23° the relative weights of vapour will be

$$\frac{m'_A}{m'_B} = \frac{56·2 \times 210·1}{9 \times 530·1} = 2·475,$$

and the percentage weight of chlorobenzene will be 71·2. In the actual experiment to which reference has been made, the percentage of chlorobenzene in the distillate was found to be 71·4. Both boiling-point and vapour composition agree well with the calculated values.

II. The vapour pressure of a mixture of two infinitely miscible liquids which are chemically closely related to each other, or, probably, for which $a_{A.B} = \sqrt{a_A.a_B}$, is given by the formula $100p = Mp_A + (100 - M)p_B$ where M is the molecular percentage of A, and p, p_A, and p_B are the vapour pressures of the mixture and of A and B respectively, at the same temperature, $t°$. In other words, the relation between vapour pressure and molecular composition is represented by a straight line (Van der Waals,

Proc. Roy. Acad. Amsterdam, 3, 170 ; Young, Chem. Soc. Trans. 81, 768 ; Young and Fortey, ibid. 83, 45 ; Zawidski, Zeitsch. physikal. Chem. 35, 129 ; Vanstone, Chem. Soc. Trans. 97, 429 ; Price, ibid. 115, 1116). The relation has been found to hold accurately for chlorobenzene and bromobenzene, and with very slight error for other pairs of closely related liquids.

In order to calculate the boiling-points of all mixtures of two such liquids under a given pressure, p, the vapour pressures of each must be known at all temperatures between their respective boiling-points under that pressure. The percentage molecular composition of mixtures which would exert the vapour pressure p must then be calculated at a series of temperatures between these limits by means of the formula $M = 100 \dfrac{p_B - p}{p_B - p_A}$. Lastly, the values of M must be plotted against the temperatures, when the curve drawn through the points will give the required relation between boiling-point and molecular composition. In the cases examined, the agreement between the observed and calculated results is quite satisfactory.

The relation between the composition of a liquid mixture and that of its vapour (distillate) has been the subject of many experimental investigations (Brown, Chem. Soc. Trans. 35, 547 ; 39, 304 ; Lehfeldt, Phil. Mag. (v.) 46, 42 ; Zawidski, Zeitsch. physikal. Chem. 35, 129 ; Carveth, J. Phys. Chem. 3, 193 ; Winkelmann, Wied. Ann. 39, 1 ; Linebarger, J. Amer. Chem. Soc. 17, 615 ; Gahl, Zeitsch. physikal. Chem. 33, 179 ; Rosanoff, Lamb, and Breithut, ibid. 66, 349 ; Rosanoff and Easley, J. Amer. Chem. Soc. 31, 953 ; Rosanoff, Bacon and White, ibid. 36, 1803 ; Rosanoff, Bacon and Schulze, ibid. 36, 1993 ; Rosanoff and Bacon, ibid. 37, 301 and 1072). Special attention may be directed to the last four of these papers. Unfortunately, however, it is only in a very few cases that the mixtures investigated consisted of closely related liquids (Young, Sci. Proc. Roy. Dubl. Soc. 15, N.S., 667). In the discussion of their results, Lehfeldt and Zawidski made use of formulæ which they derived from a general equation proposed independently by Duhem and by Margules, and it is to be noted that both formulæ, in the simplest cases, can be reduced to one originally given by Brown, $\dfrac{m'_A}{m'_B} = c.\dfrac{m_A}{m_B}$, where m'_A and m'_B are the relative weights of the two substances in the vapour, m_A and m_B the relative weights in the liquid, and c is a constant. From Zawidski's formula it would follow that $c = \dfrac{p_A}{p_B}$. So far as experimental evidence is available, it would appear that Brown's formula is applicable to mixtures of liquids for which $a_{A.B} = \sqrt{a_A.a_B}$, and that for closely related liquids $c = \dfrac{p_A}{p_B}$.

Another formula, which gives good results, is proposed by Rosanoff, Bacon and Schulze (loc. cit.).

When the components of a liquid mixture are not chemically closely related, the relation between vapour pressure and molecular composition is not, as a rule, represented by a straight

line, but by a curve, and, in all probability, the form of the curve depends on the relation between $a_{A,B}$ and $\sqrt{a_A.a_B}$, as shown in Fig. 7. That is to say, when

$$a_{A\,B} < \sqrt{a_A.a_B},\ 100p > Mp_A + (100-M)p_B,$$

and *vice versa*.

The greater the difference between $a_{A\,B}$ and $\sqrt{a_A.a_B}$ the greater will be the curvature; and it will be seen that, for any given values of p_A and p_B, if the deviation from straightness exceeds a certain limit, there must be a point of maximum or minimum pressure on the curve. It is obvious, also, that the smaller the difference between p_A and p_B, the smaller will be the deviation required to give a maximum or minimum pressure. If $a_{A\,B}$ is so much smaller than $\sqrt{a_A.a_B}$ that the two liquids are only partially miscible, the maximum pressure will not be represented by a single point, but by a horizontal line forming part of the curve

The influence of chemical relationship is well seen by the behaviour of the monhydric aliphatic alcohols towards water. These alcohols may be regarded as derivatives of water, formed
by the replacement of a hydrogen atom by the group C_nH_{2n+1}; the smaller the alkyl group, the closer is the relationship of the alcohol to water. At the ordinary temperature methyl alcohol is miscible with water in all proportions, as also are ethyl and propyl alcohols; normal butyl and *iso*butyl alcohol are only partially miscible with water; and the solubility of the higher alcohols in water diminishes with rise of molecular weight, cetyl alcohol, for example, being practically insoluble. The volume and heat changes on admixture with water similarly indicate that the attraction of the unlike molecules diminishes as the molecular weight of the alcohol increases. Lastly, the deviation of the vapour pressure curves from straightness increases (Konowalow, Wied. Ann. 14, 34), as may be seen from Fig. 8.

(The temperatures are such that the vapour pressure of each pure alcohol is 400 mm.)

The boiling-points of liquids which are not closely related cannot, as a rule, be calculated by means of the formula $M = 100\dfrac{p_B - p}{p_B - p_A}$. If, as is usually the case, the vapour pressures of the mixtures are higher than are given by the formula $100p = Mp_A + (100 - M)p_B$, the observed boiling-points will be lower than the calculated; if the vapour pressures are lower, the boiling-points will be higher. Moreover, when there is a point of maximum pressure on the curve which shows the relation between vapour pressure and molecular composition, there must be a point of minimum temperature

on the boiling-point—molecular composition curve, the composition of the mixture which exerts a maximum vapour pressure, p, at $t°$ being the same as that of the mixture which has the minimum boiling-point, $t°$, under the pressure p. So, also, two substances capable of forming a mixture of minimum vapour pressure can also form a mixture of maximum boiling-point.

Such mixtures of either minimum or maximum boiling-point, when distilled, boil at a constant temperature without change of composition, like pure substances, and they have frequently been mistaken for chemical compounds. The composition, however, depends on the pressure, which would not be the case with a definite compound; and, moreover, mixtures of minimum boiling-point are formed owing to the relatively
Fig 8.

small attraction of the unlike molecules for each other. A very striking example of the influence of pressure on the composition of the mixture of constant boiling-point has been observed by Wade (Chem. Soc. Trans. 99, 997), in the case of ethyl alcohol and water. Under normal pressure the mixture of minimum boiling-point contains 4·43 p.c. of water. At higher pressures the percentage of water is slightly higher; at lower pressures it is smaller, and it is remarkable that the diminution in the percentage of water becomes more and more rapid as the pressure falls, so that below 80 mm, no mixture of minimum boiling-point is formed at all. V. also Merriman, *ibid.* 103, 628 and 1790.

In the case of three liquids, if each of the three possible pairs is able to form a mixture of minimum boiling-point, it may happen that a particular mixture of all three liquids will boil constantly at a lower temperature than will any of the pairs or single liquids. Thus benzene and

· water form such ternary mixtures of minimum boiling-point with ethyl, n-propyl, isopropyl, and tertiary butyl alcohols (Young, Chem. Soc. Trans. 81, 707; Fortey and Young, ibid. 81, 739).

A table of mixtures of constant boiling-point is given in Young's Fractional Distillation, 67–69. Other mixtures have since been discovered by Wade (Chem. Soc. Trans. 85, 938; 87, 1656; v. also 95, 1842), and by other observers. The subject has been exhaustively studied by Lecat, La Tension de Vapeur des Mélanges de Liquides; l'Azéotropisme (Brussels, 1918). Lecat has collected the data published by other chemists, and has himself investigated more than 2000 mixtures, and has discovered and tabulated a very great number of binary mixtures of minimum boiling point, and a moderate number of binary mixtures of maximum boiling-point, and of ternary mixtures of minimum boiling-point. He has also observed the dependence of the composition of the azeotropic mixtures on the pressure in a considerable number of cases.

The composition of the vapour from a mixture of liquids which are not closely related, cannot, as a rule, be calculated from the vapour pressures of the components and the composition of the liquid, but for purposes of interpolation the formulae of Lehfeldt, Zawidski or Rosanoff may be found useful ($l c_e$) Rosanoff, Bacon and Schulze ($l c$) have discovered a simple and very useful solution between the partial pressures (number of molecules) of the components in the vapour and the vapour pressures of the mixture and of the two pure substances. They give a formula which is applicable even when mixtures of maximum or minimum vapour pressure are formed

Fractional distillation. It has been stated that Brown's formula, $\dfrac{m'_A}{m'_B} = c\dfrac{m_A}{m_B}$, is applicable to mixtures of all closely related liquids so far investigated, and that, in all probability $c = \dfrac{p_A}{p_B}$. The value of c is necessarily such that the vapour is richer than the liquid in the more volatile component. The first portion of distillate obtained by condensation of the vapour will, therefore, be richer, and the

residual liquid will be slightly poorer in that component. Continuing the distillation, the vapour evolved from the residual liquid will again be richer than the liquid in contact with it in the more volatile component, though poorer than the first portion of vapour. If successive portions of vapour be condensed, the percentage of the more volatile component in the distillates or fractions will steadily diminish, until, if the constant c differs greatly from unity, the residue will consist of the less volatile liquid in a pure or very nearly pure state. As the distillation proceeds, the temperature will, therefore, rise until, if c has a high value, the boiling-point of the less volatile component is reached.

If the fractions obtained in the first distillation were redistilled, each of them could be separated into smaller fractions, the first richer and the last poorer in the more volatile component, and by a process of systematic fractional distillation it should, theoretically, be possible to effect a separation of both components.

A mathematical and experimental investigation (Barrell, Thomas, and Young, Phil. Mag. (v.) 37, 8) of the behaviour on distillation of mixed liquids which follow Brown's law, showed that with two components it is the liquid of higher boiling-point which is the easier to separate; and that if there are three or more components boiling at fairly equal intervals the substances of intermediate boiling-point are the most difficult to separate, and the least volatile substance is the easiest. See also Lord Rayleigh, Phil. Mag [5] 4, 527, and Rosanoff, Baker and Schulze, J. Amer. Chem. Soc 36, 1993

The method employed for the fractional distillation of a mixture of two liquids can best be explained by taking a concrete example. A mixture of 100 grams of benzene (b p. 80·2°) and 100 grams of toluene (b p. 110·6°) was slowly distilled, and the distillate was collected in a convenient number of fractions, the receivers being changed when the boiling-point reached certain definite previously arranged temperatures, the actual readings being corrected for barometric pressure and for errors in the thermometer scale The results of the first four fractionations, and also of the ninth, are given in Table I.

TABLE I.

Number of receiver	Final temperature (corrected)= t	Weight of fraction = ΔW				t	ΔW
		I.	II.	III.	IV.	IX.

Pure toluene	(110·6)	10·90	22·95	31·35	42·10	(110·6)	72·10

• In the first distillation the temperature rose almost at once to 86° (corr.), and the first portion of distillate was therefore collected in receiver 4. On the other hand, the temperature reached 110·6° before the whole of the liquid had come over; the residue, therefore, consisted of pure toluene.

The distillate in receiver 4 was now placed in a smaller flask and distilled, fractions being collected in receivers 2, 3, and 4. When the temperature reached 89·2°, the flame was removed, and the contents of receiver 5 were added to the residue in the still. The distillation was recommenced, and fractions were collected in receivers 3, 4, and 5, the flame being removed when the temperature reached 92·2°. The distillation was continued in a similar manner until, after addition of the contents of receiver 12, the temperature rose to 110·6°, when the residue of pure toluene was added to that from the first fractionation. The third and fourth fractionations were carried out like the second. In the subsequent fractionations the temperature ranges of the middle fractions were gradually increased and those of the lowest and highest fractions diminished. It was not until the ninth fractionation that pure benzene began to be collected. Eventually 81·4 grams of pure benzene and 88·8 grams of pure toluene were recovered.

Full details of the systematic fractional distillation of mixtures of two liquids and three liquids, and of more complex mixtures, are given in 'Fractional Distillation,' 114–143.

If the components of a mixture are not closely related, the composition of the vapour cannot, as a rule, be calculated by Brown's formula, but even in such cases the percentage of the more volatile component in the vapour will be greater than in the liquid, and the separation by fractional distillation is theoretically possible, unless the deviation of the vapour pressure-composition curve from straight-
FIG. 9.

ness is so great that a mixture of maximum or minimum vapour pressure is formed.

For mixtures to which Brown's law is applicable, it may be stated quite generally that the greater the difference between the boiling-points of the compounds, 'the more readily can a separation be effected by fractional distillation, but for other mixtures the form of the curve representing the relation between boiling-point and molecular composition, if known, must be taken into account. If the curve for two components were of the form a

(Fig. 9), the substance of higher boiling-point could be separated very easily, but the more volatile component only with great difficulty, if at all. On the other hand, if the curve were of the form b, nearly horizontal at the higher temperature, the more volatile component would be comparatively easy, and the less volatile difficult to separate. The first case is frequently met with, the second seldom. With curves of the form c and d (Fig. 10) it would not, under any conditions, be possible to separate
FIG. 10

both components by distillation of any given mixture, but it would be possible to separate the mixture of minimum or maximum boiling-point from that component which was in excess. In a case represented by curve c, where the minimum temperature corresponds to the molecular composition q, the distillation might proceed in either of three ways : (1) If the liquid mixture had the composition q, it would distil unchanged in composition at the constant minimum temperature ; (2) if the molecular percentage of A were less than q, the liquid would tend to separate into two components, the more volatile of which would be the mixture of minimum boiling-point, and the less volatile the substance B ; (3) if the molecular percentage of A were greater than q, the components separable by distillation would be, first, the mixture of minimum boiling-point, and, second, the liquid A. A well-known case of this kind is that of normal propyl alcohol and water ; the boiling-points under normal pressure are : water, 100° ; n-propyl alcohol, 97·2° ; mixture of minimum b.p. 87·7°.' This mixture contains 43·2 molecules p.c. of the alcohol ; it was described for many years as a hydrate of propyl alcohol. If the curve had the form d, the mixture would distil like a pure liquid if it had the composition r, or it would tend to separate into two components, the first being either A or B, according as the molecular percentage of A in the original mixture was greater or less than r, and the second the mixture of maximum boiling-point. Formic acid and water behave in this manner, as shown by Roscoe (Chem. Soc.

Trans. 13, 146; 15, 270). Boiling-points : water 100°; formic acid, 99·9°; mixture of maximum b.p., 107·1°; molecular percentage of acid in mixture, 56·7°.

If, as with ethyl alcohol and water (Fig. 11), the mixture of constant boiling-point distils at nearly the same temperature as one of the two pure liquids, it is impossible to separate that liquid in a pure state by distillation. In this
Fig. 11.

case, as the curve is exceedingly flat at the lower temperature (Noyes and Warfel, J. Amer. Chem Soc. 23, 463), it is practically impossible to separate the mixture of minimum boiling-point (containing 4·43 p.c. by weight of water) in a pure state even when water is in excess, although it is quite easy to separate pure water from dilute spirit.

The correct interpretation of the results of the fractional distillation of a complex mixture may be rendered very difficult by the following causes : (1) the presence of two components boiling at nearly the same temperature ; (2) the presence of one or more components in relatively very small quantity ; (3) the formation of mixtures of constant boiling-point. It is only by plotting the total weights of distillate against the temperatures, or by dividing the weight of each fraction, Δw, by its temperature range and tabulating the ratios $\Delta w/\Delta t$, that the results are likely to be understood, and in any case, the existence of a mixture of constant boiling-point may not be discovered, and it may be difficult to decide whether a distillate collected at a practically constant temperature consists of a single pure substance or of two liquids boiling at nearly the same temperature.

All the above difficulties are met with in the fractional distillation of petroleum, which contains homologous and isomeric paraffins, polymethylenes and their alkyl derivatives (naphthenes) and aromatic hydrocarbons, Russian petroleum being relatively rich, and American petroleum poor in naphthenes and aromatic hydrocarbons. When American petroleum was carefully distilled, it appeared at first as though the distillate coming over between the ordinary temperature and 40° contained only a single component, boiling at about 33°; but by systematic fractional distillation with a very

efficient still-head, it became evident (Fig. 12) that two components, isopentane, b.p. 27·95°, and normal pentane, b.p. 36·2°, were present (Young, Chem. Soc. Trans. 71, 440). Again, in the early fractionations there appeared to be no indication of the presence of any component boiling between 40° and 60°, but by tabulating the values of $\Delta w/\Delta t$, it was seen that a very small quantity of a liquid boiling at about 50° was present, and a distillate coming over almost constantly at 49·5° was eventually obtained. A chemical and physical investigation of this distillate showed, however, that it was a mixture of pentamethylene and a hexane of low boiling-point. The presence of benzene in American petroleum is indicated by the formation of dinitrobenzene, when the distillate from, say, 60° to 80° is treated with nitric and sulphuric acids (Schorlemmer, Annalen, 127, 311). But when the petroleum was carefully fractionated, it was found that the small fraction coming over at about 80° yielded no dinitrobenzene, the greater part being obtained from the fractions below 70°. This anomaly is explained by the fact that benzene forms a mixture of constant boiling-point with n-hexane, coming over at almost the same temperature as the paraffin. The amount of benzene being relatively small, the whole of it distils over at the low temperature. In Russian petroleum the percentage of benzene is so much greater that some of it comes over at its true boiling-point, 80·2° (Young, Chem. Soc. Trans. 73, 905).

(For a detailed discussion of the interpretation
Fig. 12.

of the results of the fractionation of complex mixtures, v. Fractional Distillation, chap. 19.)

Improved still-heads. It would be quite impossible to effect really difficult separations by means of the ordinary apparatus employed for distillation, and various modifications of the still-head have been devised in order to increase its efficiency. Even when the separation is an easy one, much time and material may be saved by the employment of efficient still-heads. Great progress was made in the improvement of the still-head in commerce—notably for the better separation of alcohol from weak spirit—before

any advance was made in the laboratory. It will, however, be more convenient to consider first those forms of apparatus which are suitable for laboratory purposes.

In choosing or constructing a still-head, the first point to be considered is its efficiency in separating the components of a mixture. It frequently happens, however, that the quantity of liquid available is small, and it is therefore important that the quantity of condensed liquid in the still-head at any moment shall be as small as possible. If the residual liquid is to value, it is also of importance that the condensed liquid in the still-head shall all return to the still after the source of heat is removed.

In comparing the efficiency and usefulness of different still-heads, it is necessary always to distil a mixture of the same composition; and the rate of distillation must always be the same, because the efficiency of any still-head is greatly diminished by increasing the rate. In the comparisons mentioned in this article, equal weights of pure benzene and pure toluene were employed, and the distillate was collected at the rate of one drop per second. Unless otherwise stated, 50 grams of the mixture were distilled.

Of all possible forms, the plain vertical still-head is the least efficient. During distillation, as the vapour rises up the cylindrical tube, the outer part of it comes in contact with the condensed liquid flowing down the sides of the tube. Since the tube is constantly losing heat by radiation and by conduction to the surrounding air, this liquid is constantly cooled and fresh condensation constantly goes on, the outermost layer of vapour probably condensing almost completely with little change of composition. The central portion of vapour rises rapidly up the tube, and can only reach the liquid by diffusion or by convection currents, and much of it may pass through the still-head without reaching the liquid at all; the condensed liquid, on the other hand, flows rapidly back to the still. In order, however, that a satisfactory separation of the components may take place, as much of the vapour as possible should come in contact with the hot condensed liquid, so that equilibrium, as regards composition, may be brought about all through the tube.

The efficiency of a plain vertical still-head is, roughly, proportional to its length. For tubes of equal length the efficiency is lowest when the internal diameter is about 14 mm. On the other hand, the quantity of liquid and vapour in the still-head increases regularly with the width of the tube; it is therefore better to use very narrow rather than very wide tubing.
Better contact between liquid and vapour, and therefore greater efficiency, is ensured by sloping the middle part of the tube, the extremities being kept vertical, and the efficiency is further improved by bending the sloping portion so as to form a spiral. In Young's 'rod and disc' still-head (Fig. 13), the downflow

FIG 13

of part of the condensed liquid is greatly retarded by the discs on the central glass rod, and this liquid is protected from the cooling

action of the air; at the same time, eddies and cross-currents are produced in the vapour. The increase in efficiency caused by the introduction of the easily constructed rod with discs is very marked. Wurtz (Ann. Chim. Phys. iii. 42, 129) recommended a vertical tube with a series of bulbs blown on it, and Young has shown that the efficiency is somewhat increased and the amount of liquid in the still-head is greatly diminished by blowing pear-shaped instead of spherical bulbs on the tube (Fig. 14). The 'rod and disc' and 'pear' still-heads are specially suitable for liquids of high boiling-point.

Greater efficiency, combined with diminished condensation of liquid in the still-head, is attained in Young's 'evaporator' column, one section of which is shown in Fig. 15. The
FIG. 14.   FIG. 15.

vapour rises up the inner tube, passes down between the inner and middle tubes, and up again between the middle and outer tubes, and so reaches the section above. The liquid condensed in the upper part of the still-head falls in drops from the depression at the top of the section on to the flattened top of the inverted middle tube, and spreads itself over its surface, falling again in drops from the bottom of this tube. The temperature of the vapour passing through the inner tube of any section being higher than the boiling-point of the condensed liquid falling on to the inverted tube, re-evaporation takes place to some extent, and, if there is much difference between the boiling-points of the components of the mixture being distilled, ebullition may actually occur. The quantity of condensed liquid in the still-head is thereby greatly reduced. The 'evaporator' still-head is specially suitable for accurate work where great efficiency is required (Chem. Soc. Trans. 75, 679; Wade and Merriman, ibid. 99, 984).

The 'Hempel' still-head (Zeitsch. anal. Chem. 20, 502) consists simply of a wide vertical tube, filled with glass beads of special construction, and constricted below to prevent the beads from falling out. A short, narrower vertical tube with side delivery tube is fitted by means of a cork into the wider tube. The advantages of the Hempel apparatus are simplicity and efficiency, but the amount of liquid in the still-head is excessive. Raschig employs thin rings

of copper or some other metal in place of the glass beads, the depth of a ring being about equal to its diameter. Lessing uses split rings, the metal being also bent inwards across the ring, thus (↑). These rings are easier to construct and give a larger surface; they give very good results. Rings are much lighter than beads.

The results obtained with various still-heads are given in Table II.

In many of the still-heads employed on the large scale, for example in the Coffey still (Fig. 28), the condensed liquid is caused, by means of suitable obstructions, to collect into shallow pools, and the ascending vapour has to force its way through these pools; very good contact is thus brought about between vapour and liquid at definite intervals. The excess of liquid is carried back from pool to pool, and finally to the still by suitable trapped reflux tubes. It is convenient to reserve the term 'dephlegmator' for this class of still-head. The 'Le Bel-Henninger' (Fig. 16) and the 'Glinsky' (Fig. 17) dephlegmators have been very frequently employed for laboratory work, but they do not give good results when small quantities of liquid are distilled; the dephlegmators of Brown (Chem. Soc. Trans. 37, 49) (Fig. 18) and of Young and Thomas (ibid. 75, 679) follow the principle of the Coffey still more closely, and are much better in this respect.

In a comparison of the Glinsky, Le Bel-Henninger, and Young and Thomas dephlegmators, each with three sections, it was found that when 400 grams of the mixture of benzene and toluene were distilled, there was not a great difference in efficiency, but the Glinsky was the least satisfactory. With 50 grams of the mixture the differences (Table II.) were
FIG. 16.   FIG. 17.   FIG 18.

quite noticeable, and with 25 grams they were greatly accentuated. With the Glinsky

[1] Unnecessarily long.

column the highest temperature reached was only 107·6°, and the residue, when distilled from a very small bulb, came over between 102·2° and 110·4°. No pure toluene was therefore obtained, and the residue left in the still was distinctly less pure than the last portion of distillate collected. With the Le Bel-Henninger column the highest temperature was only 107·25°, and the residue began to boil at 105·7°; with the Young and Thomas column the temperature just reached 110·6°, and the residue began to boil at 110·4°. The 'rod and disc,' the 'pear,' and the 'evaporator' still-heads gave better results when only 25 grams of the mixture were distilled, the residue in each case consisting of pure toluene. These results show that for small quantities of liquid the Young and Thomas dephlegmator gives much better results than the Glinsky or Le Bel-Henninger, but that none of them is so satisfactory as the other still-heads.

In order that a dephlegmator may give the best results, the following requirements should be fulfilled : 1. It should be possible to greatly increase the number of sections without seriously increasing the fragility of the apparatus   2. As the amount of condensed liquid flowing back at any level is greatest at the bottom and least at the top, it follows that, in order to form a pool, more complete obstruction is required at the top of the column than at the bottom.   3. Since the amount of condensed liquid in the still-head should be as small as possible consistently with efficiency, the reflux tubes should not be wider—in that part which is filled with liquid during distillation—than is necessary to carry back the liquid freely, and the traps should be no deeper than is required to prevent the ascending vapour from forcing its way through them.   On the other hand, the upper part of the reflux tubes should be wide, so as to facilitate the entrance of the liquid.   4. There should be a rapid flow of condensed liquid through the reflux tubes, otherwise the change in composition of the liquid in these tubes will lag behind that of the distillate.   5. There should be a reflux tube connecting each section with the one below it, so that the change in composition may be regular from top to bottom of the column.   In this respect the Glinsky dephlegmator is entirely wrong in principle.   6. When the distillation is completed, the residual liquid should return as completely as possible from the still-head to the still.   In this respect the dephlegmators as a class are less satisfactory than the other still-heads.

By surrounding the still-head with water or any other liquid, the temperature of which is kept as little above the boiling-point of the more volatile component as will allow of vapour passing through, a considerable improvement in the separation is effected.   The temperature of the bath, however, requires very careful regulation if the boiling-points of the components are near together, or if one component is present in large excess, for in either case a fall of a fraction of a degree would cause complete condensation of the vapour, while a slight rise of temperature would prevent any condensation from taking place, and there would be no fractionation whatever.   In constructing a regulated temperature still-head, it is advisable to bend the tube into

the form of a spiral, because its effective length may thus be greatly increased without unduly adding to the height of the bath, and also because the spiral form is more efficient than the vertical.   But Rosanoff and Bacon (J. Amer. Chem. Soc. 37, 301) find that an annular form of regulated temperature still-head is far more efficient and quite as simple as the spiral tube form.   This class of still-head was first recommended by Warren (Annalen, Suppl. 4, 51).   A better apparatus was described by Brown (Chem. Soc. Trans. 37, 49 ; 39, 517) (Fig. 19).   A combination of a regulated temperature still-head and dephlegmator was employed by Young and Thomas (ibid. 71, 440) for the separation of normal and iso-pentane from petroleum.
Experiments to test the relative efficiency of these various forms of apparatus have been made by Kreis (Annalen, 224, 259 ; Claudon, Bull. Soc. chim. 42, 613 ; Brown, Chem. Soc. Trans 37, 49 ; Young, ibid. 75, 679 ; Fractional Distillation, chaps. 10, 11, and 14 ; Friedrichs, Zeitschr. Angew. Chem., 32, 341).

Continuous distillation of wort has long been carried out on the large scale by means of the Coffey still (Fig. 28).   In 1902 Carveth (J. Phys. Chem. 6, 253) and Lord Rayleigh (Phil. Mag. vi. 4, 521) independently suggested apparatus intended for use in the laboratory.   The liquid to be distilled (or its vapour) is introduced continuously into the middle part of a long spiral or other still-head, the lower part of which is prevented, by means of a liquid or vapour-bath, from cooling below the boiling-point of the less volatile of the two components, while the temperature of the upper part is prevented, by means of a liquid bath, from rising above the boiling-point of the more volatile component. Lord Rayleigh obtained good results in the distillation of weak spirit.   It is probable that the method might be made applicable to the distillation of mixtures of three components (Fractional Distillation, 189).   See also Rosanoff, U. S. Pat. 1171464.   Constant temperature zones are utilised to obtain products of the desired composition.

As many of the stills used in the arts are described under the headings ALCOHOL, BENZENE, PARAFFIN, &c., it will be unnecessary here to give a minute description of all of them, but an account of the principles underlying the different methods will not be out of place.

The still is usually made of copper or some other metal, but for special purposes other materials must be employed.   Thus for the distillation of sulphuric acid, vessels of glass or platinum are used ; for nitric acid, cast iron is found to be the best material ; stoneware or glass stills are employed for bromine and iodine ; and so on.

The still may be heated by the free flame

FIG. 19.

of a furnace or by steam. Fig. 20 shows an arrangement for heating a still with steam, which may be above the atmospheric pressure.

When only a rough separation of the constituents of a complex mixture is required, as in
Fig. 20.

the preliminary distillation of coal tar, dephlegmators or rectifiers are not employed, but the vapours pass directly from the still to the condenser.

For the better separation of the components of a mixture, modified still-heads are employed. A simple apparatus, devised by Mansfield for the distillation of tar oils, is shown in Fig. 21 ; the vapours are partially condensed in the still-head A, which is cooled by water, and the condensed liquid flows back into the still B, the purified vapour passing on to the condenser C.
Fig. 21.

A more perfect separation is effected by Coupier's apparatus (Fig. 22). In addition to the column A, there is a series of bulbs, B, B, placed in a cistern containing brine, which may be heated by steam by means of the pipe C. The vapour— of benzene, for example—partially freed from less volatile substances in the column, is further purified by partial condensation in the bulbs, the condensed liquid flowing back by the tubes D, D into the column, while the purified vapour passes on to the condenser by the pipe E.

A very similar arrangement is seen in the French column apparatus (Fig. 23). The liquid is heated by a steam coil in A; the vapour is

partially purified in the rectifier B; it is further freed from the less volatile components in the
Fig. 22.

condensing apparatus C, and finally reaches the condenser D.
Fig. 23.

In Savalle's apparatus also the vapours pass first through a dephlegmator or analysing column, then through a surface or multitubular condenser, which is provided with a water supply, so regulated that its temperature is about that of the boiling-point of the liquid required ; the liquid condensed in the regulated-temperature still-head returns to the dephlegmator, and the purified vapour passes on to the cold condenser.

In most of the still-heads employed on the large scale, the vapour first passes through a dephlegmator, the construction of which varies considerably in different cases. Dubrunfaut's dephlegmator, employed in the French column apparatus, is shown in Fig. 24. Two others, devised by Savalle, are represented in Figs. 25 and 26.
Fig. 24.

In the Ergot dephlegmator an arrangement somewhat similar to the dome (Fig. 24) is used, but a large number of these domes are placed in each tray, and the condensed liquid is made to follow a zigzag course from the circumference to the centre of each tray.
FIG. 25.   FIG. 26

The principle of the still-head in the Pistorius still is quite different. The vapour, entering a section (Fig. 27) of the still-head, is deflected from centre to circumference by the flat dome; it then passes back to the centre above the dome, and is partially condensed by the water in the shallow vessel above. It may be pointed out that if, in the Pistorius still-head, the 'roof'

of the section were depressed at the centre instead of the circumference, the condensed liquid would drop on to the flat dome below, and the arrangement would then be somewhat
FIG. 27.

similar to that of the 'evaporator' still-head (Fig 15). In all probability the efficiency of the still-head would thereby be greatly increased. Kubierschky (Ger. Pat. 269995. 1913) has devised an excellent column in which the liquid
FIG. 28.

falls in drops through perforated plates, whilst the vapour passes freely upwards and downwards, travelling from centre to circumference and from circumference to centre alternately, coming into intimate contact with the falling drops.

A simple and efficient still-head has been described by Foucar (Eng. Pat. 19999 of 1908). The column consists essentially of a helical septum which traverses the annular space

between two concentric cylinders. The vapour from the still passes up the long spiral passage before reaching the condenser. The inner cylinder can, if desired, be used as a thermostat, the column then acting as a regulated-temperature still-head. Dutton (J. Soc. Chem. Ind. 38, 45 T.) has described a still-head, suitable for laboratory work, somewhat similar in principle to Foucar's. A spiral of wire is wound round an inner closed tube which fits quite loosely in the

outer tube of the still-head. But excessive condensation, with consequent priming, must be prevented by covering the tube with a thick layer of cotton wool. The still-head is stated to give very good results.

A. Hirsch (J. Ind. Eng. Chem. 1910, 2, 409) recommends the use of a differential condenser in the still-head, in the form of a spiral of metal tubing, through which a current of water is regulated initial and final temperature is caused to flow. The apparatus works easily and well so long as the temperature of the vapour leaving the still-head is considerably lower than that of the vapour entering it; but the difficulty of regulation increases greatly as this temperature-difference diminishes.

For work on the large scale Hirsch recommends the introduction of a differential condenser between the lower and upper parts of a rectifying column

In England, the Coffey still is largely used; it differs considerably from those described, inasmuch as there is no large boiler, and the heat is supplied, not from an outer fire or steam-jacket, but by the condensation of steam in the wort; moreover, the process is continuous. The essential parts of the apparatus are shown in Fig. 28 (p. 568). The wort is pumped from a reservoir A, up the pipe B, and passes down the zigzag pipe CC, where it is heated by the ascending vapours, then up the pipe D, from which it is discharged into the column E It is prevented from falling through the perforated plates of the column or analyser by the ascending vapours, but falls through the pipes F, F, from one plate to another until it reaches the bottom, when it is allowed to escape. Meanwhile, steam is passed into the analyser E by the pipe H, and causes the wort to boil, so that by the time it has reached the bottom it is completely deprived of alcohol. The ascending vapours force their way through the perforated plates of the analyser, a portion of the aqueous vapour being condensed by each washing, and the descending wort being thereby heated. On reaching the top of the column, the concentrated alcoholic vapour passes down the pipe K into the rectifier, and there ascends through similar perforated plates; but in the rectifier it is not washed by wort, but by the weak alcohol formed by the previous condensation of vapour. This dilute alcohol, on reaching the bottom of the rectifier, flows off into a reservoir, from which it is pumped into the top of the analyser, where it mixes with the descending wort. In the upper part of the rectifier there are simply shelves, which compel the vapour to take the same zigzag course as the pipe which conveys the wort downwards. The purified and concentrated vapour then passes through the pipe L to the condenser. In modern continuous stills of the Coffey type there are special arrangements for the separation of (a) volatile impurities such as aldehyde, (b) pure rectified spirit, (c) fusel oil. For details the articles on ALCOHOL, etc., should be consulted. S. Y.

DISTYRENE C₁₆H₁₆. Produced by heating styrene (q.v.) with hydrochloric acid at 170° (Erlenmeyer, Annalen, 135, 122). Also, together with distyrenic acid and carbon dioxide, by prolonged boiling of cinnamic acid with diluted sulphuric acid (Fittig, Ber. 12, 1739–1744; Erdmann, Annalen, 216, 179–199).

A colourless optically inactive oil, with a blue fluorescence, which gradually disappears; sp.gr. 1·016 at 15°; b.p. 311°. On prolonged boiling yields toluene, isopropylbenzene, and some styrene; whereas metastyrene, produced from styrene on keeping, or heating in sealed tubes at 200° (Kovalevsky, Annalen, 120, 66), or with aqueous sodium bisulphite at 110° (Miller, ibid. 189, 341), passes almost quantitatively into styrene at 320° (Stobbe and Posjnak, ibid. 371, 259–286).

Distyrene yields benzoic acid on oxidation with chromic acid; and a crystalline dibromide C₁₆H₁₆Br₂ (m.p. 102°) on brominating in carbon disulphide solution.

According to Stobbe and Posjnak (Annalen, 371, 287–302), distyrene is αγ-diphenyl-Δᵅ-butene

$$C_6H_5-CH=CH-CH(CH_3)-C_6H_5$$
Distyrene disulphonic acid (dicinnamene disulphonic acid) C₁₆H₁₄(SO₃H)₂, described by Lange as obtained on heating γ-truxillic acid with sulphuric acid (Ber. 27, 1410–1415), is therefore not a derivative of distyrene.

Solid distyrene; m.p. 124°; obtained by distilling cinnamic acid or its calcium salt (Engler and Leist, Ber. 6, 256; Miller, Annalen, 189, 340), and by passing C₆H₅·C₂H₃Br₂ over red-hot lime (Radziszewski, Ber. 6, 494), has been shown by Erlenmeyer (Annalen, 372, 249–251) to be stilbene.

DISULPHO ACID S. *Delta acid,* 1-*Naphthyl-amine-*4 : 8-*disulphonic acid v.* NAPHTHALENE.

DITA BARK. *Satween* (Ph. J.' Trans. [3] 7, 110). The bark of *Alstonia scholaris* (R. Br.), an apocynaceous tree found in India, the Philippines, Eastern Australia, and tropical Africa (Ber. 11, 2234).

According to Harnack (ibid. 11, 2004; Chem. Soc. Trans. [2] 36, 332), it contains only one base, *ditaine,* a basic glucoside, having the composition C₂₂H₃₀N₂O₄; but Hesse (Annalen, 203, 144; Ber. 13, 1750; Pharm. J. [3] 11, 251, 331) found in it three bodies: *ditamine,* C₁₆H₁₉NO₂; *echitamine* (ochitammonium hydroxide), C₂₂H₂₈N₂O₄,H₂O, melting with decomposition at 106° (this base is identical with Harnack's *ditaine*); and *echitenine* C₂₀H₂₇NO₄, a brown amorphous mass, melting above 120°, soluble in chloroform, alcohol, and ether. It dissolves in nitric acid with the production of a purple-red colour which quickly passes through green into yellow.

The milky juice of this tree has the same properties as guttapercha; when inspissated it softens in boiling water, is soluble in turpentine and chloroform, and receives and retains impressions. A decoction of the bark is used as an astringent tonic.

DITAÏNE *v.* DITA BARK.

DITHION. Trade name for sodium dithio-salicylate: used as an antirheumatic.

DITTANY. The root of *Dictamnus albus* (Linn.) (ord. *Rutaceæ*), a native of the south of Europe. It contains a volatile oil, and also resin, bitter extractive matter, and gum; and was formerly employed in medicine, especially for the treatment of epilepsy (Aldis, Lond. Med. Gaz. 19, 142).

'*Cretan Ditany*' is the common name for *Origanum dictamnus* (Linn.), a native of the Levant.

DIURETIN. A compound of sodium

theobromine and sodium salicylate (*v.* SYNTHETIC DRUGS).

DIVICINE *v.* VICINE.

DIVI-DIVI. Divi-divi consists of the dried pods of the *Cæsalpinia coriariæ* (Willd.), a tree 20–30 feet high, found in the West Indies and Central America. The pods are about 3 inches long and ¾ inch broad, are very thin, and frequently resemble in shape the letter S. From 40 to 45 p.c. of tannin is present, which consists of ellagitannin and probably also gallotannin. Extracts of this material have a somewhat unfortunate tendency to ferment, with simultaneous development of a deep-red colouring matter; but this can be prevented to some extent by the use of antiseptics. Divi-divi is largely imported for the preparation of leather, and is also employed for black dyeing, but its use is far more limited in this latter respect than myrobalans.   A. G. P.

DOCIMACY or **DOCIMASY.** (*Docimasie*, Fr.) Originally the act or art of examining by test (δοκιμασία, a test), applied in metallurgy to experiments made to determine the nature and purity of a metal; in pharmacy, to the testing of medicines and poisons; in medical jurisprudence, to the different proofs to which the lungs of a new-born child are subjected, for the purpose of ascertaining whether it was born alive or dead (Dunglison). Usually employed in chemistry as synonymous with assaying.

n-**DODECANEDICARBOXYLIC ACID**

$$CO_2H(CH_2)_{12}CO_2H$$
Prepared by hydrolysing the diethyl ester obtained by the electrolysis of an aqueous solution of the monoethyl ester of suberic acid (Brown and Walker, Annalen, 261, 123); or by the oxidation of chaulmoogric acid, obtained from chaulmoogra seeds (Barrowcliffe and Power, Chem. Trans. 1907, 568); m.p. 123°.

DODECATOIC ACIDS $C_{12}H_{24}O_2$.

1. *Lauric acid*, found by Marsson in laurel fat, a glyceride obtained from *Laurus nobilis* (Linn.) (Marsson, Annalen, 41, 330); also present in cocoa-nut oil (Görgey, *ibid.* 66, 295), in pichurin beans, in Dika bread, and in the fruit of *Cylicodaphne sebifera* (Oudemans, Zeitsch. Chem. 1867, 256); m.p. 43·5; (m.p. 47·5°–48°, Levene and West); sp.gr. 0·883/20° and 0·875/43·6°; b.p. 225·5° (100 mm.).

2. *Hordeic acid* is found among the products of the distillation of dried barley with dilute sulphuric acid; forms crystalline plates; m.p. 60° (Beckmann, J. 1855, 513).

DOG-TOOTH SPAR. The scalenohedral form of calcspar (*v.* CALCITE or CALCSPAR).

DOLERITE. An igneous rock composed essentially of plagioclase-felspar (labradorite to anorthite) and augite, and of the same general chemical and mineral composition as the coarse-grained plutonic gabbros and the fine-grained volcanic basalts, but intermediate in texture between these two extreme types. Other minerals may also be present, especially olivine, giving the varieties olivine-dolerite, enstatite-dolerite, hornblende-dolerite, mica-dolerite, and quartz-dolerite. Accessory minerals, usually present, are magnetite and ilmenite; and secondary minerals, produced by alteration, include quartz, calcite, epidote, chlorite, and serpentine. Dolerites occur as intrusive veins,

dykes, and sills; and very often they pass imperceptibly into basalts. The texture may be coarse enough for the individual mineral to be distinguishable to the unaided eye, or it may be so fine that these can only be distinguished in thin sections under the microscope. In the latter case the rock is compact and dark greenish-black or black in colour. Often, owing to the presence of secondary minerals, the colour is distinctly green, and the rock is then frequently included under the general term 'greenstone.' The specific gravity ranges from 2·8 to 3·0, and the crushing strength is about 1500 tons per square foot. The following analyses are of dolerite from I, Rowley Regis, Staffordshire; II, Clee Hill, Shropshire; III, quartz-dolerite from the Whin Sill, Co. Durham (including MnO 0·16, CO_2 0·19, P_2O_5 0·25, FeS_2 0·49); IV, olivine-dolerite from Skye (including MnO 0·17, BaO 0·06, P_2O_5 0·17).

	I.	II.	III.	IV.
SiO_2 . .	49·0	48·4	51·22	50·33
TiO_2 .	2·8	3 1	2·42	1·81
Al_2O_3 .	15·3	13 4	14·06	19·97
Fe_2O_3 .	2 6	4·0	4·32	2·81
FeO .	8 2	8·5	8·73	6·23
CaO .	8·2	8·6	8 33	8·03
MgO .	4 9	6·5	4·42	3·24
K_2O .	.2·6	2·1	1·25	1·19
Na_2O	2·5	3·1	2 55	4·30
H_2O .	3·3	2 2	1·28	1·86

Dolerites are of wide distribution and are much quarried for road-metal and paving-setts. Being difficult to work and of a dull colour, they are not much used as building stones (*v.* DIABASE).
                                        L. J. S.

DOLOMITE. This term includes both dolomite-spar and dolomite-rock, both of which are often referred to simply as dolomite. They bear the same relation to one another as calcite (calc-spar) to limestone, and as quartz to quartzite; these being cases in which a single mineral species builds up a rock-mass. The name dolomite, after the French geologist, D. G. Dolomieu (1750–1801), was first applied to the rock, being later extended to the crystallised mineral. The rock is now often referred to as dolomitic limestone or magnesian limestone.

The pure mineral (*Dolomite-spar*) is a double salt of calcium and magnesium carbonates, $CaMg(CO_3)_2$; containing $CaCO_3$ 54·28, $MgCO_3$ 45·72 p.c., or CaO 30·42, MgO 21·86 p.c. It is a member of the isomorphous series of rhombohedral carbonates (calcite group), and has an angle of 73° 45' between the surfaces of the perfect rhombohedral cleavages. It, however, differs from the other members of the group in the degree of symmetry of its crystals, which are hemihedral with parallel faces. It further differs from calcite in the fact that it never shows lamellar twinning on the obtuse negative rhombohedron. The most usual form of crystal is the primary rhombohedron, the faces of which are parallel to the cleavage directions (this being an unusual form in calcite, except in combination with other forms). The faces are frequently curved, sometimes to such an extent that the crystals are saddle-shaped. The most perfect crystals, such as those found in the crystalline dolomite rock of the Binnenthal

in Switzerland, are colourless and transparent with a vitreous lustre. More often the crystals are white or creamy-white and opaque with a pearly lustre; hence the popular name *pearl-spar*. The mineral is harder (H. 3½–4) and denser (sp.gr. 2·85) than calcite. It may be readily distinguished from the more commonly-occurring calcite by the fact that it is only slightly attacked by cold dilute acid; in hot acid it dissolves with a brisk effervescence. Dolomite is much less soluble in water containing carbon dioxide (3 parts in 10,000 at 18°) than is calcite. Various micro-chemical tests have been devised for the purpose of distinguishing dolomite and calcite, especially in thin sections of rocks. Lemberg's solution contains aluminium chloride and a staining material (haematoxylin or an aniline dye); a stained film of aluminium hydroxide deposits on calcite, but not on dolomite. The composition of dolomite may be varied somewhat by isomorphous replacement. Iron and manganese may replace magnesium, forming a passage through *brown-spar* to ankerite (*q.v.*). Zinc or cobalt is also sometimes present in small amount. Any excess of calcium over the double salt ratio may perhaps to some extent be present in isomorphous mixture, but more often it is probably present as mechanically admixed calcite. Simple ratios of $CaCO_3 : MgCO_3$ other than the 1 : 1 of ' normal dolomite,' probably do not exist. Several trivial names have been applied to varieties of dolomite showing peculiarities of structure or supposed differences in composition; the analyses have not, however, always been made on well-crystallised material.

The best crystallised specimens of dolomite are met with in mineral veins and other metalliferous deposits. For example, with iron ores at Traversella in Piedmont, and Cleator Moor in Cumberland; with lead and zinc ores at Laxey in the Isle of Man, and Joplin in Missouri; with silver ores at Schemnitz in Hungary, and Guanaxuato in Mexico. Crystalline masses occur in serpentine, talc-schist, and other magnesian silicate rocks. As a rule, only quite small crystals are found in dolomite rocks, but occasionally good crystals are found in cavities.

Dolomite rock, dolomitic or magnesian limestone, is, as a rule, more indefinite in its characters and composition, since here the dolomite mineral is mixed with other mineral substances, such as calcite, carbonates of iron and manganese, oxide and hydroxides of iron, argillaceous matter, quartz, etc. With increasing calcite the rock may pass into ordinary limestone; and some authors restrict the term ' magnesian limestone ' to rocks intermediate between ' normal dolomite ' and ordinary limestone. The presence of calcite in a magnesian limestone containing a molecular excess of calcium over magnesium may be demonstrated by etching a polished surface or a thin section with cold dilute acid, when the calcite will be readily dissolved out leaving pits; or by means of the staining test with Lemberg's solution mentioned above.

The purest dolomite rocks are the snow-white crystalline dolomite marbles of the Swiss Alps, Norway, &c., which have sometimes the character of a statuary marble and can be used for ornamental purposes. More often, however, the rock is yellowish, grey, creamy, or brown, and very often cavernous in texture. It is

usually minutely crystalline, consisting of an aggregate of tiny rhombs of dolomite-spar more or less firmly held together, but at times quite loose and sandy. Dolomite rock is of wide distribution and is met with in sedimentary strata of all geological periods. In England a long narrow outcrop extends along the eastern slopes of the Pennines from Nottinghamshire to the Durham coast. This has long been extensively quarried as a building stone, the principal quarries being near Anston in Yorkshire, Bolsover Moor in Derbyshire, and Mansfield Woodhouse in Nottinghamshire. Here the rock is of Permian age. In the Dolomite mountains of southern Tyrol the rock is of Triassic age, whilst that of Swabia belongs to the Jurassic formation.

The origin of dolomite rock has been a subject of much speculation and experimental work of a chemical character. A review is given in Doelter's Handbuch der Mineralchemie, 1912, vol 1. (here also is given a large collection of analyses, methods of analyses, &c.). That of Permian age, which is usually associated with beds of gypsum and rock-salt, is supposed to have been deposited as the double carbonate by chemical precipitation from the salt waters of inland seas. In some other cases the rock has been formed by the action of magnesium-bearing solutions on limestone; either contemporaneously and progressively with the formation of the limestone (as proved by the dolomitisation of coral-limestone—the magnesium in this case being derived from sea-water); or long subsequently by the action of subterranean mineral-waters percolating along the bedding and joint planes (as in the Carboniferous Limestones of Derbyshire and South Wales). Or again, it may have been formed by weathering and the solution of the more soluble calcium carbonate from limestones containing a small proportion of magnesium.

The following are analyses of dolomite rock: I, from Bolsover, Derbyshire; II, Mansfield, Nottinghamshire; III, Anston, Yorkshire; IV, Southern Tyrol —

	I.	II.	III.	IV.

H_2O .	3·3	2·1	0·75	—

The economic applications of dolomite are confined to the rock, since this is much more plentiful and of wider distribution than the crystallised mineral. Its principal use is as a building stone. For this purpose it is more suitable than ordinary limestone, being harder and more resistant to solvents, but it needs to be carefully selected. It is also used for paving and road-metal. The Houses of Parliament are built of stone from the three English localities noted above (Anal. I.–III). The stones from these quarries have a crushing strength of 484–883 tons per square foot, absorption of 4·6–7·5 p.c., and weigh 134–152 lbs. per cubic foot. Certain varieties of dolomite rock (dolomite marble) find an application as an ornamental stone. Dolomite rock is also extensively used for the basic linings of Bessemer converters and

open-hearth furnaces in the manufacture of steel. For this purpose the rock is calcined until it commences to sinter, crushed, mixed with gas-tar, and moulded in the furnaces or shaped into bricks. The best result is obtained when the rock contains 3–4 p.c. of Fe_2O_3 and Al_2O_3, and about $2\frac{1}{2}$ p.c. of SiO_2. (On British sources of dolomite rock for use as a refractory material, v. Mineral Resources of Great Britain, Mem. Geol. Survey, 1918, vol. vi.) The rock is completely burnt or half burnt below a red heat (giving $MgO+CaCO_3$) for the preparation of cements and plasters; when it contains quite a small amount of argillaceous matter it gives a good hydraulic cement. It is also burnt for agricultural purposes, and is said to be especially beneficial for leguminous crops. It is a readily available source for the manufacture of magnesium compounds, e.g. Epsom salts, magnesium chloride, magnesia alba; but in this direction it was not able to compete with the large quantities of soluble magnesium salts obtained as by-products from the Prussian salt-deposits. Various processes have been suggested for extracting the magnesia for use as a refractory material. In one, the calcined dolomite is mixed with magnesium chloride, forming calcium chloride which is readily removed in solution. In another, the calcined dolomite is treated with a solution of sugar, when the calcium passes into solution as saccharate, from which the sugar can be recovered by precipitating the calcium as carbonate with carbon dioxide. When half burnt to $MgO+CaCO_3$ the magnesia can be extracted by carbonated water under pressure. The pure white dolomite marble is used for the manufacture of pure carbon dioxide for use in the manufacture of aerated waters.   L. J. S.

DOMEYKITE. A copper arsenide, Cu_3As, corresponding to copper 71·7 and arsenic 28·3 p.c. It occurs in reniform, botryoidal, and compact masses, of white or grey colour, with metallic lustre, rapidly tarnishing. H.=3–3·5; sp.gr. 7–7·5. Readily fusible before the blowpipe, with emission of arsenical vapours. Soluble in nitric acid, but not in hydrochloric acid. It is found at Coquimbo and Copiapo in Chile, at Cerro las Paracatas in Mexico, and at Zwickau in Saxony.

Several other arsenides of copper, more or less like domeykite, are known. The *Algodonite* of F. Field is Cu_6As, and occurs at the Algodones mine, near Coquimbo. *Whitneyite*, from Houghton Co., Michigan, U.S., described by F. A. Genth, is Cu_9As; and D. Forbes's *Darwinite*, named after Charles Darwin, is a similar mineral from near Copiapo. *Condurrite*, from Condurrow mine, Cornwall, appears to be a mixture of arsenide of copper with various oxidised products derived from the alteration of tennantite or some kindred species. The names *Keweenawite*, *Mohawkite*, and *Ledouxite* have been applied to various copper arsenides from Michigan, in which the copper is in part replaced by nickel and cobalt.   L. J. S.

DONARITE. An explosive consisting of a mixture of ammonium nitrate (80 pts.), trinitrotoluene (12 pts.), nitroglycerine (3·8 pts.), gun-cotton (0·2 pt.), flour (4 pts.).

DORMIGENE. A urea derivative of α-bromo-isovalerianic acid. Used as a nervous sedative.

DORMIOL. A condensation product of chloral and tertiary amyl alcohol. V. SYNTHETIC DRUGS.

DOSS. Japanese name for a dyewood from an evergreen tree *Ilex Mertensii* (Maxim.), found in the Ogasawara and Okinawa Islands. Contains a dyestuff, *dossetin* $C_{15}H_9O_8$, crystallising in yellow needles; m.p. 271°–272° (Ito, J. Soc. Chem. Ind. 1908, 440).

DOUBLE SCARLET, BRILLIANT SCARLET v. AZO- COLOURING MATTERS. ·

DRACYL. An obsolete synonym for toluene.

DRAGON'S BLOOD. A resin used as a red pigment (v. PIGMENTS; also RESINS).

DRIERS (in the United States also termed 'Japans') is the trade term for those metallic oxides, chiefly oxides of lead, manganese (litharge, red lead, manganese dioxide) and cobalt or their inorganic salts, which were formerly used exclusively in the process of oil boiling as 'driers.' More recently acetate, oxalate, and borate of manganese have been employed. Since metallic salts of linseed oil have the same property, such salts are also manufactured as 'driers.' They are obtained either by precipitating rosin soap solutions with solutions of metallic salts, or by fusing together a metallic oxide with colophony. Hence these are distinguished in commerce as 'precipitated' driers, and 'fused' driers. The latter are readily discriminated from the former by their not containing any moisture. Metallic salts of linseed oil fatty acids are now used as driers; they can be prepared either by precipitation or by the dry process, hence both 'precipitated' manganese linoleate, 'precipitated' lead linoleate, and 'fused' manganese linoleate, &c., are obtainable. The driers prepared from linseed oil fatty acids, as also from rosin (colophony), are soluble in oil of turpentine, ether, chloroform, and linseed oil itself. Hence they are also termed in commerce 'soluble driers.' Solutions of these driers in linseed oil or in turpentine oil, or in a mixture of both, are obtainable in commerce under the name 'liquid driers,' 'terebene,' and other fancy names.

The function of these driers appears to be to absorb oxygen from the air and transfer it to the linseed oil, thus accelerating its drying to a flexible film when exposed to the air. On this assumption, the fact that litharge and manganese dioxide act as driers will be best explained by stating that at the high temperature at which linseed oil is 'boiled,' the oxides saponify the linseed oil, forming therewith lead or manganese soaps, which then act in their turn in the manner indicated above. From experiments on the behaviour of cerium salts obtained from various drying oils, Morrell (Chem. Soc. Trans. 1918, 113, 111) concludes that a change occurs in the intra-molecular linkings when drying oils are polymerised by heat. The action of cerium α-oleostearate (from tung oil) as a drier may be represented by the following scheme:—

$$CeX_3 \text{ or } CeOX_6 \rightarrow Ce_2(XO_2)_6$$
$$CeO(XO_3)_6 + \text{drying oil}$$
$$\rightarrow CeX_3 + O\cdot CHY$$
$$| \quad \text{[oxidised oil]}$$
$$O\cdot CHZ$$

This representation is also in accord with the

conclusions of Ingle (J. Soc. Chem. Ind., 1917, 318) as to the behaviour of lead linolenate. Cerium driers are less effective than cobalt or manganese linoleate in accelerating the drying of a varnish containing a lead drier. The following are the analytical data obtained by the author in the examination of a drier :—

				Per cent.
Ash	.	.	.	18·6
Fatty and rosin acids	.	.	83·4

The more detailed examination gave the following result :—

				Per cent.
Lead oxide	.	.	.	10·99
Manganous oxide	.	.	6·79
Iron peroxide	.	.	.	0·47
Calcium oxide	.	.	.	0·56
Rosin acids	.	.	.	38·32
Oxidised acids	.	.	4 24
Other fatty acids	.	.	40·86

It should, however, be understood that the results furnished by chemical analysis alone are not sufficient to supply the data on which to base an opinion as to the properties which a drier will impart to the oil The colour and drying power of the boiled oil to be prepared and other conditions greatly influence the choice and the quantity of a drier to be employed on a large scale. J. L.

DROP GUM or **GAMBOGE** v. PIGMENTS.

DROSERA WHITTAKERI. *Drosera whit-takeri* is found in Australia, and grows plentifully on the hills near Adelaide. The tuber of this plant consists of an inner solid but soft nucleus full of reddish sap or juice, and an outer series of easily detached thin, and more or less dry, layers of an almost black material. Between these layers are to be found small quantities of a brilliant red colouring matter, the amount varying in tubers of different size and age, but apparently more plentiful in the older plants (Rennie, Chem Soc. Trans , 1887, 51, 371 ; 1893, 63, 1083).

The colouring matter is extracted from the tubers by means of hot alcohol, the solution evaporated, and the residue, containing a little alcohol, is then mixed with water and allowed to stand. The product is dried, sublimed, and the brilliant vermilion powder, which contains two substances, is fractionally crystallised from boiling alcohol, or acetic acid.

The •more sparingly soluble compound $C_{11}H_8O_5$ forms red plates, melts at 192°-193°, dissolves in alkaline solutions with a deep red violet colour, and gives a *triacetyl derivative*, $C_{11}H_5O_5(C_2H_3O)_3$, melting-point 153°-154°.

The *monosodium* compound $C_{11}H_7O_5Na,2H_2O$, gives dark reddish-brown needles, the *disodium* compound $C_{11}H_6O_5Na_22H_2O$, brown needles, and the *calcium* compound $(C_{11}H_7O_5)_2Ca,3H_2O$, dark brown crystals.

By treatment with stannous chloride or hydrochloric acid, this substance $C_{11}H_8O_5$ yields a reduction product $C_{11}H_{10}O_5$, yellow needles, melting-point 215°-217°. When dry, this is stable in air, but if left in contact with alcohol or water, it soon becomes red owing to oxidation. According to Rennie it is probable that the original colouring matter is a *trihydroxymethyl-naphthoquinone*, in which case the substance $C_{11}H_{10}O_5$ will consist of the corresponding

hydroquinone derivative. The more readily soluble compound contained in the tubers possesses the formula $C_{11}H_8O_4$. It crystallises in red needles, melting-point 174°-175°; dissolves in alkaline solutions with a deep-red colouration; and gives a *diacetyl* derivative, $C_{11}H_6O_4(C_2H_3O)_2$, yellow needles, melting-point 107°-110°. A. G. P.

DRUMINE. An alkaloid stated to be present in *Euphorbia Drummondii* (Ogston, Brit. Med. Jour. 1887, 451).

DRY CLEANING. French or chemical cleaning, *Nettoyage à Sec*. A process of removing dirt, grease, &c., from fabrics by solvents other than water, such as petroleum benzine, coal-tar benzene, carbon tetrachloride, &c. The substitution of such liquids for water seems to have been first made in France during the middle of the last century by the application of ' camphene,' a terpene used at that period for illuminating purposes.

The process was introduced into the United Kingdom, in 1866, by Messrs. Pullar & Sons, who greatly developed it, employing machinery to a large extent in place of the hand labour formerly used.

The solvents mainly used at the present time are ' benzines,' usually obtained from American and Borneo petroleum, of sp.gr. 0·78 ; boiling between 80° and 120°. The benzols employed are what are known commercially as 90's and 50's. They may contain sensible quantities of carbon disulphide, thiophen, and possibly other sulphur products, which are apt to impart a disagreeable smell to the fabric. Carbon tetrachloride, on account of its relatively high price, is only used to a limited extent. It has the great advantage over the hydrocarbons that it is uninflammable, and can be employed in particular cases where the use either of benzine or of benzol is inadmissible. (For a method of valuing benzine for the purpose of the dry cleaner, v. Trotman, J. Soc. Chem. Ind. 1906.)

Thiophen in benzol may be detected by the isatin and sulphuric acid reaction (v. THIOPHEN). (*Cf.* Schwalbe, Chem. Zeit. 1905.)

Carbon disulphide may be detected by the formation of a precipitate with phenylhydrazine, and determined quantitatively by conversion into potassium xanthate by means of alcoholic potash (v. CARBON DISULPHIDE).

An admixture of paraffin hydrocarbons with the benzol may be recognised by nitrating the sample with nitrosulphuric acid and subsequent steam distillation. •

The carbon tetrachloride employed for degreasing should be free from hydrochloric acid or traces of free chlorine. It should also contain no chloroform or phosgene gas, which are apt to act deleteriously upon the workpeople.

Special soaps, soluble in benzine, are employed in dry cleaning. They not only assist the degreasing, but diminish the risk of fire. The soaps consist of practically anhydrous oleates or stearates of potash or soda made by melting together oleic acid and soap, or by dissolving the alkali in methylated spirit, and adding to the solution the requisite quantity of oleic acid or melted stearic acid. Strong ammonia solution may be employed instead of potash or soda. •

(For a description of the methods and

machinery employed in modern processes of dry cleaning, and of the apparatus for the recovery and purification of the solvents used, v. Dyeing and Cleaning, by F. J. Farrell, Griffin & Co., Ltd. 1910.)

DULCAMARA. *Bittersweet, Woody night-shade.* (*Douce amère*, Fr. ; *Bittersuss*, Ger.) The young branches of the *Solanum dulcamara* (Linn.), were formerly administered as a decoction in rheumatism and skin diseases. They contain an amorphous glucoside *dulcamarin* $C_{22}H_{34}O_{10}$ (Geissler, Arch. Pharm. [iii.] 6, 1010) ; and *solanine* $C_{42}H_{75}O_{12}N$, m.p. 235° ; *solanidine* $C_{41}H_{71}O_2N$, m.p. 205° ; and *solaneine* $C_{48}H_{78}O_{13}N$ (Davis, Pharm. Y. [iv.] 15, 160). G. B.

DULCIN. *p*-Phenetol-carbamide

$$C_2H_5O \cdot C_6H_4 \cdot NH \cdot CO \cdot NH_2$$

A sweet substance. Used as a substitute for saccharin.

DULCITOL *v.* CARBOHYDRATES.

DUMASIN. Pentamone. *v.* KETONES.

DUNGING SALT. *Sodium Arsenate v.* ARSENIC.

DUOTAL. Guaiacol carbonate
formed by the action of phosgene gas on an alkaline solution of guaiacol. Used in the treatment of phthisis.

DURA or **DARI.** A grain imported from India and the Sudan, chiefly as a poultry food. Composition : moisture, 8·45 ; proteins, 12·98 ; other nitrogenous substance, 0·08 ; fat, 3·30 , starch, 62·66 ; other carbohydrates, 9·74 ; fibre, 1·03, ash, 1·71 p.c. ; food units 113·3 ; nutrient ratio, 1 : 6·1. Contains no alkaloids or cyanogenetic glucosides (Bull. Imp. Inst 1913, 11, 33) For the use of Sudan Dura as a brewing material, *see* Briant & Harman, Journ. Instit. Brewing, 1918, 209.

DURENE *v.* CYMENES.

DURENOL *v.* PHENOL AND ITS HOMOLOGUES.

DUTCH PINK or **ITALIAN PINK** *v.* PIGMENTS.

DUTCH ULTRAMARINE. *Cobalt blue v.* COBALT AND PIGMENTS.

DURINE. A preparation of formaldehyde.

DYEING. The art of dyeing consists in imparting colour to the substance of various materials, usually textile fabrics, in such a manner that it is not readily removed or altered by those influences to which the dyed material is subsequently exposed. *Tinting* is essentially the same as dyeing, but the term is applied to the production of light shades only. In *staining*, the colour is not so permanently fixed as in dyeing, but in all these processes the colouring substance is presented to the material in a dissolved condition. In textile *printing*, the colour is applied to portions of the material only, thus producing a pattern, but in other respects, many printing operations are, in principle, similar to dyeing. In some processes of textile printing, as in *painting*, on the other hand, a more or less opaque pigment is applied to the surface of the material by means of adhesives, thus partially or entirely obscuring the true surface.

Dyeing is of chief importance in connection with the textile industries, but many other materials are coloured by dyeing processes, such, for example, as leather, feathers, horn, ivory, bone, straw, and wood.

The various materials above enumerated show remarkable differences in behaviour towards any particular dyestuff. Wool, silk, leather, feathers, horn, and animal skin products in general, behave somewhat similarly towards colouring matters, but the dyeing properties of cotton, linen, and other vegetable products are quite different.

Differences quite as marked are to be noted in the behaviour of various colouring matters towards one and the same material, and thus, in dyeing operations, both the nature of the material to be dyed and of the colouring matter employed, have to be taken into account.

The theory of dyeing. The precise cause or causes of the different behaviour of the textile fibres in dyeing is still a matter of uncertainty ; but there is little doubt that the chemical and physical properties both of the fibre and of the dyestuff are all factors of the complicated phenomena of dyeing.

The earliest theory with regard to the fixation of dyes was that the action is purely mechanical, and it is still urged by many that rarely in dyeing processes is there direct evidence of chemical combination between fibre and dyestuff Both bodies, as a rule, retain their individual chemical and physical properties unchanged, and the dye can frequently be removed from a fibre by means of alcohol or another solvent.

In its earliest form, the mechanical theory was put forward by Hellot and d'Apligny in 1780. (See Hellot's L'Art de la Teinture des Laines (1734) ; and d'Apligny's L'Art de la Teinture des fils de Coton (1776).) They assumed that the particles of colouring matter became embedded in the minute pores permeating the fibre substance. Crum (Chem. Soc. Trans. 16, 404) strongly supported this theory, while Muller-Jacobs (J. Soc. Dyers, 1885, 63) expressed much the same idea in attributing the fixation of dyes to membranous diffusion. It has, however, been shown by several investigators that dyeing processes do not obey the general laws of osmosis. v. Georgievics (J. Soc. Chem. Ind. 1895 149) considers dyeing is chiefly due to surface attraction. Witt (Farber-Zeit. 1890) put forward a modification of the mechanical theory. He regards the fibres as solid solvents in which the dyestuffs dissolve, the latter being withdrawn from its aqueous solution in the same way as, *e.g.* ether will extract many substances from their aqueous solution. The degree to which a dye-bath can be exhausted will then depend upon the relative solubility of the dyestuff in the acid or neutral dye liquor and in the fibre substance under the conditions (concentration and temperature) used. Krafft (Ber. 1899, 1608) attributes dyeing phenomena to a separation of the dyestuff upon the fibre in a colloidal state, and this view has been supported by Biltz (*ibid.* 1904, 1766), Linder and Picton (Chem. Soc. Trans. 1905, 1931), and Dreaper (J. Soc. Chem. Ind. 1905, 223).

The chemical theory of dyeing was originally put forward by Macquer and Bergman in opposition to the mechanical theory of Hellot and d'Apligny, and has received much experimental

support from Persoz, Berthollet, Chevreul, Kühlmann, Vignon, Knecht, and many others. It is mainly based on the following facts : wool and silk fibres contain amino-acids, and thus possess strongly marked acidic and basic functions. Cellulose, the essential constituent of the vegetable fibres, is chemically much less active, and dyes much less readily than wool and silk, but under certain conditions it exhibits weakly acidic functions. All dyestuffs (with few exceptions) possess either acidic or basic properties, or are in the form of salts, which dissociate in the dye-bath ; and chemical combination between fibre and dyestuff would thus, *primá facie*, be expected. Moreover, *lanuginic* and *sericinic acids*, which are produced respectively by the hydrolysis of wool and silk, precipitate both acid and basic dyes from their aqueous solution (Knecht and Appleyard, J. Soc. Dyers, 1889, 72).

A full discussion of the evidence for and against the mechanical and chemical theories of dyeing cannot be here entered upon, but a general review indicates that the attempt to cover all dyeing phenomena by any one simple explanation must fail, and that many factors are concerned, the relative importance of which varies in different cases. In the dyeing of wool or silk, with acid or basic dyes, it may be taken as established that chemical combination occurs, but prior to this some hydrolysis of the fibre, and more or less complete ionisation of the dye-stuff takes place. Surface concentration of the dye on the fibre probably also occurs, and the coagulation and precipitation of the dissociated colloidal dyestuff also plays a part. This is supported by the observation that the temperature of maximum *absorption* of dye does not (in the cases investigated) correspond with that of maximum *fixation* (Dreaper, Trans. Faraday Soc. 1910, pt. i. Haldane-Gee and Harrison, *ibid.*) ; the former possibly coinciding with the point of maximum coagulation and precipitation, and the latter indicating the point of maximum degree of chemical combination. Whether the superficially precipitated dye penetrates the fibre by osmosis or by 'solid solution' is mainly a question of definition of terms.

In the case of the dyeing of vegetable fibres, the same factors probably operate, but their relative importance is not the same, the physical factors—precipitation, surface attraction, and osmosis—predominating over the effect of direct chemical action.

Classification of colouring matters. It has already been pointed out that dyestuffs vary in their behaviour. If, *e.g.* separate pieces of wool are boiled in solutions containing, (*a*) logwood, (*b*) indigo, (*c*) magenta, and (*d*) picric acid, the following results are obtained : (*a*) the wool acquires a brown stain ; (*b*) the wool remains undyed, the indigo floating about in an insoluble condition ; (*c*) the wool is dyed a magenta colour ; and (*d*) the wool is dyed a full yellow. If the experiment is repeated on wool which has been previously boiled with a solution of potassium dichromate, the result will be that in (*a*) the wool is dyed black, whereas in (*b*), (*c*), and (*d*), similar results are obtained to those of the previous experiments. Logwood, therefore, must be applied in conjunction with potassium dichromate or some similar substance, *i.e.* with a mordant ; whereas magenta and picric

acid dye without such aid, and indigo requires a special process, the nature of which is not indicated by the results of the above-described experiments.

Colouring matters may be divided into three groups on the lines indicated above, viz. : (1) those which must be applied in conjunction with a mordant ; (2) those which dye direct from their solutions ; and (3) those requiring special processes.

As regards groups (1) and (2) this classification is practically identical with that of Bancroft (Philosophy of Permanent Colours, i. 118, London. 1794), who, upwards of a hundred years ago, divided colouring matters into *substantive dyes* and *adjective dyes* ; the former class comprising those which dye directly from their solutions, and the latter being composed of those dyes which require mordants. Nietski (Farber-Zeit. 1889–90, 8) uses the terms *direct dyes* and *mordant dyes* in exactly the same sense, and both Bancroft's and Nietski's terms are still in use. Hummel (The Dyeing of Textile Fabrics, 1st ed. 1885, 147) also classifies dyestuffs into two groups ; *monogenetic dyes* being such as are capable of producing one colour only, while *polygenetic dyes* produce distinct colours with different mordants. The members of the first group are *coloured bodies*, and these merely require to be fixed upon the fibre, whereas the *colouring principles* comprising the second group as a rule only develop a colour when chemically combined with a mordant.

It will be seen that these three systems of classification closely correspond, the terms *substantive dyes, direct dyes*, and *monogenetic dyes* being almost synonymous, as are *adjective dyes, mordant dyes*, and *polygenetic dyes*. It should, however, be pointed out that none of these classifications is absolute ; magenta, for example, is a direct dye as applied to wool, but requires a mordant when used for cotton.

A distinct method of grouping dyestuffs is that of Benedikt (The Chemistry of the Coal-tar Colours, 1886, 29), who distinguishes between *colour acids, colour bases*, and *neutral colouring matters*. Both colour acids and colour bases are fixed on the fibre in the form of salts, but whereas in the colour acids the essential colour-producing group resides in the acid portion of the compound, in the colour bases the reverse is the case. Alizarin red, dyed on wool, is a salt of which alumina forms the basic and alizarin the acidic constituent. Alizarin is therefore a *colour acid.* Similarly, the red pigment formed on dyeing tannin-mordanted cotton with magenta is a combination of rosaniline base with tannic acid. Magenta is therefore a *colour base.* Indigo and other vat dyes are *neutral colouring matters.*

All the above schemes of classification are defective, either from the point of view of the practical dyer, or the chemist. As regards practical application, the large number of dyestuffs now on the market may, however, be satisfactorily classified into the following groups : (1) *mordant dyes* ; (2) *acid-mordant dyes* ; (3) *acid dyes* ; (4) *direct dyes* ; (5) *basic dyes* ; (6) *sulphide dyes* ; (7) *vat dyes* ; (8) *ingrain dyes.*

The classification of dyes according to chemical constitution is based upon the existence,

of a certain group of atoms, in all members of each class, upon the integrity of which their colouring power depends. This is termed the *chromophorous group*, the theory being first put forward by O. N. Witt, in 1876. The introduction of such a chromophor into a suitable colourless compound is accompanied by the development of colour, *e.g. benzene* (C_6H_6) is colourless, but *azobenzene* ($C_6H_5-N=N-C_6H_5$) is orange-coloured. Many substances, however, such as azobenzene, although strongly coloured, are devoid of dyeing power. Such bodies are termed *chromogens*, and in order to convert them into useful dyes, the introduction of a salt-forming group is necessary ; such groups, in this connection, being termed *auxochromous groups*. Thus, whilst *azobenzene* is not a dye-stuff, both *amino-azobenzene* and *hydroxy-azobenzene* are useful dyes. In these compounds, the azo- group ($-N=N-$) is the *chromophor*, and the amino- or hydroxyl- group is the *auxochrome*.

The presence of both a chromophor and an auxochrome does not, however, necessarily indicate that a substance is a useful dye. For example, *trinitroaniline*, $C_6H_2(NO_2)_3NH_2$, contains the chromophor (NO_2) and the salt-forming auxochrome group (NH_2) ; but it is not a useful dyestuff, because the basic character of the auxochrome is neutralised by the strongly acidic chromophor. On the other hand, trinitrophenol $C_6H_2(NO_2)_3OH$ is the useful dyestuff picric acid.

Those dyestuffs which do not contain a salt-forming auxochrome cannot be applied by ordinary dyeing processes, and the fact that a special process is required, *e.g.* for indigo, is not primarily due to its insolubility, but to its neutral character.

The scheme of classification, based on the chromophor, distinguishes the following groups—

Group	Chromophor	Typical dyes
1. *iso*-Nitroso- or oxime	$>C-O$ $>C-N'OH$	Resorcin green, dioxine, gambine.
2. Nitro-	$-NO_2$	Picric acid, naphthol yellow.
3. Azo-	$-N=N-$	(a) *Basic*—chrysoidine, Bismarck brown, Janus red (b) *Acid*—azo- oranges and scarlets, naphthol black, diamond black. (c) *Direct*— benzopurpurin, diamine colours, direct blacks (d) *Mordant*—'acid mordant' or 'chrome' colours
4. Triphenyl-methane,	(ring)	Magenta, methyl violet, Victoria blue, *patent blue, malachite green.
5. Oxyketone	CO (ring) CO	The alizarin dyes, indanthrene and algol vat dyes.
6. Pyrone	$-O-$ $-C=$	Rhodamine, violamine, eosins.
7. Acridine	$<$N$>$C$>$	Acridine yellow, orange, and scarlet.
8. Oxazine	$<$O$>$N$>$	Meldola's blue, gallocyanin, Capri blue.
9. Thiazine	$<$S$>$N$>$	Methylene blue, thiocarmine, hydron blue.

Group	Chromophor	Typical dyes
10. Azines	(N ring) or $<$N$>$N$>$	Safranines, indulines, aniline black.
11. Thiazol-	$-S$ $-N$$>C-$	Primuline, thioflavin.
12. Quinoline	$-CH-CH$ N_2CH	Quinoline yellow, cyanine.
13. Flavone	$-O-C-$ $-CO-CH$	Fustic, weld, logwood, Brazil wood.
14. Indigoids	$-CO-C=C-CO$	Indigo, helindone and ciba vat dyes.
15. Miscellaneous.		

This classification of dyestuffs into chemical groups is of importance in the identification and testing of dyestuffs, as the constitution of the compound determines its behaviour towards reagents. It is not, however, a convenient one as regards the practical application of the dyestuffs.

Essential properties of a dyestuff. In order to rank as a useful dye, a substance must possess certain essential features. A *direct dye* must not only possess a colour of considerable intensity and permanence, but must also be capable of easy fixation on textile fibres without injury to fibre or dyestuff. For example, both vermilion and azo-scarlet possess a brilliant colour, but the former is not a dyestuff, because it cannot be applied or produced by dyeing processes. A *mordant dye*, on the other hand, need not possess a strong colour, and may, in fact, be colourless. It must, however, be capable of producing strongly coloured and insoluble colour-lakes in combination with suitable mordants. *Vat dyes—e.g.* indigo—are, as a rule, quite insoluble in water, and therefore cannot be applied by an ordinary process. The essential feature of this group is that their reduction products are soluble in alkaline solutions, and on this fact the method of application depends.

In order to constitute a dyestuff a body must, therefore, either be strongly coloured in itself or be capable of producing coloured lakes. It must also be of such a character that it can be fixed upon textile material from an aqueous solution, and it must produce a colour which possesses sufficient permanence and resistance to washing and other influences. (In so-called 'dry dying' alcohol or other volatile solvent is used)

Operations preliminary to dyeing processes. In any dyeing operation, the chief bodies concerned are the fibre to be dyed and the dyestuff. In their natural condition, all textile fibres contain impurities which not only detract from their appearance, but prevent their being satisfactorily dyed. The removal of these impurities is the object of the washing, scouring, and bleaching processes which the ' raw ' fibres undergo.

A great bulk of manufactured textile material, chiefly cotton and linen, is used in the undyed condition, but wool and silk are usually dyed.

Dyeing processes. Dyeing may take place at various stages of the manufacture of textiles. ' *Piece dyeing* ' is generally employed when a plain-coloured material is required, being the most economical and convenient process. If a coloured pattern is required, the material must either be printed, or dyed before weaving, and

the process may then be carried out on the raw wool or cotton ('*wool dyeing*,' '*cotton dyeing*'), at an intermediate process ('*sliver*' or '*slubbing dyeing*') or upon the spun yarn ('*yarn dyeing*,' '*hank dyeing*,' '*cop dyeing*,' '*cheese dyeing*,' '*warp dyeing*').

Wool is dyed in all these forms; silk, almost exclusively in the form of yarn; and cotton, chiefly as warps, cops, or pieces.

The dyeing of wool. Wool may be dyed with a greater range of colouring matters than any other textile fibre. All the various classes of colouring matters enumerated in the classification based on practical application (*see* p. 575) are used in the dyeing of wool; the most important groups being the *mordant*, the *acid mordant*, the *acid* and the *direct* dyes, as well as the *vat dye*, indigo. In boiling solutions, the affinity of wool for dyestuffs is generally greater than that of silk, but at temperatures below 60° the relative affinity is frequently reversed. By a suitable selection of dyestuffs and control of the process, it is therefore possible to dye the wool and silk in a woven fabric either to different shades, or to produce a uniform colour on the two fibres. As a general rule, dyeing processes which produce good results on wool are entirely unsuited for cotton, and it is an easy matter to dye one of the two fibres when present in a mixed fabric and leave the other practically unstained. If both fibres are to be dyed the same or different colours, two distinct processes are, as a rule, required.

Different varieties of wool behave differently in dyeing, the finer wools, such as merino, requiring a larger amount of dyestuff to produce a given shade than the coarser qualities, *e.g.* Lincoln or '*crossbred*' wool. The absorption of dye is, however, by no means entirely governed by the diameter of the fibre, *e.g.* fine silky mohair is very difficult to dye, probably on account of the close texture of the external scales. Fibres taken from different portions of the same fleece also vary somewhat in dyeing properties; and wool taken from the skin of animals slaughtered for meat, or from diseased animals, also differs from '*fleece*' wool as regards its affinity for dyes. All these differences are shown to a much greater extent with some dyestuffs than with others.

The affinity of wool for certain dyestuffs may be increased by suitable treatment with acids, alkalis, or oxidising agents (bleaching powder or hydrogen peroxide solution), or may be diminished by a treatment with tannic acid solution and in other ways. Various colours may thus be produced by a '*piece-dyeing*' process by weaving together untreated wool and wool treated with one or other of the above-mentioned reagents.

The behaviour of wool towards solutions of metallic salts governs the use of these bodies as mordants. When boiled in solutions of salts of the heavy metals having an acid character (*e.g.* sodium dichromate), a decomposition of the salt takes place, and an insoluble basic salt or a hydrated oxide is fixed upon the fibre.

The dyeing of silk. In general behaviour towards colouring matters, silk resembles wool, but, as a rule, dyes are fixed on silk in a less permanent manner than on wool. The dyeing of silk appears to depend, to a greater extent, on absorption, and to a less extent on chemical action. The *acid*, *basic*, and *direct* dyes are

chiefly used on silk, but other classes, *e.g.* the *mordant* and *vat* dyes, are also employed, though they tend to detract somewhat from the brilliant lustre and suppleness on which the beauty of silk depends. The maximum absorption of dyes by silk usually takes place at 60°–80°, and not at 100° as in the case of wool.

The so-called '*dry dyeing*' process sometimes employed for silk consists in the use of benzine or other volatile liquid as a solvent for the colouring matter in place of water. The usual dyestuff-salts are not soluble in benzine, but the fatty acid compounds or resinates of basic dyes are readily soluble.

The mordanting of silk with metallic salts is usually carried out in cold concentrated solutions of basic salts, chiefly basic aluminium sulphate for colours, and basic ferric sulphate or ferrous acetate for blacks.

The production of black upon silk is a matter of great importance, and is almost a trade to itself. The silk is first immersed in a solution of chestnut extract or other tannin matter, and then in a solution of basic ferrous acetate (pyrolignite of iron) or ferric sulphate ('nitrate of iron'). By successive alternate treatments in these liquors, the silk may be weighted to the extent of 400 p.c. It is then dyed with logwood extract. There are a number of alternative processes for the black dyeing of silk.

Wild silks, of which *Tussur* is the chief variety, are much more difficult to dye than ordinary silk, the fine fibrillæ of which the fibre is composed being very impervious. The bandlike flat surface of the fibre also reflects the light in such a manner that a white shiny appearance is liable to be produced instead of a rich, intense colour or black

Artificial silks, consisting essentially of cellulose, are more allied to cotton than to silk as regards dyeing properties. Those varieties produced from collodion (Chardonnet silk) dye more readily with the basic dyes than do cotton or the artificial silks obtained from a cuprammonium solution of cellulose (Pauly, Lehne, Thiele or 'glanzstofle' silk) or from cellulose xanthate ('viscose silk'). There is, however, much individuality in the dyeing properties of the various forms of artificial silk.

The dyeing of cotton. Cotton is dyed chiefly in the form of hanks or warps, less frequently as loose cotton or piece goods. The dyeing of cotton on the spool, cop or beam is, however, now of great importance.

The dyeing properties of cotton differ greatly from those of wool, and therefore the processes and materials used also differ. Until the discovery of Congo red in 1884, there were three dyestuffs only which were capable of dyeing cotton directly from their aqueous solution—*turmeric*, *safflower*, and *annatto*—but there are now a large number of synthetic substantive dyes by means of which any desired shade can be obtained. The very numerous class of *acid dyes* which are of such great importance in wool and silk dyeing do not produce reasonably fast colours on cotton.

Cotton has no affinity for metallic salts, and therefore does not become mordanted by boiling in their solutions. Indirect methods have therefore to be adopted in applying the

basic mordants required for the fixation of the mordant dyestuffs on cotton. This fibre exhibits a remarkable affinity for tannic acid, which is withdrawn from dilute solution and concentrated on the fibre to a considerable extent. The tannic acid may then serve for the fixation either of metallic mordants or of basic dyestuffs upon the fibre.

The *vat dyes* and sulphide dyes are now of first importance, since, by their use, extremely fast colours are obtained upon cotton.

The so-called *ingrain dyes* are used almost exclusively on cotton. The term is applied to designate a class of dyes which are produced *in situ* on the fibre by precipitation.

Mercerised cotton is virtually a distinct textile fibre, and whilst its dyeing properties are essentially the same as those of ordinary cotton, its treatment requires special precautions on account of its great affinity for the direct dyes.

The dyeing of linen. The behaviour of linen towards the respective classes of dyestuffs is similar to that of cotton, but it is more difficult to dye. The inferior dyeing affinity of linen is probably due to the different physical structure of the fibre.

The dyeing of jute. Although a cellulose derivative, jute differs from cotton and linen, both in its chemical composition and properties. As regards dyeing processes, it behaves, to a certain extent, like tannin-mordanted cotton, and may be dyed not only with *direct*, but with *basic* colouring matters without the aid of a mordant.

The dyeing of leather. Leather resembles wool in dyeing properties, but the difficulty of dyeing it in fast colours is increased by the necessity of using lukewarm liquors only, since boiling water destroys ordinary leather. Certain of the newer methods of producing leather, *e g* chrome tannage, yield a product which will withstand boiling solutions. It is very important as regards the permanence of the leather (when used *e.g* for bookbinding or furniture covering) that no mineral acid should be employed in the dyeing process. As a substitute, formic acid may be recommended. The *acid* and *basic* colouring matters are chiefly employed, the *mordant* dyes being used to a less extent.

The dyeing of feathers. The chief cause of difficulty in the dyeing of feathers is their natural water-resisting property. This is due partially to their ultimate physical structure, and partially to the natural grease present. The midrib is specially difficult to dye. Apart from these special difficulties, feathers behave in dyeing, like wool, and may be dyed with *acid*, *basic*, *direct*, or *mordant* dyes. Reds, browns, blues, and other colours are usually dyed with acid dyes, but the most satisfactory blacks are obtained by successive and repeated treatments with logwood extract, and ferrous sulphate with potassium binoxalate. Dyeing must proceed for a considerable period at the boil, in order to ensure penetration.

The dyeing of horn. Horn is dyed in strong solutions of *acid* dyes by steeping for a long period in the cold or slightly warm baths, which are acidified with acetic or formic acid. Since it contains sulphur, horn may be dyed brown by steeping in a solution of sodium plumbite, which results in the formation of lead sulphide. Black is also produced by alternate steepings in solutions of mercuric nitrate and potassium sulphide.

The dyeing of ivory. Both *acid* and *basic* dyes may be employed in the dyeing of ivory, the former being used with addition of acetic or formic acid in hot solutions. Alcoholic solutions of colouring matters may also be employed. Red is frequently dyed by the cochineal single-bath process used for wool (see p. 590).

Black is produced either by the logwood and iron or aniline black process, as used in cotton dyeing, or by means of silver nitrate.

The dyeing of wood. The method of dyeing wood in bulk is to boil or steam it to remove the resins, and then treat it in an apparatus similar to that employed in creosoting. The wood is placed in a closed vessel which is exhausted by a vacuum pump, and when the air has been sucked out from the pores as completely as possible, the hot dye liquor is admitted into the vessel and put under pressure by a force pump. The direct and basic dyes may be employed Wood is usually dyed black by alternate treatments with logwood extract and sodium dichromate solution.

The dyeing of straw. Straw is largely dyed for use in the manufacture of hats and baskets. There are two commercial varieties, distinguished as *chip* and *straw*. Chip is readily dyed by means of the *direct cotton dyes* of the *sulphide dyes*, and many *basic* and *acid dyes* in neutral solution may also be employed. The process must be continued for 2 to 3 hours at the boil.

'Straw' is more difficult to dye than 'chip,' on account of the highly siliceous character of the surface. The straw should be steeped for several hours in warm water before dyeing. Blacks are usually obtained with logwood and iron, but for colours the *direct cotton* and the *basic dyes* are chiefly used.

MATERIALS USED IN DYEING OPERATIONS.

A great variety of chemical substances are used in dyeing processes—acids, alkalis, oxidising and reducing agents, metallic salts, and a wide range of organic bodies. Two groups only need be here considered, viz. : (*a*) *mordants*, and (*b*) *colouring matters*.

Mordants. The function of a mordant is to chemically combine with the dyestuff employed, and fix the latter upon the fibre. It has already been mentioned that many colouring matters do not require the aid of mordants, but dye direct from their solutions. This applies to the *acid*, *direct*, *basic*, and *vat* dyes when used for wool and silk, and the *direct*, *sulphide*, and *vat* dyes when used for cotton. On the other hand, the *mordant* and *acid-mordant* dyes (as their name implies) demand the use of mordants on wool, as do the *mordant* and the *basic dyes* on cotton.

It is evident that the chemical properties of the dyestuff will govern the character of the mordant required for its fixation, and two types of mordants may thus be distinguished : (1) the *metallic* or *basic mordants*, used for the *mordant' dyes* ; and (2) the *acid mordants*, required in applying the *basic dyes* to cotton or other vegetable fibre.

Basic mordants are employed for fixing on

animal and vegetable fibres those colouring matters which are of an acidic character, *i.e.* either true acids or bodies containing hydroxyl-groups, of which the hydrogen is replaceable by metals. They are metallic salts, of which the most important are certain compounds of chromium, aluminium, iron, and tin.

Wool is mordanted by boiling it with dilute solutions of these metallic salts, usually with the addition of certain acids or acid salts, *e.g.* cream of tartar, sulphuric acid, formic acid, oxalic acid, &c. During this operation, the wool assists in the dissociation of the metallic salt; an insoluble basic salt being fixed within and upon the fibre, while a more acid salt remains in solution. The acids or acid salts, which are added along with the metallic salt, possibly assist the dissociation of the latter by forming more sensitive salts (tartrates, oxalates, &c), and are conveniently termed *assistants*.

As a rule, the mordanting operation precedes that of dyeing, not infrequently, however, the two operations take place simultaneously, and the dyeing is thus effected by the so-called 'single-bath' or 'one-dip' method, as, for example, in producing cochineal scarlet on wool In such cases, the wool is boiled in a solution containing colouring matter, metallic salt, and assistant, in certain accurately determined relative proportions. Combination takes place between the colouring matter and the mordant, but the pigment which would otherwise be precipitated, is retained in solution by the liberated acid of the mordant or the assistant present, and is only gradually withdrawn from solution by the fibre, which thus becomes dyed.

In the case of the 'acid-mordant' dye-stuffs, the application of the mordant follows that of the colouring matter.

Silk may be mordanted in the same manner as wool, by boiling with metallic salt solutions; but, more usually, it is steeped for about 12 hours in cold solutions of the mordants previously rendered more or less basic and sensitive. By subsequently washing with (calcareous) water, the metallic salt absorbed by the silk is dissociated, and an insoluble basic salt is precipitated within the fibre.

Cotton is mordanted with metallic salts by processes very different from those adopted for wool and silk, since it has not the property of causing the dissociation of the metallic salts when boiled or steeped in their solutions. The methods adopted also vary according to the form of the material, *i.e.* whether it be cotton-wool, yarn, or cloth.

With calico, it is usual to impregnate the fabric with solutions of metallic *acetates*, then to dry it, and expose for several hours to a moist warm atmosphere. During this so-called 'ageing' process, dissociation of the salt takes place, acetic acid escapes, and a more or less basic salt remains fixed upon the fibre.

Sometimes the 'ageing' is replaced by a 'steaming process,' in which the fabric is exposed from ½ to 1 hour to the action of high or low pressure steam in a closed chamber. This method is adopted by the printer of textile fabrics in the so-called 'steam style,' in which a mixture of colouring matter and metallic salt (usually acetate) is printed upon the fabric, which is then dried and steamed. The metallic salt is decom-

posed, a basic salt is precipitated upon the fibre, and at the same time the mordant combines with the colouring matter and produces the coloured pigment. This method is analogous to the single-bath process of the woollen dyer.

Cotton may also be mordanted by impregnating it with a metallic salt solution, drying, and then passing through a solution of an alkaline substance, *e.g.* ammonia, chalk, sodium carbonate, &c., to neutralise the acid and precipitate upon the fibre a basic salt or metallic oxide. Solutions of an alkali salt, the acid of which forms an insoluble compound with the base of the mordant, *e.g.* sodium phosphate, silicate, arsenate, &c., are also employed. The substances used in this manner for fixing the mordant upon the fibre are termed *fixing agents*.

In some cases of mordanting, the cotton is first impregnated with the fixing agent (*e.g.* tannic acid, sulphated oil, &c.), then dried and afterwards passed through the mordant solution, as for example, in Turkey-red dyeing.

Special methods of mordanting cotton are occasionally adopted, in accordance with the properties of the metallic salt employed. Stannic oxide, for example, may be fixed on cotton by passing the fabric through a solution of sodium stannate, and then through dilute sulphuric acid, and finally washing Alumina is precipitated on the fibre by the mere exposure to air of cotton impregnated with sodium aluminate, in which case atmospheric carbonic acid is the active fixing agent.

The *chromium mordants* are of the first importance, since, with different colouring matters, they yield a considerable range of colours which are remarkable for their permanence. The most important chromium mordants are potassium and sodium dichromates, and they are more largely used as mordants in wool dyeing than all other metallic salts. In cotton dyeing they are not used as mordants, but are frequently employed as oxidising agents, *e.g.* to develop the colour in dyeing catechu brown or aniline black. Dichromates are also used in producing 'chrome yellow' and 'orange' (chromates of lead) on cotton. Chromium fluoride ($CrF_3,4H_2O$) is also used to a limited extent as a mordant for wool. Other chromium salts employed as mordants, chiefly for cotton, are chrome alum, chromium acetate, and various chromates of chromium. Chrome alum is obtained in large quantities as a by-product during the manufacture of alizarin; chromium acetate is prepared by mixing together solutions of chrome alum and lead acetate.

Wool is mordanted with chromium by boiling for 1–1½ hours in a solution containing 3 p.c. potassium (or sodium) dichromate calculated on the weight of wool. In many cases it is beneficial to add 1 p.c. sulphuric acid (sp.gr. 1·84) or 1·5 p.c. hydrochloric acid (sp.gr. 1·16), or 6 p.c. tartaric acid, or 1 to 2 p.c. formic acid, whereby fuller or brighter colours are ultimately obtained. ●When potassium dichromate alone is employed, partial decomposition of the salt occurs, accompanied by some reduction, the wool absorbing some chromic acid and chromium●chromate as well as potassium di-chromate. When an addition of●sulphuric acid is made, the wool ●bsorbs only chromic acid. In both cases the mordanted wool

has a yellow or buff colour, and only in the dye-bath does the reduction to the real mordanting body, chromic oxide, take place within the fibre through the interaction of the colouring matter. When formic or tartaric acid is the assistant employed, the mordanted wool has a green colour, reduction of the chromic acid taking place already in the mordanting bath, and chromic hydrate being deposited within the wool substance. If large amounts of potassium dichromate are employed in mordanting, especially if sulphuric acid is also added to the bath, bad results may be obtained through the colouring matter being oxidised and destroyed by the excess of chromic acid present in the wool. This defect is known as ' over-chroming.' In certain cases, potassium dichromate may be usefully applied in the same bath with the colouring matter (*e.g.* with alizarin), or by an after process (*e.g.* in the case of camwood).

Silk is not usually mordanted with chromium. It becomes mordanted, however, if boiled with a solution of potassium dichromate and tartaric acid after the manner of wool, but not if potassium dichromate alone, or with the addition of sulphuric acid, is employed. The fibre is somewhat injured by this process.

Cotton may be mordanted with chromium by impregnating it with a moderately concentrated solution of chrome alum, drying, and passing through a boiling solution of sodium carbonate or caustic soda. Better results are obtained by the use of ' chromium mordant G. A. I.' or ' G. A II.' (M. L. & B.), which are solutions of chromium chromates. Other satisfactory mordants for cotton are chromium bisulphite (Knecht) and sodium chromite (Koechlin). A method in vogue with the printer is to impregnate (pad) or print the cotton with a mixture of colouring matter and chromium acetate, dry and steam (' steam colours ').

The chief *aluminium mordants* employed for *wool* are aluminium sulphate and alum. The best results are usually obtained by boiling the wool for 1–1½ hours with a solution of 8–10 p.c. of the aluminium salt calculated on the weight of the wool, with the addition of cream of tartar, in the proportion of 3 mols to 1 mol. aluminium sulphate. Aluminium tartrate also gives excellent results, but it is cheaper to allow this salt to be formed in the mordanting bath itself in the manner described. With some colouring matters, oxalic acid or potassium binoxalate are to be preferred as assistants to cream of tartar.

Silk is mordanted by boiling with dilute aluminium sulphate solution, or by steeping 24 hours in a concentrated solution, and then washing in water, preferably calcareous.

The methods of mordanting *cotton* with aluminium are various. It may be impregnated with a moderately concentrated solution of alum or aluminium sulphate, dried, and then passed for a few minutes into a hot solution of sodium phosphate, arsenate, or silicate, or ammonium carbonate. Or the cotton may be impregnated with a cold solution of neutralised sulphated oil, or of tannic acid, then dried, and steeped in a solution of aluminium acetate or basic aluminium sulphate. Another method consists in impregnating the cotton with a solution of sodium alumihate, drying and exposing to the air, or passing through a solution of ammonium chloride. Normal and basic aluminium acetates are also employed, the cotton being impregnated with their solutions, then dried, and exposed to a moist warm atmosphere (' ageing '), and finally passed through a hot solution of, *e.g.*, sodium arsenate. The aluminium acetates employed are prepared by dissolving aluminium hydrate in acetic acid, or by decomposing a solution of aluminium sulphate with calcium or lead acetate (' red liquor '). The more basic the aluminium salts are, the more readily do their solutions precipitate by heating or on dilution with water, and the larger the quantity of alumina they yield to the fibre when used as mordants.

The chief *iron mordants* employed are ferrous sulphate and acetate, and ferric sulphate, acetate, and nitrate.

The ferrous acetate employed is made by dissolving scrap iron in pyroligneous acid. The ' pyrolignite of iron ' or ' black iron liquor ' thus obtained is preferable to that ,made by the mutual decomposition of ferrous sulphate and lead acetate solutions, being less liable to oxidise because of the presence of tarry matter and reducing agents, *e.g.* pyrocatechol, &c. Ferric sulphate is prepared by heating a mixture of definite proportions of ferrous sulphate, sulphuric acid, and nitric acid. Although the last-mentioned substance is only used as an oxidising agent, the final preparation is generally termed by dyers ' nitrate of iron.' The so-called ' pure nitrate of iron ' (ferric nitrate) is prepared by dissolving scrap iron in nitric acid.

Wool may be mordanted by boiling in a solution of 7 p.c. ferric sulphate $[Fe_2(SO_4)_3]$ and 4 p.c. potassium binoxalate, calculated on the weight of the wool, but iron is now very little used as a mordant for wool.

Silk may be mordanted by steeping for about 12 hours in a cold solution of pyrolignite of iron (sp.gr. 1·025), and afterwards washing well. The most usual mordant, employed largely in black-silk dyeing, is the basic ferric sulphate $Fe_4(SO_4)_5(OH)_2$. The silk is steeped in a somewhat concentrated solution of this salt (sp. gr. 1·25) for about 1 hour, then squeezed and well washed. The operations are repeated seven or eight times, after which the silk is boiled in an old soap-bath and finally washed. In this process, the very sensitive basic ferric sulphate absorbed by the fibre is decomposed during the several washings, a still more basic and insoluble salt being precipitated within the fibre.

Cotton is usually mordanted with iron by first impregnating it with a cold solution of tannin matter (*e.g.* myrobolans), and then, with or without drying, passing into a dilute solution of ferrous acetate, ferric sulphate, or nitrate (sp.gr. 1·01–1·02). The cotton may alternatively be impregnated with ferrous or ferric acetate, dried, and exposed to a moist warm atmosphere (' ageing '), finally fixing the mordant by passing through a hot solution of, *e.g.*, sodium phosphate.

Tin mordants are now rarely used, but if required the stannous salts are employed for *wool* and the stannic salts for *cotton*. The chief stannous mordant is stannous chloride or ' tin crystals.' It is frequently sold as a somewhat acid solution under the names of ' single muriate of tin ' (sp.gr. 1·3), or ' double muriate of

tin ' (sp.gr. 1·6). The general name ' tin spirits ' is given to a variety of solutions of tin in mixtures of hydrochloric, sulphuric and nitric acids.

Wool is mordanted by boiling in a solution containing 6 p.c. of the weight of wool of stannous chloride, and 6–10 p.c. cream of tartar. Large proportions of stannous chloride should be strictly avoided, otherwise the dyed wool feels harsh and its general properties are impaired.

Silk may be mordanted in the same manner as wool, or steeped several hours in a more or less concentrated solution of stannic chloride, and then well washed.

Cotton is mordanted with stannic oxide by impregnating the cotton with cold tannin solution (*e.g.* sumach) for 3 hours, then squeezing, and, with or usually without drying, steeping 1 hour in a dilute solution of stannic chloride (sp.gr. 1·02), and washing. Cotton thus mordanted was much used formerly for fixing mordant dyes—peachwood, logwood, &c , in which case the stannic oxide constituted the mordant, the tannic acid acting as fixing agent. Now that the basic coal-tar dyes are so much employed in dyeing cotton, although the same method of mordanting is employed, the *rôles* of the tin salt and tannic acid are reversed, for it is really the tannic acid which is the essential mordant, while the stannic chloride serves only as the fixing agent.

Acid mordants are employed for fixing basic colouring matters on cotton. They are not used in wool or silk dyeing, since these fibres themselves act as acid mordants, and are dyed directly without the aid of any external mordant

Tannic acid is the mordant *par excellence* for fixing the basic coal-tar colours on cotton This fibre absorbs tannic acid from its cold solution, and, when thus prepared, if immersed in a solution of a basic colouring matter, the tannic acid combines with the colour base, a coloured lake is formed within the substance of the fibre, and the cotton becomes dyed. During the dyeing process, the acid originally in combination with the colour base is displaced, and since in the free state it interferes with the complete formation of the colour lake, it is found beneficial to add a small proportion of sodium carbonate or acetate to the dye-bath. Since the tannates of colour bases are somewhat soluble, in excess of tannic acid or in alkaline (or soap) solutions, it is necessary in practice to fix the tannic acid on the fibre, previous to dyeing, in the form of an insoluble metallic tannate. This is done by passing the tannic-acid-prepared cotton through a hot or cold solution of tartar emetic or stannic chloride ; tannate of antimony or tin is thus fixed on the fibre, and these salts have as great an affinity for the colour base as free tannic acid has. Cotton thus mordanted and dyed is probably permeated with a very insoluble double tannate of antimony or tin and colour base ; a triple compound which is insoluble in alkaline solutions, and therefore fast to washing with soap, &c.

The tannin mordants, chiefly used by the dyer, are gall nuts and sumach, for light colours ; and myrobolans, divi-divi, quebracho, and chestnut extract, for dark colours and blacks.

As already pointed out, tannic acid is sometimes used as a *fixing agent* for tin, iron, or aluminium mordants, and since its iron compound is of a bluish-black colour, it sometimes serves as a useful *colouring matter.*

Tannic acid. is not used as a mordant·for wool, but for *silk* it is largely employed, partly for adding weight to the silk, and partly for the purpose of dyeing it black in conjunction with iron mordants. Its utility as a weighting agent is owing to the fact that under suitable conditions silk absorbs as much as 25 p.c. of its own weight of tannic acid from a hot solution, whereby the fibre gains not only in weight, but also in volume.

Fatty acids are used as mordants, very much in the same way as tannic acid, for fixing the basic coal-tar colours on cotton. They are, however, not attracted by cotton from their solutions, but they form insoluble lakes with the colour bases. The method of procedure is to impregnate the cotton with a more or less concentrated solution of their alkali salts, viz. soap ; after drying, the fabric is passed through, or preferably steeped in, a cold solution of aluminium sulphate, and washed. Although the fatty acid is thus fixed on the fibre as an insoluble aluminium soap, it is still capable of combining with the colour base when the cotton is passed into a solution of a basic colouring matter Colours dyed by this method are brighter than, but not so fast to washing as those fixed by means of tannic acid

Instead of ordinary soap, a more convenient fatty-acid mordant to employ is the so-called ' sulphated oil.' This is prepared by mixing two parts by weight of castor oil with about one part of sulphuric acid (sp.gr. 1·84), and allowing the mixture to stand for 24 hours. It is then washed with a strong solution of common salt to free it from excess of acid, and is finally neutralised with ammonia or caustic soda. The product of the action of the acid upon the oil is somewhat complex, but its practical utility depends upon the fact that it behaves like a fatty acid and gives an extremely soluble soap with alkalis. Ordinary castor-oil soap produced by boiling the oil with caustic soda is also very soluble, and may be used as a mordant. Sulphated oil is frequently called ' Turkey-red oil,' ' alizarin oil,' and ' soluble oil,' since it is largely used in the modern short process of Turkey-red dyeing as the fixing agent for the necessary aluminium mordant, and it gives the characteristic brilliancy of colour obtained by the use of the oil preparations formerly employed. Monopole oil is a similar product.

Phenolic colouring principles, *e.g.* alizarin, and certain acid colouring matters derived from benzidene, stilbene, fluorene, &c. (the direct cotton dyes) can also be fixed on cotton, and serve as mordants for basic colouring matters, but they are only occasionally used for this purpose for the production of compound shades.

COLOURING MATTERS.

(For Classification, see p. 575).

GENERAL METHODS OF APPLICATION.

CLASS I.—**Mordant dyes.** This group of dyestuffs includes the majority of the *natural dyes,* also the numerous class of *alizarin dyes,* a number of derivatives of *pyrogallol* and other *phenols,* and certain *azoquinone-oximes* and *nitroso- dyes.* The following are the chief members of the group.

Mordant dyes of natural origin—Logwood; madder; cochineal; limawood and other 'soluble redwoods'; camwood and other 'insoluble redwoods'; fustic; weld; quercitron bark and flavin.

Synthetic mordant dyes.—Alizarin; anthrapurpurin, flavopurpurin, and purpurin; nitroalizarin (alizarin orange); alizarin maroon (aminoalizarin); alizarin bordeaux; anthracene brown; alizarin blues; alizarin cyanins; anthracene blues; alizarin greens; cœrulein; anthracene yellow; mordant yellow, galloflavin, &c.; alizarin black; gallein; gallocyanin; cœlestine blue; naphthol green, dark green, gambine, &c.

The mordant dyes are largely used in the dyeing of wool and in the dyeing and printing of cotton and silk. Generally speaking, they yield colours which are of great fastness to light, soaping, acids, alkalis, bleaching agents, &c As regards cotton dyeing, they have largely been replaced by 'after-treated' direct dyes and the very fast vat and sulphide dyes recently introduced.

When a fabric, previously mordanted with a metallic salt, is dyed with a mordant dye, a chemical reaction takes place, resulting in the formation of a new compound which is the actual colouring substance; this compound being, at the same time, fixed upon the fibre, which thus becomes dyed. These *colour lakes* or *pigments* may, for the most part, be equally well produced by bringing together the mordant and the dyestuff under suitable conditions in the absence of the fibre. Many colour lakes of this class are indeed manufactured in bulk for use in printing or painting.

There are three methods by which mordant dyes may be applied : (1) the mordant may be first applied to the fibre, and afterwards the dyestuff in a separate operation (' mordanting and dyeing method '); (2) the order of application of mordant and dye may be reversed (' dyeing and saddening method '); or (3) the mordant and dyestuff may be applied simultaneously (' single-bath method '). All three methods are in use. If equally good results can be obtained, the ' single-bath ' process is to be preferred, but usually the ' mordanting and dyeing ' process gives the maximum fastness.

The dyeing of wool with mordant dyes.— When potassium dichromate is employed as mordant, the ' *mordanting and dyeing* ' process is usually preferable, because, in the ' single-bath ' process, the acid necessarily added to dissolve the colour lake formed in the dye-bath, converts the mordant into such a powerful oxidising agent by liberating chromic acid, that most dyestuffs are injuriously affected. In the two-bath process, the wool should be thoroughly washed after mordanting. If this operation is omitted, a portion of the mordant passes from the wool into the dye-bath, and, combining with an equivalent amount of colouring matter, forms a precipitate which floats about in an insoluble condition. This not only leads to loss of dyestuff, but also tends, by superficial absorption, to cause the dye to 'rub off.' The dyeing process consists in boiling the wool for from 1 to 2 hours with the colouring matter in aqueous solution. The final washing, after dyeing, has for its object the removal of any colouring

matter which is imperfectly fixed ; but, however thorough the washing may be, there is usually a small amount of colouring matter present on the dyed wool, which has merely been absorbed without combining with the mordant. This free colouring matter will dissolve out or ' bleed ' during milling or scouring, because most mordant dyes are readily soluble in alkaline solutions. A slight supplementary mordanting (' afterchroming ') is frequently used to fix this small amount of free dyestuff.

The ' *dyeing and saddening* ' method is not much used with the true mordant dyestuffs, but is the chief process used in applying the *acid mordant dyes*. Since the ultimate intensity of colour depends chiefly upon the amount of dyestuff which is fixed in the first bath, whilst the colour is only developed by the mordant in the second bath, it is obviously more difficult to exactly match a pattern when this process is used than when the mordant is applied first.

In the ' *single-bath* ' method ,of dyeing, the bath is prepared with the necessary amount of mordant and dyestuff with an addition of sufficient acid (usually oxalic or acetic acid) to dissolve the colour lake formed. This process is therefore only suitable when the colour lake is soluble in dilute acid, and thus is particularly characteristic of the tin and aluminium colour lakes : although the single-bath process is also frequently applicable in the case of ferrous sulphate or chromium fluoride mordants.

The dyeing of silk with mordant dyes.—The mordant dyes are not very largely used on silk, chiefly because they detract somewhat from the lustre of the fibre. The degree of fastness of the acid dyes, if suitably selected, is, moreover, usually sufficient for the requirements of the silk dyer. The methods of mordanting have already been dealt with. Dyeing must take place at the boil for about an hour, and the silk is subsequently brightened by working in a warm dilute solution of acetic or tartaric acid, and dried without washing.

Dyeing of cotton with mordant dyes.—The ' mordanting and dyeing ' method is generally used in cotton dyeing Aluminium is the chief mordant employed, and, in conjunction with alizarin, it yields the important Turkey-red dye. This is a complex compound containing an alizarin-aluminium-calcium lake in combination with polymerised fat acids. In the production of this colour, the cotton is first prepared with sulphated oil, then dried, mordanted with alum, and subsequently dyed with alizarin. The complete process involves a large number of operations, for the details of which manuals of dyeing must be consulted. The dyeing of Turkey red is a very ancient process, having been carried out centuries ago in India by the aid of milk (as fatty matter) and munjeet, the Indian madder plant. No alum was employed, but the plant with its earthy incrustations contained sufficient alumina to produce the alumina lake. The art spread from the East through Persia and Turkey, and was first introduced into this country (Glasgow) in 1790. Madder has now been entirely replaced by synthetic alizarin in Turkey-red dyeing, and the substitution of ' sulphated oil ' for olive oil or soap has also greatly simplified the process.

Another important mordant dye on cotton

is logwood black, which is obtained by dyeing with logwood on tannin-iron mordant. It is largely used in hank and warp dyeing. Catechu brown is produced by the 'dyeing and saddening' method, the cotton being first steeped in a strong solution of catechu, and subsequently treated with potassium dichromate. The latter acts essentially as an oxidising agent, producing the so-called *japonic acid* on the fibre.

A great variety, of permanent and bright colours may be obtained with mordant dyes on cotton mordanted with chromium or aluminium, but they are not very largely used, fast colours being chiefly produced by means of the *sulphide, vat,* and *ingrain* dyes (Classes VI., VII, VIII).

CLASS II.—Acid-mordant dyes. These dyes are suitable only for wool and silk, and are largely used on wool. They are now very numerous, and are chiefly azo- compounds containing salicylic acid or orthoaminophenol components. Some, however, are anthracene or pyrogallol derivatives. Unlike the mordant dyes, they usually contain sulphonic acid groups.

Many of the acid-mordant dyes may be employed as ordinary acid dyes, since a mordant is not essential to the development of their colour. Usually, however, such dyestuffs produce faster colours when applied in conjunction with a mordant.

An exhaustive list of acid-mordant dyestuffs cannot be given, but the following will serve as examples. They include dyes giving a complete range of colours. *Reds* : acid-alizarin, anthracene, chrome, cloth and milling reds. *Oranges and yellows* : cloth oranges and yellows, alizarin yellows (certain marks are mordant dyes), chrome yellows, milling orange and yellow, diamond, and mordant yellow. *Greens* : acid-alizarin, chrome, diamond and milling greens. *Blues* : acid-alizarin, brilliant-alizarin and chrome blues ; chromotropes (chromotropes dye red as acid dyes). *Violets* : alizarin heliotropes ; anthraquinone and chrome violets ; fast violet. *Blacks and greys* : acid-alizarin, acid-chrome, anthracene-acid, anthracene chrome, chrome, chromotrope and diamond blacks. *Browns* : acid-alizarin, acid-anthracene, chrome, cloth, diamond, and palatine browns ; chromogen.

Dyeing of wool with acid-mordant dyestuffs.— The usual method of application of this class of dyestuffs is to prepare a bath containing the necessary amount of dyestuff along with 1 to 3 p.c. sulphuric or 3 to 5 p.c. acetic acid, and 5 to 10 p.c. sodium sulphate (Glauber's salt) (all calculated on the weight of wool). After the solution has been brought gradually to the boiling-point, the boiling is continued until the colouring matter is entirely fixed, an additional amount of acid being added if necessary. Excess of acid, however, frequently retains the dyestuff in solution. The wool is then removed from the bath, the metallic salt is added, and the wool is again boiled in the bath for half an hour. In most cases, potassium dichromate, to the extent of one-half the weight of the dyestuff, is the mordant employed.

A modification of this process is used with the *metachrome* series of dyestuffs. The *metachrome mordant* is a mixture of yellow potassium chromate and ammonium sulphate. The bath is prepared with 3 to 5 p.c. of this mordant

together with the dyestuff. A prolonged boiling is necessary, during which the ammonium salt is decomposed, ammonia being evolved and the liberated sulphuric acid gradually converts the chromate into dichromate and assists in the fixation of the dye and the formation of the colour lake.

The *anthracene chromate dyes* are applied in a bath containing colouring matter, dichromate, and sodium sulphate ; this being another modification of the usual process.

The mercerol and autochrome dyes are also applied by special processes.

The acid-mordant dyes are of increasing importance in wool dyeing, but are little used on silk, and not at all on cotton.

CLASS III.—Acid dyestuffs. The acid dyes constitute the most numerous class of synthetic colouring matters. The chief chemical groups of acid dyes are *azo- dyes, nitro- compounds, sulphonated basic dyes,* and *phthaleins* ; the greatest number being azo- dyes. The azo- dyes contain few greens, blues, and violets ; but the reds, oranges, yellows, browns, and blacks are very numerous. The nitro- compounds are few in number and are all yellows, the chief being picric acid and naphthol yellow. The greater number of the sulphonated basic dyes, on the other hand, are greens, blues, and violets, but acid magenta belongs to this group. The resorcin or phthalein dyes are chiefly brilliant pinks or reds, the eosins being the most important group.

So extremely numerous are the acid dyes, and their names are so varied, that no useful purpose would be served by the enumeration of a small number of the products.

The dyeing of wool with acid dyes.—The commercial acid dyes are, in most cases, the sodium salts of sulphonic acids. The nitro- compounds, however, owe their acid character to the presence of nitro- groups in the molecule.

The simplest and most usual method of dyeing acid colours on wool is to prepare a bath containing the requisite amount of dyestuff with 1 to 4 p.c. of sulphuric acid and 10 to 20 p.c. of sodium sulphate (Glauber's salt). The wool is dyed in this solution for about an hour, boiling for the greater part of the time. Some dyes require smaller, and some larger percentages of acid. The sodium sulphate has a levelling influence on the fixation of the dyestuff, probably by reason of the solvent action which it exerts, since acid dyes are readily removed ('stripped ') from wool by boiling in a solution of sodium sulphate. Another reason is to be found in the retarding action which it exerts in the liberation of the free colour acid by the sulphuric acid. The equation, which may be expressed as :

$$\text{Colour salt} + H_2SO_4 \rightleftarrows \text{colour acid} + Na_2SO_4,$$
is reversible. (See also M. Firt, Theory of the Acid Dyebath, J. Soc. Dyers, 1916, p. 33.)

Sodium bisulphate or 'nitre cake' may be used in place of the sulphuric acid and sodium sulphate, or the sulphuric acid may be entirely replaced by acetic or formic acid.

In the case of dyestuffs which do not readily produce level colours on the fabric, the acid may be added to the bath gradually in small portions at a time, or may be substituted by an ammonium salt, e.g. ammonium sulphate

or acetate. The acid is then liberated very gradually as the ammonium salt is decomposed in the boiling bath, and the colouring matter is therefore converted very slowly from the condition of the soluble sodium salt to that of the more or less insoluble free sulphonic acid.

The dyeing of silk with acid dyes.—Acid dyes are very largely used in silk dyeing. They are applied in a bath containing a large quantity (up to 25 p.c. in volume) of 'boiled-off' liquor, the soapy solution of the silk gum obtained in the 'ungumming' of raw silk. The bath is rendered slightly acid by means of sulphuric, acetic, or formic acid. Dyeing usually takes place at about 80°, at which temperature silk has more affinity for acid dyes than in a boiling bath.

After dyeing, the silk is washed and is then 'brightened' by working in a dilute (sulphuric, acetic, or tartaric) acid solution and dried without washing.

The dyeing of cotton with acid dyes.—There is no satisfactory method of fixing the acid dyes upon vegetable fibres, but for cheap work they are often applied by a 'padding' process.

CLASS IV.—**The direct dyes.** The direct dyes have the special property of dyeing cotton without the aid of a mordant. Like the acid dyes, they are for the most part azo- compounds, but contain the chromophor $-N=N-$ twice in the molecule, and thus belong to the tetrazo-group of azo- dyes. They further resemble the acid dyes in that they are alkali salts of sulphonic acids, but as regards dyeing properties, they differ greatly from the simpler azo-acid dyes. Since the introduction, in 1884, of the first of the direct dyes, a very large number have been placed on the market, and the group contains dyes of all colours—reds, oranges, yellows, greens, blues, violets, browns, and blacks. As examples of these dyes may be mentioned the congo, benzo, diamine, mikado, titan, and chlorazol dyes.

Primuline is an example of a direct dye which is not an azo- compound. It contains the chromophor $\genfrac{<}{}{0pt}{}{S}{N}\geq C-$.

Turmeric is the only important natural direct dye for cotton.

The direct dyes are largely used upon all fibres. No satisfactory explanation has been given of the fact that they readily dye cotton, whereas the acid dyes are entirely devoid of this property. The further fact that the direct dyes dye wool in a neutral, or even slightly alkaline bath, whereas the acid dyes require the addition of acid, also requires explanation.

The dyeing of wool with direct dyes—These colouring matters are applied to wool in a neutral or feebly acid bath with or without the addition of sodium sulphate (Glauber's salt). In some cases, an after-treatment with a metallic salt gives improved fastness, the dyes then practically falling into the class of acid-mordant dyes.

As a class, the direct dyes on wool are much faster to milling than the ordinary acid dyes. When fixed on wool, they are also faster to acids, washing, and light than when dyed on cotton. In some cases, the colour produced by a direct dye on wool and cotton is identical, in other cases it differs considerably.

The dyeing of silk with direct dyes.—These dyes are largely used on silk both for self shades

and also on account of their property of permanent reduction to colourless bodies, in the so-called 'foulard' style of printing. They are applied in a similar manner to the acid dyes, but smaller amounts of 'boiled-off liquor' and acid are required.

The dyeing of cotton with direct dyes.—The application of the direct dyes to cotton is very simple. They are dyed either from a cold, luke-warm, or boiling solution, to which is added a small amount (up to 2 p.c.) of sodium carbonate, and an amount of a neutral salt (up to 20 grams $NaCl$ or Na_2SO_4 per litre), which is governed by the solubility of the dyestuff employed. At low temperatures more concentrated solutions of colouring matter are required. Brighter colours are obtained by passing the dyed material through a solution of Turkey-red oil before drying or by adding this substance to the dye-bath.

Mercerised cotton has a much greater affinity than ordinary cotton for the direct dyes, and in dyeing this fibre special precautions are necessary to produce level colours.

Many of the direct dyes produce on cotton colours of great brilliance and richness, but they bleed out into hot water, and are still more readily attacked by soap. Most of them are also comparatively fugitive to light.

There are three processes by means of which the fastness-properties of certain of the direct dyes can be improved.

1. *The diazotising and developing process.*—This process is applicable only in the case of those dyestuffs in which amino- groups constitute the auxochrome. The cotton is first dyed by the general process above described, then washed, and afterwards worked for a few moments in a cold dilute solution of nitrous acid (2 p.c. $NaNO_2$ and 4 p.c. HCl on the weight of the cotton). This treatment diazotises the amino- groups The cotton is then well washed in cold water and entered immediately into the developing bath, which contains a solution of a phenolic or amino- compound; sufficient alkali or acid respectively being added to bring the 'developer' into solution. The chief developers used are phenol, resorcinol, α- or β-naphthol, aminonaphthol, aminodiphenylamine, m-tolylenediamine, and certain of the naphthol sulphonic acids.

Primuline is applied by the process just described.

A modification of this method is known as the '*coupling process.*' The cotton is first dyed with the direct dye, and, after rinsing, is worked in a diazotised solution of the 'coupler.' The chief body used as coupler is p-nitraniline. Ready prepared stable diazo- compounds of this base are sold under the names 'nitrazol,' 'azophor red,' and 'nitrosamine red.'.

2. *After-treatment with metallic salts.*—In this process for improving the fastness of the direct dyes on cotton, the fibre is first dyed in the ordinary way, and then, after rinsing, is treated for half an hour in a warm slightly acidified solution of a suitable metallic salt. The salts chiefly employed are copper sulphate, potassium dichromate, and chromium fluoride; from 1 to 3 p.c. with addition of 2 to 4 p.c. of acetic acid being used. A mixture of the two first-mentioned salts is frequently used. This process is mainly employed in the case of blues, greens,

browns, and blacks. The chromium salts exert the greatest influence in increasing the fastness to washing, and the copper salt in regard to the fastness to light.

This process is only applicable to the case of dyestuffs containing free OH or COOH groups.

3. *After-treatment with formaldehyde.*—This process, which is chiefly used for navy blues and blacks, is carried out by working the dyed cotton for half an hour at 70° in a solution containing about 3 p.c. formaldehyde (on the weight of the cotton). The fastness against washing is considerably improved thereby.

Cotton dyed with direct dyes may be 'topped' with basic dyes, for which the direct dyes act as mordants.

CLASS V.—**The basic dyes.** This group of colouring matters is numerically smaller than the mordant, acid, or direct dye groups. It includes, however, the most brilliant dyes known, rhodamine pink, auramine yellow, malachite green, methylene blue, and methyl violet being well-known examples.

The basic dyes are very diverse in their chemical constitution Many are derivatives of di- or tri-phenylmethane (magenta, malachite green, methyl violet); others are azo- compounds (chrysoidine, Bismarck brown); some are azine-derivatives (safranine and induline); whilst the thiazines contain sulphur as an essential constituent (methylene blue).

The commercial basic dyes are usually hydrochlorides of the colour bases, but some are acetates, oxalates, sulphates, or zinc chloride double salts. They are characterised by great tinctorial power, 1 p.c being usually sufficient to produce a full rich colour. As a class, they are not fast to light.

Janus dyes. These occupy an intermediate position between the basic and the direct dyes. They are azo- dyes of strongly basic character, and possess an extraordinary affinity for both animal and vegetable fibres. They are only of slight importance.

The dyeing of wool with basic dyes.—These dyes are little used on wool, the acid dyes being applied in an equally simple manner and producing faster colours. Wool has a strong affinity for basic dyes, and readily becomes dyed if immersed in their solutions. A small amount of sulphuric or acetic acid may usually be added with advantage. Certain of the basic dyes, *e.g.* Victoria blue, are very fast to milling when dyed on wool, and such are still employed.

The dyeing of silk with basic dyes.—Members of this group of colouring matters are largely used by the silk dyer when fastness to light is not important. The silk yarn is dyed at 60°-80° in a slightly acidified solution of the dyestuff, to which is added some 'boiled-off liquor.' After rinsing, the dyed silk is brightened in a dilute solution of acetic or tartaric acid.

The dyeing of cotton with basic dyes.—Cotton has little affinity for basic dyes, which, on this fibre, must therefore be applied in conjunction with a mordant, and since the dyestuffs of this class are basic in character, the mordant must be of an acidic nature.

Three types of acid mordants are available, viz. : tannin matters, fat acids, and colour acids.

1. *Tannin mordants.*—As mentioned in dealing with the mordants, cotton has a natural affinity for tannic acid, which it withdraws from solution. Since tannic acid forms lakes with the basic colouring matters, cotton thus prepared may be dyed with basic dyes, but the colours produced in this manner are not fast against washing. As previously explained, however, if after mordanting with tannin the cotton is treated with a salt of antimony, tin, or iron, an insoluble metallic tannate is formed on the fibre, which compound has the same affinity for basic dyes as tannic acid has. The fastness properties of the double tannate of colour base and metal are much superior to those of the simpler tannates of the colour bases.

For the production of pale or bright colours, commercial tannic acid, gall nuts, or sumac are the tannins employed. The cotton is saturated ('padded') with a solution of 2° to 3°Tw. strength, or steeped for 2 to 3 hours in a solution containing 2 to 5 p.c tannic acid or 10 to 30 p.c. ground gall nuts or sumac; the amount being calculated on the weight of cotton. The yarn or fabric after squeezing is then at once passed into a 'fixing bath' containing 1 to 2·5 p.c. of tartar emetic or an equivalent amount of antimony oxalate or fluoride After well washing, the cotton is dyed with 0·1 to 1 p.c. of basic dye.

Additions of acetic acid to the tannin bath, ammonium chloride and chalk to the fixing bath, and a little acid to the dye-bath, are frequently made. The mordanting and fixing baths may be used for several successive lots of material.

If the brightest possible shades are not required, some cheaper tannin matter (myrobolans or quebracho) may be employed, and stannic chloride may replace tartar emetic as fixing agent. For dark shades, ferrous acetate ('black iron liquor') is used as fixing agent, the blueblack tannate of iron producing a composite colour with the basic dyestuff.

2. *Fatty mordants.*—If Turkey-red oil or soap is used as mordant, the colour produced with a given basic colour is brighter, but less fast, than when tannin mordant is used.

The fat acids are fixed on the cotton as metallic salts, usually aluminium salts; the fibre being first saturated with a solution containing 1 lb. of sulphated oil or soap per litre, then dried and passed into a solution of aluminium acetate ('red liquor') of about 8°Tw.

3. *Colour acids as mordants.*—Mention has already been made of the fact that the direct dyes act as mordants towards the basic dyes, compound shades being thus obtained. Mordant, sulphide, and acid dyes also possess the property of attracting basic dyes, but these combinations are not much employed.

The dyeing of jute with basic dyes.—Although jute is a vegetable fibre, it does not consist of free cellulose, but of a bastose-cellulose compound, *corchorobastose* (Cross and Bevan). The dyeing properties of this substance differ materially from those of cellulose; jute, in fact, behaving in a very similar manner to tannin-mordanted cotton, and dyeing direct with basic dyes.

CLASS VI.—**The sulphide dyes.** The dyes of this group are numerous and important. They are chiefly employed for the production of fast blacks, blues, greens, browns, and yellows on cotton and other vegetable fibres. They come into the market in the form of powders, which

are usually insoluble in water, but soluble in solutions of sodium sulphide. They are also rendered soluble by other reducing agents, *e.g.* sodium hydrosulphite or glucose in alkaline solution.

The sulphide dyes are commercially known under such names as : sulphur, sulphurol, thiogene, thionol, thional, thioxine, cross-dye immedial, katigen, kryogen, pyrogen, pyrol rexoll, eclipse, vidal, or auronal dyes. They are produced by melting together under suitable conditions aromatic nitro-, amino-, or imino-compounds with sulphur and sodium sulphide. The constitution of the sulphide dyes is not known, but the commercial products are probably mixtures of polymers or homologues and not homogeneous bodies. They contain free sulphur in amount varying from 1 to as much as 12 p.c. (Gardner and Hodgson, J. Soc. Chem. Ind. 1910, 672), and also contain very variable amounts of sodium sulphide and polysulphides.

The dyeing of wool with sulphide dyes.—Wool is rarely dyed with sulphide dyes, on account of the injurious action of sodium sulphide on the fibre. The wool may be protected to some extent against this action by the addition to the dye-bath of glucose, tannic acid, or ammonium salts. A previous treatment of the fibre with formaldehyde has also been recommended (R. Kann, Eng. Pat. 3492, 1903), but this reduces the affinity of the wool for these dyestuffs.

Greater success in the application of sulphide dyes to wool or union material has been attained by E. Lodge (Eng. Pats. 19852, 1913 ; and 23386, 1914) by the use of sodium hydrosulphite and sodium sulphite as reducing agents, and ammonia as solvent for the reduced dyestuff (J. Soc. Dyers, 1915, 252).

The dyeing of silk with sulphide dyes.—Owing to the harmful effect of their alkaline solutions upon the silk fibre, the sulphide dyes are not used.

The dyeing of cotton with sulphide dyes.— This group of dyestuffs is now of the greatest importance in cotton dyeing for the production of fast blacks, and to a less extent, fast blues, greens, browns, &c. The necessary ingredients in the dye-bath, in addition to the dyestuff, are sodium sulphide, sodium sulphate, or other neutral salt, and an alkali, usually sodium carbonate. The actual and relative amounts of these substances vary considerably with different dyestuffs, depending upon the ease with which the colouring matter employed undergoes reduction and the solubility of the reduced product. An addition of Turkey-red oil, monopole oil, or glue, tends to produce more level and brighter shades ; glucose aids the reduction. Dyeing takes place just below the boil, and it is usually desirable to keep the cotton completely immersed during the operation, in order to prevent irregular oxidation. The baths are used in a very concentrated condition, with the result that only a small proportion of the dyestuff is withdrawn, and for reasons of economy ' standing baths ' are employed, that is, the baths are used continuously and replenished with dyestuff, &c., as required. The dyeing takes place in iron, wooden, or lead-lined wooden vessels ; copper being rigidly excluded, on account of the ease with which it is attacked by sodium sulphide.

Some of the sulphide dyes do not require any treatment subsequent to dyeing other than

exposure to air, but with many dyes of the group an after-treatment greatly improves their fastness to light and other influences. The chief object of the after-treatment is to ensure the complete oxidation of the colouring matter ; and, as oxidising agents, chromium salts, or hydrogen peroxide are used. Steaming the material in presence of air is employed in the case of immedial blue.

After-treatment with potassium dichromate and acetic acid is now usually practised, since the use of copper salts has proved to be dangerous in regard to the subsequent tendering of the fibre on account of their catalytic action in inducing acid formation (Gardner and Hodgson, J. Soc. Chem. Ind. 1910, 676).

The tendering of cotton dyed with sulphide blacks has greatly retarded the use of these dyestuffs. The defect does not usually develop for some weeks or months after the material has been dyed, and it has been shown to be due to the slow formation of sulphuric acid on the fibre. The development of acid arises mainly from the oxidation of free sulphur present on the dyed fibre, but even in the absence of free sulphur, acid development may take place by decomposition and oxidation of the colour molecule.

The risk of tendering, during storage, of cotton dyed with sulphide blacks is entirely eliminated by a final treatment of the material, before drying, with sodium acetate ; but, of course, the protective influence of this salt disappears if the material is washed.

CLASS VII.—**The vat dyes.** Until comparatively recently, indigo was the sole representative of this group of dyestuffs. The synthetic production of indigo was, however, followed by that of a number of derivatives of this body. Other series of vat dyes have also been produced, and by their use it is now possible to produce on cotton, and in a .more limited degree on wool, many bright colours of a degree of fastness hitherto unattainable.

The essential features of a vat dye are its easy reduction to a form soluble in dilute alkali, its attraction in this condition by the fibre, and its ready reoxidation on the fibre to the original insoluble condition. The reduced solution is termed the ' vat,' the composition of the vats differing for wool and for cotton.

The vat dyes are mainly derivatives of indigotin or anthracene. They include the following : indigo (indigotin) ; mono-, di-, tri-, and tetra-halogen derivatives of indigotin ; methyl and tolyl indigotins ; ciba dyes (brom indigotins) ; thioindigo red and scarlet ; helindone dyes (sulphur derivatives) ; algole dyes ; cibanone dyes, and the indanthrene dyes. The group includes dyes of all hues.

Indigo is the oldest and by far the most important of the vat dyes. It has been employed in India for at least 3500 years, by methods not differing essentially from some of those which are still employed. It is used upon all fibres, but least commonly upon silk.

Various reducing agents are employed for the conversion of the insoluble indigo blue into indigo white, and they are always associated with an alkali to dissolve the latter substance. After saturating the fibre with the alkaline solution, the indigo white is reconverted into

indigo blue upon the fibre by atmospheric oxidation.

The dyeing of wool with indigo vat blue.—The two chief indigo vats used for wool are the fermentation vat and the hydrosulphite vat, the former being chiefly used for dark shades on woollen cloth (Army and Navy cloth, &c.), and the latter for light colours on slubbing, yarn, &c. There are several forms of fermentation vat, of which the woad vat is the most important in this country. The precise composition and 'setting' of the vat is largely a matter of experience, the ingredients being somewhat as follows : finely ground indigo, 12 to 18 lbs. ; woad, 300 lbs. ; bran, 10 lbs. ; madder, 12 to 18 lbs. ; lime, 12 lbs. ; water, 600 gallons. After warming the liquor, various fermentations set in, the essential bacterium being the *Desmobacterium hydrogeniferum*. The starchy matters present are first converted into glucose, which then splits up into lactic acid, the latter undergoing butyric fermentation with evolution of hydrogen.

Excessive fermentation is prevented by making suitable additions of lime, or it is accelerated, if necessary, by adding further quantities of bran.

In the so-called German or soda vat and the Indian or potash vat, the woad is replaced by bran with the addition of molasses, and the lime by sodium or potassium carbonate.

To avoid the derangements to which all fermentation vats are liable, Collin and Benoist (J. Soc. Chem. Ind. 1885, 493) proposed to employ a pure ferment and a completely fermentable food material ; but this process has not come into practical use.

Natural indigo is still largely used in the fermentation vats, but in the hydrosulphite vat the synthetic product is generally employed. The hydrosulphite vat may be prepared as follows : synthetic indigo (20 p.c. paste), 10 lbs. ; caustic soda solution 42°Tw., 3 pints ; sodium hydrosulphite solution 20°Tw., 7½ gallons; water, 50 gallons. The liquid is heated to 50° until it becomes clear greenish-yellow. The solution of indigo white thus obtained is diluted to 250 gallons with water at 50°, to which a little hydrosulphite has been previously added.

The hydrosulphite solution may be replaced by 3 lbs. of solid sodium hydrosulphite, in which case the amount of caustic soda must be increased. 3½ lbs. of natural indigo (60 p.c. indigotin) are about equivalent to 10 lbs. of synthetic indigo (20 p.c. paste). After working in the vat, the goods are well squeezed, and then exposed to the atmosphere to oxidise the indigo white : they are then well washed.

Dark shades of indigo blue on wool are usually 'bottomed,' with a red dye (alizarin, diamine fast red, or barwood) before vatting, and are frequently 'topped' after vatting with orchil or other dyestuff in order to add 'bloom' to the colour.

In most respects indigo vat blue is an extremely fast colour, but has the defect of being liable to 'rub off.'

The dyeing of silk with vat indigo.—This dye is not much employed on silk. If used, the most suitable vat to employ is the hydrosulphite vat set with synthetic indigo.

The dyeing of cotton with vat indigo.—The

hydrosulphite vat is largely employed in cotton dyeing as well as in the dyeing of wool, but it is used cold in the case of cotton. Other cotton vats are the 'copperas vat' and the 'zinc-powder' vat.

A strong copperas vat contains, indigo (60 p.c.), 10 lbs. ; ferrous sulphate, 30 lbs. ; and quicklime 35 lbs., in about 200 gallons of water. The lime decomposes the ferrous sulphate, with the production of ferrous hydroxide, and this in the presence of lime and indigo decomposes water, yielding ferric hydroxide and hydrogen ; the latter at once combines with the indigotin and produces indigo white, which dissolves by reason of the excess of lime present. The normal colour of the vat liquor thus obtained is brownish-amber.

The zinc-powder vat is made up with water, indigo, zinc-powder, and lime. In the presence of the lime and indigo, the zinc decomposes water even at the ordinary temperature, and the liberated hydrogen effects the reduction of the indigo.

Vat dyes other than indigo.—These may be divided into two groups : (a) the *indigoids*, which may be considered as derivatives of indigotin ; and (b) the *anthracene* derivatives. They all possess the common property of forming vats when treated with hydrosulphite of soda, but whereas the indigoids may be applied to the animal as well as to the vegetable fibres, the anthracene derivatives are only suitable for cotton on account of the large amount of caustic alkali required for their solution. The reduced anthracene vat dyes also do not appear to possess much affinity for wool.

(a) *Indigoids.*—Examples of dyes of this series are : thioindigo red and scarlet ; helindone red and scarlet ; ciba red and scarlet ; vat red ; helindone orange and yellow ; ciba green ; brom indigos ; ciba blues and greys; ciba violets and helidtropes ; helindone brown. Some of the algole reds also probably belong to this group.

(b) *Anthracene vat dyes.*—Indanthrene red ; algole reds ; indanthrene yellows and oranges ; algole yellows and oranges ; cibanone yellows and oranges ; indanthrene greens ; algole greens ; indanthrene, chloranthrene, duranthrene and caledon blues ; algole blues ; indanthrene grey ; indanthrene browns ; algole browns ; cibanone browns.

The application of the indigoid vat dyes to wool and silk—Vats suitable for the dyeing of wool and silk are obtained by reduction with sodium hydrosulphite in alkaline (caustic soda) solution. Bright reds of excellent fastness are obtained with these dyes, and they are used in conjunction with indigo for producing bright purplish blues. Separate vats are preferable for the indigo blue and the red dye, since the best conditions of dyeing do not coincide in the two cases.

The application of indigoid vat dyes to cotton. —Vegetable fibres are readily dyed with these dyes from a hydrosulphite vat, or alternatively they may be dyed from a sodium sulphide bath, as used for the sulphide dyestuffs. They may be mixed with most sulphide dyes and dyed from the same vat.

The application of the anthracene vat dyes.— This group of dyes is also applied in the hydrosulphite vat, but usually requires such a strongly

caustic solution that its application to wool and silk is not practicable.

By use of the vat dyes, it is now possible to produce a great variety of colours on cotton which are extremely fast to light, washing, bleaching, and other influences. The high cost of these dyes at present somewhat limits their application.

Indophenol is a vat dye of different type, being obtained by the action of nitroso-dimethyl aniline on a-naphthol. On reduction, it is converted into *indophenol white*, a body sufficiently stable to admit commercially. On oxidation with chromic acid, indophenol white is reconverted into indophenol blue.

Indophenol has been employed in conjunction with, or as a substitute for indigo, but has the defect of being readily affected by acids.

Tyrian purple.—As the result of an extremely interesting investigation, P. Friedländer has shown (Ber. 1909, 765) that this ancient dyestuff is identical with one of the dibrom-indigotins. Tyrian purple, as described by Pliny, was obtained from various species of the mollusc *murex*, and from 12,000 of the species *M. brandaris* Friedländer obtained 1·4 grams of the colouring matter.

Under the law of the ancient Romans, the use of Tyrian purple was confined to royalty, and the method of its production was a lost art for many centuries. At the beginning of the 18th century, it was investigated by Reaumur (Mem. de l'Acad. Royale des Sciences, 1711), but it never again assumed any importance as a dye-stuff.

CLASS VIII.—**The ingrain dyes.** The term *ingrain dye* may be used to designate those colouring matters other than mordant dyes which are produced from their constituent bodies *upon the fibre*. Three sub-groups may be distinguished : (*a*) *aniline black* ; (*b*) *the insoluble azo- dyes* ; and (*c*) *the metallic dyes*.

(*a*) *Aniline black.*—This term is applied to the insoluble black pigment which is produced by the oxidation of aniline in acid solution. In 1834 Runge noticed that a blue-black compound was produced by oxidising aniline with chromic acid, but Wilm, in 1860, first described the formation of the product on the cotton fibre. The first successful process for producing aniline black on the fibre was patented by Lightfoot, in 1863. He used potassium chlorate and cupric chloride as oxidising agents, and the black proved to be of such excellent fastness that innumerable modifications of the process have since been proposed, and the literature of the subject is very extensive.

Numerous oxidising agents have been employed in the production of aniline black, *e.g.* chlorates, chromates, salts of copper, vanadium, tungsten, cerium, &c. Aniline black may also be produced by electrolytic (Goppelsröder, Jahresber. 1876, 702) or by atmospheric (Green, J. Soc. Dyers, 1908, 231) oxidation.

Pure aniline on oxidation yields a blue-black, the homologues and allied compounds giving somewhat different shades ; *e.g.* orthotoluidine produces a brownish-black, paraphenylene diamine a deep black, and para-aminodiphenyl-amine (diphenyl base) a greenish black. The oxidation of a-naphthylamine on the fibre results in the formation of *naphthylamine violet*, but this colour is not of much importance.

The composition of aniline black has been the subject of much investigation (*see* Armand Müller, Chem. Zentr. 1871, 288 ; Goppelsröder, Jahresber. 1876, 702 ; Nietzki, Ber. 1878, 1094 ; Caro. Verhandt. d. Ges. Deutscher Naturforchen u. Arzte, 1896, 119 ; Willstätter and Moore, Ber. 1907, 2665 ; Marsden, J. Soc. Dyers, 1908, 9 ; Willstatter and Moore, Ber. 1909, 4118 ; Green and Woodhead, Chem. Soc. Trans. 1910, 223).

Three chief and successive products of the oxidation of aniline may be distinguished—*emeraldine, nigraniline,* and *ungreenable black*.

Emeraldine is produced by the limited oxidation of aniline, several residues linking up to form a chain of 4 molecules (Willstatter and Moore) or a chain or ring of 8 molecules (A. G. Green). The aniline residues are in all probability linked by nitrogen atoms in para- position, since para- compounds only have been obtained on oxidation or reduction.

Emeraldine is a greyish-green body which is always formed during the early stages of the production of aniline black. By the action of oxidising agents, it is converted into nigraniline and by the action of reducing agents it forms first proto emeraldine by addition of two atoms, and then leuco-emeraldine by addition of four atoms of hydrogen (Green, Chem. Soc. Trans 1910, 223). More powerful reducing agents split the molecule and produce amino- and para diamino-compounds or quinone.

Nigraniline, the second oxidation product of aniline, appears to contain eight aniline residues, and is said to be produced either by removal of two hydrogen atoms from the emeraldine molecule (Green) or by polymerisation with loss of hydrogen (Willstatter and Moore).

Nigraniline or aniline black is a violet-black body which is unaffected by alkalis, but which is turned green by mild reducing agents (sulphurous acid). owing to its reconversion into emeraldine. Dilute mineral acid also brings about indirectly the production of emeraldine from nigraniline. Oxidation of a portion of the latter substance probably takes place at the expense of the reduction of other molecules, since both quinone and emeraldine are formed in the reaction.

Ungreenable black, the final product in the technical formation of aniline black, is produced by the further oxidation of nigraniline in presence of aniline. It is a very stable body, and is not readily attacked by acids, alkalis, oxidising or reducing agents. Powerful oxidising agents, however, convert it almost quantitatively into quinone, and powerful reducing agents into a brown leuco- compound which is reoxidised to the original black on exposure to air. The presence of free aniline is essential to the production of ungreenable black, which suggests that it is a condensation product of emeraldine and aniline.

Technical production of aniline black.—Of the large number of modifications of Lightfoot's original process which have been suggested, very few have withstood the test of practical experience. The following technical methods may be distinguished : (1) *dyed blacks* ; (2) *aged blacks* ; (3) *steam blacks.*

(1) *Dyed blacks,* also known as *one-bath blacks,* are used for the dyeing of cotton yarn, which is often previously dyed in a sulphide black

vat. The ingredients used are (e.g.) aniline (12 lbs.), hydrochloric acid (18 lbs.), sulphuric acid (24 lbs.), and sodium dichromate (24 lbs.), in 40 gallons of water. The use of hydrochloric acid alone produces a bluish-black, and sulphuric acid alone a reddish-black, the mixed acids yielding a jet black.

The yarn is worked in the solution whilst slowly heating to the boiling-point, and the bronzy black thus produced is steamed to convert it into a good black which is ungreenable. This process does not tender the cotton. Many modifications of the process are used.

(2) *Aged blacks* are obtained by padding (saturating) the cotton with a solution containing aniline salt, some oxidising agent (sodium chlorate) and an oxygen carrier (copper sulphate, or vanadium chloride), after which the fabric is dried and 'aged'; the colour being developed by passing through an ageing chamber in which a moist atmosphere and a temperature of about 45° are maintained. The padded cotton has a green colour (emeraldine) which turns black (nigraniline) during ageing. The final change to ungreenable black is brought about by working the fabric in a solution of sodium dichromate.

Copper aged blacks are very largely produced on cotton piece goods by a process which differs only in detail from Lightfoot's original process.

Vanadium blacks are chiefly used in calico printing. Lightfoot (Bull. Soc. Ind. de Mulhouse, 1871, 285) first noticed the special efficiency of vanadium salts as oxygen carriers in the production of aniline black, and Witz (Bull. Soc. Ind. de Rouen, 1876, 310) showed that 1 part of vanadium chloride was sufficient to convert 40,000 parts aniline into aniline black.

The production of aged blacks is liable to tender the cotton unless the process is very carefully controlled.

Air oxidation black.—A. G. Green (J. Soc. Dyers, 1909, 191) has introduced an aniline black process in which atmospheric oxygen is the oxidising agent; some carrier such as cuprous chloride being present. The mineral acid usually employed is also replaced by formic acid, and by these modifications the liability to tendering of the fibre is greatly reduced.

The process is based on the fact that aniline oxidises much more rapidly in presence of a small quantity of a paradiamine or a para-aminophenol.

After padding, the goods are dried, aged, and chromed as in the case of the ordinary aged black.

(3) *Steam blacks* are more costly than aged blacks, but safer as regards tendering of the fibre. They are produced by padding with an aniline solution which contains sodium chlorate as oxidising agent, and sodium ferrocyanide as oxygen carrier. After padding, the goods are dried, steamed, and chromed. Lightfoot's original steam black only differed from this in that it contained potassium ferricyanide in place of the less expensive sodium chlorate and ferrocyanide.

Aniline black, when successfully dyed on cotton, is the fastest and most intense black which it is possible to produce. Its chief drawbacks are the tendency to turn green and the liability to tendering of the fibre, unless great experience and close supervision are exercised.

Application of aniline black to wool and silk. —The animal fibres are rarely dyed aniline black.

The black may be produced on silk by the same methods as on cotton, but the process is chiefly confined to the silk-cotton union material used as umbrella cloth.

Aniline black does not readily develop on wool, but if the wool is previously chlorinated (Lightfoot) or boiled with a mineral acid (Bethmann, Eng. Pat. 21236, 1901); the aged black may be produced. It is rarely met with.

(b) *The insoluble azo- dyes.*—The sulphonated azo- dyes which are so largely used in the dyeing of wool and silk have little or no affinity for cotton. Azo- compounds, however, may be produced on cotton by impregnating the fibre with one of the constituents, and then passing it into a solution of the necessary combining body. The non-sulphonated compounds are used in this process, and the insoluble dyes thus obtained are, in many cases, useful colours.

The constituent parts of an azo- dye are (a) a phenol or amine, and (b) a diazotised base; and the process (introduced by Holliday, in 1880) consists in saturating the cotton with an alkaline solution of a phenol, drying, and then developing in a solution of the diazotised base.

In calico printing (rarely in dyeing) the fibre may be impregnated with a paste containing the whole of the colour ingredients, and the colour developed by steaming.

Substances employed in the process : Phenols. —The only phenols practically employed in the padding operation are β-naphthol and β-oxynaphthoic acid anilid (naphthol AS). Amines are not used.

Aromatic bases.—The following list gives the principal bases employed and the colours they produce when combined with β-naphthol :—

Base	Colour produced with β-naphthol
Aniline	Orange yellow
Paranitraniline	Red (with copper, brown)
Paratoluidine	Yellow orange
Nitroparatoluidine	Orange
Xylidine	Red
Cumidine	Bluish-scarlet
Phenetidine	Scarlet
α-Naphthylamine	Blue shade of claret red
Aminoazobenzene	Crimson
Benzidine	Purplish-brown
Tolidine	Reddish-brown
Dianisidine	Blue (with copper)
Azo-black base	Black

Padding or grounding.—The intensity of the ultimate colour depends entirely upon the concentration of the padding solution, which, for a shade of medium strength may contain, per litre, 25 grams β-naphthol, 45 grams sodium hydroxide solution 36°Tw., and 75 grams Turkey-red oil. Cotton is evenly saturated in the cold with this solution, then dried at a low temperature and developed.

The developing process.—The most important dye produced by this process is *paranitraniline red*, which is dyed on a very large scale and used as a substitute for Turkey-red. The diazo-solution is prepared as follows : stir to a paste 10 lbs. paranitraniline with 2 gallons water ; then add 2 gallons hydrochloric acid (35°Tw.) and 6 gallons water. After mixing well, add 5½ lbs. sodium nitrite dissolved in 2 gallons water. Dilute to 200 gallons, and add sodium

acetate to neutralise the excess of hydrochloric acid. The colour is produced instantaneously on passing the padded cotton into this solution, the cotton being subsequently washed, dried, and soaped.

Various stable forms of the diazotised base appear under the names azophor red, nitrazol, and nitrosamine red.

Azo-oranges, yellows, crimsons, claret-reds, &c., are obtained in a similar manner by the use of the various bases given in the above table.

Azo-browns are produced by adding an alkaline solution of copper to the β-naphthol prepare, and developing with paramitranilme or β-naphthylamine.

Azo-blues are obtained by padding with β-naphthol, developing with dianisidine, and subsequently treating with cupric chloride and chromic acid.

(c) *The metallic dyes* : *Iron buff and Nankin yellow.*—These two colours, which differ only in depth of shade, are produced by precipitating hydrated ferric oxide on the fibre. They are dyed chiefly on cotton, and produce yellow to light-brown colours which are fast to light, washing, or alkalis, but are readily attacked by acids. The cotton is padded in a solution of a ferrous or ferric salt, and then passed into an alkaline solution. If the cotton is previously mordanted with tannin, more even shades are produced, the black tannate of iron being subsequently destroyed by a treatment with sodium peroxide (Knecht) or other oxidising agent. Iron buff is only produced on wool or silk as an intermediate product in dyeing Prussian blue.

Manganese bronze.—This colour is produced on cotton by precipitating manganous hydroxide on the fibre, and oxidising this to the brown manganic peroxide.

Chrome yellow is produced on cotton by impregnating with a solution of lead acetate, drying, and passing into a solution of potassium dichromate.

Chrome orange—This compound is a mixture of normal lead chromate (chrome yellow) and basic chromate. It is obtained by treating cotton dyed chrome yellow with lime water.

Prussian blue is produced on cotton by first dyeing an iron buff, and then passing into an acid solution of potassium ferrocyanide. This colour is extremely fast to light, but is sensitive to alkalis. It is produced on silk in a similar manner as a constituent in dyeing that fibre black. Prussian blue is little used on wool, but is readily produced either by a process analogous to the above, or by making use of the fact that when heated in acid solution with wool, the prussiates undergo decomposition with formation of Prussian blue.

COLOURING MATTERS USED IN DYEING.

Natural dyestuffs : *Indigo.*—There are two distinct methods of applying indigo in dyeing, and the most important, the vat method, has already been described (*v.* Vat *dyes*, p. 586). Indigo may also be used as an acid dyestuff by converting it into the disulphonic acid. This sulphonic acid is known as indigo carmine or indigo extract. It dyes a brighter blue shade than vat indigo, but it is much less fast to light and washing. It is largely used on wool and silk, but is inapplicable to cotton.

Logwood is a mordant dyestuff and is used for all fibres. On *wool* it is largely employed for producing blacks, and in conjunction with other dyestuffs for browns, olives, greys, &c.

Potassium or sodium dichromate is the usual mordant, but a single-bath logwood black may be produced by using a mixture of logwood, ferrous sulphate, and oxalic acid. Logwood is now chiefly employed in the form of unoxidised (for cotton) or oxidised (for wool) extract. On *silk* and *cotton*, logwood is only used for black dyeing.

Brazilwood, peachwood, and Limawood constitute the class of soluble red woods. They are now very little employed, the colours they produce being fugitive to light. They produce reds with aluminium, reddish-browns with chromium, and purples with iron mordants.

Camwood, barwood, and sanderswood are known as the insoluble red woods. If wool is boiled with the ground wood, it acquires a reddish-brown colour, which is still employed as a ' bottom ' for indigo vat blue. They are, however, mordant dyestuffs, producing brownish reds with chrome mordant.

Madder.—This dyestuff, once of great importance, has now been almost entirely superseded by synthetic alizarin. It is still used to a limited extent in the dyeing of wool felt, since it penetrates through the material more readily than alizarin. With chromium mordant it gives a reddish-brown ; with aluminium a red, and with iron a purple shade. The use of madder in the woad vat has already been referred to (*v.* Vat *dyes*). This dyestuff is not now used on cotton or silk.

Cochineal.—The use of this valuable dyestuff in dyeing is now confined to the production of scarlet shades on woollen cloth, for which purpose considerable quantities are still imported. Stannous chloride is the mordant employed, and the colour is produced by the one-bath method. The aluminium and tin lakes are used as pigments in painting and printing.

Lac-dye may be employed in the same way as cochineal, and gives similar shades. Since the commercial product contains a considerable amount of mineral matter, the ground dyestuff is treated with dilute hydrochloric acid before use.

Cudbear and orchil (or *archil*).—These products are essentially the same dyestuff, the former in the solid and the latter in the condition of paste. It is one of the few natural colouring matters which dye wool without a mordant. Wool and silk may be dyed in a neutral, slightly acid, or slightly alkaline, solution. It produces full, rich crimsons, and is still used to a considerable extent. The colouring matter is not applicable to cotton.

Safflower was formerly much used in dyeing bright pinks upon cotton, but is now obsolete as a dyestuff.

Annatto produces orange shades on silk without a mordant ; it is applied in a hot soap-bath. Annatto is still used in colouring cheese and butter.

Weld.—This mordant dyestuff produces pure yellows in conjunction with aluminium mordant. When used as a ' topping ' for indigo vat blue, a special shade of green, known as ' carriage green,' is obtained.

Fustic is the most important of the natural yellow dyewoods, and is still employed in

conjunction with chrome mordant on wool as the yellow constituent in compound browns, olives, greys, &c. It is chiefly used in the form of fustic extract.

Osage orange is closely allied to fustic. Its utilisation as a dyestuff is only of recent date and is confined to America.

Quercitron bark and flavin are also natural yellow mordant dyes, producing somewhat brighter shades than fustic, but are now obsolete.

Persian berries.—This mordant dyestuff is employed by the calico printer for producing bright orange shades with tin mordant.

Turmeric is the only representative of the natural colouring matters which acts as a direct dye towards cotton, silk, and wool. It produces yellow shades, which are brighter if dyed in a bath acidified with alum.

Catechu, cutch, and gambier.—These dyestuffs are still largely employed in cotton dyeing. The cotton is steeped in a strong solution of the dye, and attracts the colouring matter. The cotton is then passed into a boiling solution of potassium dichromate, which, by oxidation, produces insoluble brown japonic acid upon the fibre. A little copper sulphate is frequently added to the catechu bath, whereby fuller and faster shades are produced.

Silk is dyed in a similar manner for the production of weighted blacks, the chromium, fixed during the oxidising process, subsequently acting as a mordant for logwood.

Other natural dyestuffs.—Colouring matters are very widely distributed in the vegetable kingdom, and all countries where the textile arts have attained any great development (notably India, Persia, and Japan) had until recently each its own series of indigenous products which were used as dyestuffs. In Donegal, Sutherland, and other localities, the homespun tweeds, &c, are still largely dyed by means of the various lichens, roots, barks, nuts, &c., found in the neighbourhood.

Synthetic dyestuffs. The number of individual synthetic dyestuffs now at the dyer's disposal is very large, and includes dyes yielding all possible hues. There is infinite variety in the characteristics of the various artificial dyes, and in most cases it is not difficult to match a given shade or to comply with given conditions as regards properties. Being, therefore, more convenient to use, and in very many cases cheaper and faster than the natural dyestuffs, the latter have been largely superseded.

The dyeing properties and the characteristics of the dyed colours depend chiefly upon the chemical groups to which the dyes belong, but, as indicated in the section dealing with the classification of dyes, the chemical groups do not coincide with groups based on the method of application (*v. Classification of colouring matters,* p. 575).

(1) *Nitroso colouring matters.*—This class includes fast-green or dark-green and naphthol-green. In conjunction with iron mordants, both these dyestuffs give olive-green colours remarkable for their fastness to light.

Cotton is dyed with dark-green by mordanting with iron, and dyeing in a neutral bath. Wool is mordanted with ferrous sulphate and oxalic acid, and dyed in a neutral bath. Silk is dyed in a similar manner.

Naphthol green which contains iron as a constituent is only applicable to the animal fibres. Wool is dyed with the addition of sulphuric acid.

(2) *Nitro-colouring matters.*—The most important members of this class are : picric acid, Victoria orange, aurantia, palatine orange, naphthaline yellow, naphthol yellow. These colouring matters are only applicable to the animal fibres, which are dyed in a bath slightly acidified with sulphuric acid. The colours they yield are not fast to light. Picric acid yellow is remarkable for its extreme freedom from any trace of orange. On exposure to light it rapidly becomes brownish, owing to reduction of the nitro groups.

(3) *The azo- group.*—These may be divided into monazo, disazo, trisazo, and tetrakisazo-dyes, according to the number of azo- groups they contain. They may be further classified into aminoazo- (NH_2) and oxyazo- (OH) dyes, and into other subdivisions based upon the state of combination of the azo- group. A few of the azo- colours are basic dyes ; a large number of the acid dyes, and acid-mordant dyes, belong to this group, and practically the whole of the direct dyes. The azo- dyes vary greatly in their degree of fastness to light, and in other properties.

(4) *The di- and tri-phenylmethane group.*—This group includes most of the basic dyes, such as auramine, magenta, methyl violet, malachite green, &c. These bodies, when sulphonated, form acid dyes, and therefore such dyestuffs as acid magenta, guinea green, &c., and also patent blue, Victoria blue, fall under this group. As a class, these dyestuffs are fugitive to light.

(5) *The oxyketone group.*—This group includes most of the artificial mordant dyes ; *e.g.* the alizarin reds, yellows, blues, browns, &c. Most of the dyestuffs of this group are extremely fast to light and other influences, which renders them of the greatest importance.

(6) *The pyronine group.*—This includes (1) the pyronines proper, a small class of basic dyes, of which pyronine red is an example ; (2) the much more important group of the phthaleins. The latter includes both basic and acid rhodamines, the eosins and the mordant dyestuffs gallein and cœrulein.

(7) *The acridine group.*—This includes a few basic dyestuffs of which the chief is **acridine** orange.

(8 and 9) *The oxazine and thiazine group.*—This group also includes both acid (thiocarmine), basic (methylene blue), and mordant dyes (gallocyanin).

(10) *The azine group* includes the valuable basic dyes the safranines, and the basic and acid indulines and nigrosines.

The dyeing of mixed fabrics of cotton and wool may be carried out by selecting those colouring matters for which both fibres have an attraction, *e.g.* the benzidine dyes, &c., or by first dyeing the wool in the usual manner with an acid colouring matter, then mordanting the cotton with tannic acid and tartar emetic or stannic chloride, and dyeing in the cold with a basic colouring matter. The so-called 'cross-dyeing' process is carried out by first dyeing the cotton (usually with sulphide or other 'fast' dyes) in warp form, then weaving with a

wool weft and dyeing the latter by means of acid dyes. Logwood blacks on union are dyed by first mordanting the cotton in the cold with myrobolans and nitrate of iron, then the wool with a boiling solution of potassium dichromate, and finally dyeing both fibres thus mordanted in a hot decoction of logwood. Mixtures of cotton and silk are dyed by methods similar to those employed for cotton and wool. Fabrics of wool and silk are dyed by methods similar to those usual for wool or silk alone.

When dyeing *compound shades*, the main principle to be observed is to apply simultaneously only such colouring matters as are applicable, when used singly, by methods as similar as possible to each other. Basic and acid colouring matters ought not to be applied together in the same dye-bath, since the one requires a neutral, the other an acid, bath in order to yield their full colouring power. Basic colouring matters, however, may be quite well applied to mordanted cloth along with phenolic colouring matters, since both these classes usually dye in a neutral bath.

It is very irrational to produce compound shades by the application of a mixture of fast and fugitive colours ; the best results are obtained by employing colouring matters of about equal fastness to various influences. If this rule is not observed, the dyed colour is liable to change materially in shade under those influences to which it is subsequently submitted, e.g. light, washing, &c.

DYESTUFFS, IDENTIFICATION OF, ON FABRICS. The recognition of the particular dyestuff which has been employed in dyeing a fabric is frequently a matter of considerable difficulty. If one dyestuff only has been used, it may be possible to identify it with little trouble, but when, as is often the case, two or more dyes have been employed to produce a given colour, their separation and recognition may be a very complex problem.

In the identification of dyestuffs, the ordinary basis of qualitative analysis is as far as possible made use of, i.e. the *group* to which the colouring matter belongs is first determined, and then tests are applied to identify it as an individual substance. There are, however, such a large number of closely related compounds amongst the dyestuffs, many being isomeric, and differing only (e g.) in the position of a sulpho- group, that with the small amount of substance frequently at disposal it is quite impossible to definitely identify a specific commercial product This is, however, of minor importance.

The recognition of a dyestuff is much facilitated by a knowledge of the dyeing properties of the various groups of colouring matters. In a given case this may greatly limit the possibilities. For example, no one with a knowledge of dyeing processes would search for a cochineal scarlet on cotton or a paranitraniline red on wool. The presence or absence of certain metallic bases in the ash of the incinerated material is also a useful indication of the nature of the dyestuff under investigation, and an examination of this point should be made.

What may be termed the ' dyeing groups ' of colouring matters do not coincide with the ' chemical groups.' For example, the dyeing group of ' basic ' dyes, the members of which are fixed on cotton by means of a tannin mordant, includes members of the triphenyl methane, azine, azo-, acridine, and other chemical groups.

To determine the dyeing group to which a colouring matter present on a fabric belongs, acid and alkaline solvents are used as ' stripping ' agents. The following are the general reactions :

ACTION OF 'STRIPPING AGENTS.'

Dyeing group	Stripping solution
Mordant dyes	50 c.c. HCl (conc.) per litre
Basic dyes on wool	5 p.c. acetic acid
„ „ on cotton	3 p.c. sodium hydroxide
	3 p.c. ammonia 0·880 s.g.
Acid dyes ⎫	A small piece of mer-
Direct cotton dyes ⎭	cerised cotton is placed in the solution.

In each case the fabric is boiled for 5 minutes in the solution.

With direct cotton dyes the small piece of white cotton placed in the solution becomes dyed. With acid dyes this does not occur.

The action of the above stripping agents can only be considered as general in regard to a particular group, and many exceptions will be found in dealing with particular members of the group, e.g. some acid dyes are only slightly stripped by boiling in dilute ammonia, and a few of them stain mercerised cotton. Too much reliance must not, therefore, be placed on these stripping reactions.

The most satisfactory group reagents for classifying dyestuffs into the chemical groups are acid or alkaline reducing agents ; on the use of which several schemes of identification have been based. These reagents were first proposed by Witt, in 1886, whose scheme was extended by Weingaertner, in 1887 ; but the systematic development of the scheme of analysis is mainly due to A. G. Green.

The reactions of dyestuffs are considerably influenced by the nature of the fibre upon which they have been fixed, which also determines the particular dyeing process necessary. For example, the basic colours dye wool and silk direct, whereas their fixation on cotton involves the use of a tannin mordant. It is convenient, therefore, to treat separately the identification of dyestuffs on animal and on vegetable fibres.

Identification of dyestuffs on wool.—Tables for the identification of dyestuffs on wool have been published in Hummel's Dyeing of Textile Fabrics ; in Knecht, Rawson, and Loewenthal's Manual of Dyeing ; in Lehne's Färber Zeitung, and by many other authors ; but the most systematic and reliable scheme is that of Green (Analysis of Dyestuffs, 2nd edit. 1915). In this scheme, which is now to be described, the dyeing groups are first distinguished by the action of suitable solvents, and then further differentiation is carried out by the use of reducing agents with subsequent reoxidation. The various groups of dyestuffs as dyed on animal fibres, show the following reactions :—

| Decolourised by hydrosulphite | | | | Not decolourised, but changed in |
Colour restored on exposure to air	Colour not restored by air, but restored on oxidation with persulphate	Colour not restored either by air or persulphate	Not altered by hydrosulphite	shade. Original colour restored by air or persulphate
Azines, oxazines, thiazines, indigoids	Triphenyl-methane group	Nitro-, nitroso-, and azo- groups	Pyrone, acridine, quinoline, and thiazol groups. Some members of the oxyketone group.	Most dyestuffs of the oxyketone group

In Green's scheme the following reagents are employed, and must be used of the strength indicated :—

Dilute ammonia (1 : 100) —1 c.c. conc. ammonia ; 100 c.c. distilled water.

Aqueous-alcoholic ammonia.—1 c.c. conc. ammonia ; 50 c.c. strong alcohol or methylated spirit ; 50 c.c. water.

Dilute acetic acid (5 p.c.).—5 c.c. glacial acetic acid ; 95 c.c. water.

Dilute alcohol (1 : 1).—50 c.c. strong alcohol or methylated spirit ; 50 c.c. water.

Dilute hydrochloric acid (1 : 10).—10 c.c. conc. hydrochloric acid ; 90 c.c. water.

Caustic soda (10 p.c.).—10 grams solid caustic soda in 100 c.c. of water.

Hydrosulphite AX.—Dissolve 50 grams hydrosulphite NF conc. or rongalite C, i.e. the formaldehyde compound of sodium sulphoxylate, in 150 c.c. of hot water. Add to the solution at 80°-90° 0·25 gram of precipitated anthraquinone previously ground to a paste with a little of the solution, and dilute the whole to 500 c.c. with cold water. The solution should be slightly alkaline. It may become acid on keeping.

Hydrosulphite B.—Dissolve 50 grams hydrosulphite NF conc. or rongalite C in 500 c.c. water, and acidify with 2 c.c. of acetic acid. This is used only for yellows and oranges.

Persulphate.—A cold saturated solution of potassium persulphate, or a 1 p.c. solution of ammonium persulphate. If alkaline, neutralise carefully with acetic acid.

Sodium acetate (5 p.c.) —5 grams crystallised sodium acetate ; 100 c.c. distilled water.

Procedure.—The reactions are carried out in test-tubes upon pieces of the material about ¾-1 inch square, which are covered with about 1-1½ inches of the reagent. The tests should be carried out exactly as described. Except when specially stated, the reagents are to be applied in succession to fresh portions of the material. In making 'stripping tests,' the degree of stripping is judged by comparing the remaining depth of shade with that of the original pattern. The colour of the stripping solution cannot be relied upon as a guide. In boiling with dilute acetic acid and dilute ammonia, it is found advantageous to repeat the extraction, as a better stripping is thereby obtained, and with acid dyestuffs any staining of the cotton by the first strong extract is removed during the second boil. In testing with dilute ammonia or sodium acetate, the material is placed in a test-tube with a piece of white mercerised cotton cloth, somewhat smaller in size, and boiled for the time prescribed. If the shade is a pale one, the size of the sample should be increased and that of the cotton

diminished. The dilute ammonia is replaced by aqueous alcoholic ammonia in the case of the violet and black dyestuffs (Tables III. and VII.), as in these cases the acid dyestuffs are less easily extracted, and the cotton is more liable to be stained by them. In making reduction tests, the sample is boiled for from one-quarter to one minute with the hydrosulphite, then rinsed well under the tap, and allowed to lie on white paper. With most dyestuffs which form air-oxidisable leuco- compounds, the colour returns immediately or in a few minutes, but with others a longer time is required. The reaction is accelerated by exposing the pattern to ammonia vapour. If the colour does not return, the pattern is boiled with a little water in a test-tube, and potassium persulphate is added drop by drop, carefully avoiding an excess. If this also fails to cause any return of colour, the dyestuff is to be regarded as a nitro-, nitroso-, or azo- compound. The depth of the restored colour varies greatly in different cases ; with some dyestuffs the colour reappears with nearly its original depth, but with others (probably on account of the greater solubility of their leuco-compounds) only a pale shade may return. Safranine and its azo- derivatives are peculiar in yielding a violet colour on reoxidation of the leuco- compound, this being due to the condensation of the leuco-safranine with the formaldehyde present in the hydrosulphite NF.

The tables (I. to VII., pp. 596-602) give the scheme of analysis.

These tables do not always differentiate between closely related individual dyes, for which purpose further tests must be made At this stage of the investigation it is very desirable to procure small pieces of material dyed with such known colouring matters as the group tests, combined with the colour of the sample, have indicated as probable Parallel individual tests should then be applied with these and with the sample under examination.

The following series of reagents have been found by W. M. Gardner to be convenient for this purpose. They should be applied in the order given, and used as follows :—

Application of cold reagents.—Steep a piece of the material 1 by ½ inch in (say) 5 c.c. of reagent for 5 minutes in a small porcelain dish.

Application of reagents by boiling.—In a test-tube place 10 c.c. of reagent and a piece of material 1 by ½ inch. Boil *gently* for 3 minutes.

Application of nitric acid test.—On a white glazed porcelain plate, spot the material by dipping a glass rod into the acid and then pressing it on to the cloth. Note the changes in colour which occur during the formation of the spot, and re-examine after several hours, noting any further change.

Reagents for identifying individual dyestuffs :

1. Boiling water.
2. 5 p.c. acetic acid, boiling.
3. 3 p.c. ammonia, boiling.
4. 3 p.c. soap, boiling.
5. Boiling alcohol.
6. Concentrated sulphuric acid, cold.
7. 3 p.c. ammonium persulphate, cold.
8. Bleaching powder solution, 5°Tw., cold.

Use small pieces of white wool, silk, and cotton along with the dyed sample.

9. 50 grams $SnCl_2.2H_2O+100$ c.c. HCl. 32°Tw. per litre, cold.

10. 5 c.c. $NaNO_2$ (5 grams per litre), and 5 c.c. H_2SO_4 (3·5 grams per litre) boiling.

11. Apply test 10 cold, then wash and steep the material in a solution of sodium β-naphtholate 5 grams per litre.

12. Concentrated nitric acid (spot test).

If the sample under examination shows the same reactions as any one of the control samples, with each of the above reagents, its identity may be considered as clearly established.

Knecht (J. Soc. Dyers, 1904, 98) states that titanous chloride possesses advantages over both stannous chloride and sodium hydrosulphite as a test for dyestuffs. The solution is prepared by boiling together 25 c.c. commercial titanous chloride solution (20 p.c.) and 25 c.c. HCl, 32°Tw., and diluting to 1000 c.c. with water.

IDENTIFICATION OF DYESTUFFS ON COTTON.

Green (Analysis of Dyestuffs, 1915) has worked out an analytical scheme for the detection of dyestuffs on cotton on the same lines as that previously described for wool.

The reagents are as follows :—

1. *Dilute ammonia* —1 c.c. strong ammonia to 100 c.c. distilled water.

2. *Dilute caustic soda.*—10 grams caustic soda in 100 c c. water.

3 *Saline caustic soda* —10 c.c. caustic soda solution (35-40 p.c. NaOH) to 100 c.c. saturated solution of salt.

4. *Formic acid* 90 p.c.—Concentrated commercial acid.

5. *Dilute formic acid.*—1 c.c. formic acid (90 p c.) to 100 c.c. distilled water.

6. *Dilute hydrochloric acid.*—5 c.c. hydrochloric acid (30 p.c.) to 100 c.c. of water.

7. *Soap solution.*—10 grams soap in 300 c.c. of water.

8. *Tannin solution.*—10 grams tannic acid and 10 grams sodium acetate in 100 c.c. of water.

9. *Bleaching powder solution.*—Fresh solution at 5°Tw.

10. *Hydrosulphite AX* (same as for wool, see p. 593).

11. *Hydrosulphite B* (same as for wool, see p. 593).

12. *Hydrosulphite BX.*—Dissolve 50 grams of rongalite or hydrosulphite NF conc. in 125 c.c. of hot water. Grind 1 gram of anthraquinone (precipitated, not sublimed) to a fine powder, and reduce to a smooth paste with a little of the rongalite solution. Add this paste to the remaining solution, and heat the whole for 1 or 2 minutes at about 90°. Then dilute with cold water to 500 c.c., and, after standing until cold, add 1½ c.c. of glacial acetic acid. Keep in a well-stoppered bottle with greased stopper. The reagent should be tested occasionally by trying its effect on cotton dyed with α-naphthyl-amine bordeaux, which should be fully discharged after boiling for 1 or 2 minutes. The anthraquinone may be replaced by β-oxyanthra-quinone, which can be employed in the same way or previously dissolved in a little alcohol before it is added to the hydrosulphite. It has the advantage of giving a clearer solution, but is not so generally available.

13. *Persulphate solution.*—A cold saturated

solution of potassium persulphate, or a 1 p.c. solution of ammonium persulphate.

14. *Acid stannous chloride.*—100 grams stannous chloride to 100 c.c. hydrochloric acid (30 p.c.) and 50 c.c. water. The hydrochloric acid must be free from arsenic. In testing for sulphide colours, this reagent may be replaced with advantage by a strong solution of titanous chloride.

15. *Chromium fluoride reagent.*—A solution of 10 grams chromium fluoride and 5 grams sodium acetate in 100 c.c. water.

Procedure : General.—All the reactions are performed in test-tubes, with pieces of material about ½–¾ of an inch square, which are covered to the depth of from 1½ to 2 inches with the reagent. The degree of stripping is judged by comparing the remaining shade with that of the original pattern ; the colour of the stripping solution cannot be relied upon as a guide. In testing the colours of calico prints, the separate colours should be cut out and the reactions tried upon them separately. With cotton and wool, or cotton and silk unions, the weft is separated from the cotton warp, and each submitted to examination. Doubt may frequently exist as to how a particular shade should be classified, whether, for instance, a reddish-blue is to be regarded as a blue or a violet. In such cases the tables referring to both colours should be employed ; but since the same general scheme is adopted throughout the tables, this can scarcely give rise to confusion. The same remark applies to possible mixtures ; thus in examining a certain green shade, both the yellow and the blue tables may have to be used.

To distinguish between individual dyestuffs of the same group the same method should be adopted as in the case of wool (*see* p. 594).

It is obvious that in many instances the analytical procedure may be greatly simplified by exclusion of dyestuffs the presence of which is rendered improbable or impossible by the special circumstances of the case, *e.g.* by the material, shade, or mode of application of the colour.

Stripping test.—A few of the direct dyestuffs are partially stripped by dilute ammonia, and may thus give rise to the impression that they are acid colours. To avoid this error, it is advisable to add a small piece of white cotton when carrying out the test. With an acid dyestuff the cotton is either not tinted or becomes white on boiling a second time with dilute ammonia.

Transference of basic dyes to wool.—The tannin mordant is first removed, as in testing for a basic colour, by boiling the pattern for half a minute with saline caustic soda. It is then well washed to remove all alkali, and is boiled with a piece of white wool (half the size of the cotton or less) in a little water for 1 or 2 minutes. In most cases the dye base will leave the cotton almost entirely, and dye the wool a full shade. If the colour does not develop on the wool, one or two drops of dilute formic acid (1 : 100) may be added. In the case of a few dyestuffs which are more difficult to strip (*e.g.* basic greys), it is necessary to extract the colour with dilute hydrochloric acid (1 : 20), carefully neutralising the extract with ammonia before adding the wool.

Tannin test for basic dyes.—Add a few drops of tannin solution to the formic acid extract. Shake well, and if the precipitate does not form at once, allow to stand a few minutes. Some colouring matters such as the rhodamines, gallocyanines, and chrome colours of the rosaniline series (which contain carboxyl- or hydroxyl- groups in addition to basic groups) only precipitate slowly, and the precipitate, being more finely divided, is sometimes difficult to see.

Bleeding test for direct dyestuffs.—In testing for direct dyestuffs by the bleeding test, the sample is placed in a test-tube together with a smaller piece of white mercerised cotton cloth, and boiled with soap solution for about a minute. The soap solution may be replaced by a 5 p.c. solution of sodium carbonate.

Lead acetate test for sulphide dyes.—The sample is first boiled for two minutes with a 10 p.c. solution of sodium hydroxide to remove any adventitious sulphur compounds. It is then well washed and just covered with acid stannous chloride solution. The mouth of the test tube is closed by a cap of filter paper closely wrapped round it, into the centre of which is placed, by means of a glass rod, one drop of lead acetate solution. The contents of the test-tube are slowly heated to the boiling-point, when a blackish-brown stain of lead sulphide appears if a sulphide colour is present. The brown spot will again disappear on continued boiling on account of the decomposition of the lead sulphide by the hydrochloric acid evolved. It is important to pay special attention to the cleanliness of the test-tubes employed for this test, as tubes which have been previously used for hydrosulphite reductions acquire a thin invisible deposit of sulphur upon their walls, which, on boiling with stannous chloride, gives rise to hydrogen sulphide, and thus may lead to error.

Reduction and reoxidation tests.—The reduction with hydrosulphite BX is carried out by boiling the sample with the reagent for from a minute to a minute and a half. The azines, thiazines, oxazines, &c., and most of the azo-dyestuffs are fully reduced in about half a minute, but the insoluble azo- colours and some direct dyestuffs require longer boiling to complete their reduction. In testing the reoxidisability by air, the reduced sample may be exposed to the fumes of ammonia, which in many cases accelerates oxidation.

Tests for vat dyestuffs.—(*See* Green and Frank, J. Soc. Dyers, 1910, 83 ; and Grand-mougin, Tabellarische Uebersicht der Kupen-farbstoffe.)

The analytical tables worked out by Green for the identification of dyestuffs on vegetable fibres, are given on pp. 603–609, Tables VIII. to XIV.

S. T. Mulliken (Identification of the Commercial Dyestuffs, 1910) has published a systematic scheme of analysis, primarily intended for the examination of the dyestuffs in a substance. The tables give the reactions of 1475 distinct dyestuffs, and are of great service in the identification of dyes on the fibre.

Spectroscopic examination of dyestuffs.—The absorption spectra of dyestuffs may be used as an aid to their identification. In the second

RECOGNITION OF DYES ON WOOL OR SILK.

TABLE III.—PURPLE AND VIOLET COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Test sequence	No.	Dyes
Little or no colour is stripped : Acid, Vat, Mordant, or Salt dyestuff. Boil twice for one minute with aqueous alcoholic ammonia (1 : 100) and hydrosulphite AX — **Little or no colour is stripped : Vat, Mordant, or Salt dyestuff.** Boil with hydrosulphite AX. — Colour changed to orange-brown or brown : **Alizarin class.** A mordant is present. Boil original fibre with dilute hydrochloric acid (1 : 10). — Fibre and solution red-brown to violet-brown	18	Alizarin bordeaux, alizarin claret, alizarin maroon.
Fibre and solution orange	17	Alizarin red S, &c., on Fe.
Decolourised. Colour is not restored either by air or by per-sulphate. **Azo class.** Test for a mordant (Cr) — Mordant absent : **Salt dyestuff.** Confirm by boiling with 5 p.c. sodium acetate and a piece of white cotton. Stained	16	Diamine, benzo, dianil, columbia, chlorazol, naphthamine, chlorantine, &c., violets.
Mordant present : **Acid-mordant dyestuff.**	15	Acid alizarin violet, acid chrome violet, eriochrome violet, Palatine chrome violet.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate . **Triphenyl-methane class.** A chrome mordant is present	14	Chromogene violet, metachrome violet, chrome violet
Decolourised. Colour returns to air. Test for a mordant — Mordant absent · **Indigoid Vat dyestuff.** Confirm by extraction with aniline and sublimation	13	Helindone violet, ciba violet, ciba heliotrope, thioindigo violet, &c.
Mordant present · **Azine, Oxazine, or Thiazine class.**	12	Gallocyanine, prune, celestine blue, correine.
Colour unaffected . **Pyrone class.** A chrome mordant is present	11	Galleine.
Much colour is stripped, but cotton remains white . Acid dyestuff. Boil with hydrosulphite AX. — Colour is changed to orange-yellow, restored by persulphate to a violet-brown · **Anthraquinone class**	10	Anthraquinone violet, alizarin direct violet, alizarin irisol, alizarin cyanol violet.
Decolourised. Colour is not restored either by air or by per-sulphate : **Azo class**	9	Lanacyl violet, azo acid violet, sulphon violet, Victoria violet erio fast purple, wool violet.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate : **Triphenyl-methane class.** — Little colour is stripped. Spot original fibre with conc. hydrochloric acid — Yellow spot	8	Acid violets, alkali violet, guinea violet, formyl violet, kitone violet, &c.
Pyrone classes. Boil with 5 p c. sodium acetate for one minute — Fibre unchanged	7	Pyrone colours, e.g., fast acid violets, violamines, and violet 4R, &c.
Fibre becomes reddish-brown	6	Red-shade soluble blues.
Much colour is stripped, but solution remains colourless. Treat original fibre with cold conc. sulphuric acid — Colour of fibre yellow to orange	5	Certain red-shade acid violets, e.g., acid violet 4RS and 5RS, red violets 4RS, &c.
Decolourised. Colour returns on exposure to air : **Azine, Oxazine, or Thiazine class**	4	Fast blue R, red shade indulines, &c.
Much colour is stripped : Basic dyestuff or Soluble Red Wood. Boil twice for one minute with dilute alcohol (1 : 1). — Unaffected. Al or Cr is present in ash. On boiling with dilute ammonia, the colour becomes much bluer	3	Soluble red woods, e.g., Brazilwood, Lima-wood, sapanwood, peachwood, &c.
Much colour is stripped : Basic dyestuff. Boil with Hydrosulphite AX — Decolourised. Colour does not return on exposure to air, but is restored by per-sulphate : **Triphenyl-methane class**	2	Methyl violet, ethyl violet, crystal violet, benzyl violet, brilliant violet, &c.
Decolourised. Colour returns on exposure to air : **Azine, Oxazine, or Thiazine class**	1	Neutral violet, rhoduline violet, methylene violet, tannin heliotrope, iris violet, &c.

RECOGNITION OF DYES ON WOOL OR SILK.
TABLE IV.—BLUE COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Little or no colour is stripped : Acid, Vat, Mordant, or Salt dyestuff. (1 : 100) and a piece of white cotton. Keep the ammoniacal extract.

Boil twice for one minute with dilute ammonia

Little or no colour is stripped.—Vat, Mordant, or Salt dyestuff. Boil with hydrosulphite AX

Branch conditions	No.	Dyestuff
Colour changed to brown, becoming blue again on exposure to air :—**Alizarin class** Mordant present	26	Alizarin blue (Anthraquinoline class).
Decolourised. Colour is not restored either by air or by persulphate :—**Azo class**. Test for a mordant — Mordant absent :—**Salt dyestuff.** Confirm by boiling with 5 p.c. sodium acetate and a piece of white cotton. Cotton stained	25	Diamine, benzo, dianil, Chicago, chlorazol, naphthamine, &c., blues and sky blues, sulphon acid blue, sulphoncyanine, sulphonazurine, erio fast blue SWR, tolyl blue GR extra and 5R extra, &c.
Mordant present. Boil with 5 p.c. sodium acetate and a piece of white cotton for 2 or 3 minutes — Cotton is stained :—**Salt-mordant dyestuff**	24	Autochrome blue.
Cotton remains white :—**Acid-mordant dyestuff**	23	Chromotrope blue, acid chrome blue, chrome fast blue, anthracene chrome blue, fast mordant blue, salicine chrome blue, &c.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—**Triphenylmethane class.** Test for a mordant — Mordant absent	22½	Brilliant milling blue B.
Mordant present	21	Chrome blue.
Decolourised. Colour returns on exposure to air. Test for a mordant — Mordant absent. Treat fibre with aniline — Colourless solution :—**Pyrone dyestuff**	20	Fast acid blue R, violamine 3B.
Blue solution giving on evaporation a sublimable residue.—**Indigoid Vat dyestuff**	19	Indigo, helindone blue 3G and 2B, ciba blue, thioindigo blue, &c.
Mordant present :—**Anthra-quinone class.** Treat fibre with cold conc. sulphuric acid — Fibre and solution red	18	Eriochrome azurol, eriochrome cyanine, chrome worsted blue, chromal blue, chromoxane blue, &c.
Fibre and solution blue or violet	17	Gallocyanine, celestine blue, correine, prune, gallamine blue, delphine blue, brilliant delphine blue, indahzarin; lanoglaucine, ultra cyanine, ultra violet, &c.
Fibre and solution green	16	Brilliant alizarin blue, mercerol brilliant blue, indochromine, &c.
Mordant absent	15	Indanthrene blue WB.
Mordant present	14	Alizarin cyanine, brilliant alizarin cyanine, anthracene blue, alizarin indigo blue, acid alizarin blue 2B and GR, &c.

Much colour is stripped, but cotton remains white :—Acid dyestuff. Boil with hydrosulphite AX

Branch conditions	No.	Dyestuff
Colour un-affected, or slightly dark-er :—**Anthra-quinone class.** Fibre is not de-colourised, but colour changes — **Anthraquinone class.** Colour of re-duced fibre is — bright yellow to orange-brown, returning with persulphate	13	Alizarin astrol, alizarin uranol, cyananthrol, alizarin direct blue B, alizarin cyanol B, alizarin sky blue, anthraquinone blue, &c.
red-violet, returning with persulphate	12	Alizarin saphirol, anthracyanine, alizarin direct blue EB and E3B, alizarin cyanol EF, brilliant anthrazurol, eriocyanine LM, fast sky blue, &c.
Decolourised. Colour is not restored either by air or by persulphate.—**Azo class**	11	Lanacyl blue, azo acid blue, azo merino blue, azo navy blue, chromazone blue, azocyanine, &c.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—**Triphenyl-methane class** — Ammoniacal extract is colourless, but becomes blue on acidifying	10	Soluble blue, water blue, alkali blue, chlorazol brilliant blue 14B, isamine blue 8B, dianil blue 6G, brilliant sky blue 8G, &c.
Ammoniacal extract is blue. Treat fibre with cold conc. sulphuric acid — Fibre and solution colourless to pale yellow	9	Patent blue, new patent blue, Neptune blue, xylene blue, brilliant acid blue, kitone blue, erioglaucine, eriocyanine, eriochlorine, cyanole, cyanine, fast acid violet 10B, cyanogene, &c.
Fibre and solution red-brown to orange-brown	8	Wool blue, cyanole FF, intensive blue, &c.
Decolourised. Colour returns on exposure to air.—**Azine, Oxazine, Thiazine, and Indigo classes. Also Prussian blue** — The ammoniacal extract is colourless. Fe is present in ash	7	Prussian blue.
The ammoniacal extract is blue. On adding caustic soda — becomes violet on heating	6	Thiocarmine, fast blue, induline, acid cyanine, fluorescent blue, lazuline blue, &c.
at once becomes yellow	5	Indigo extract, indigo carmine.

Much colour is stripped :—Basic dyestuff. Boil with dilute alcohol (1 : 1). Boil twice for one minute

Branch conditions	No.	Dyestuff
Unaffecte d. Al or Cr is present in ash. On spotting with hydrochloric acid the blue is changed to brick-red	4	Logwood blue.
Much colour is stripped :—Basic dyestuff. Boil with hydrosulphite AX — Decolourised. A violet colour returns on exposure to air :—**Safranine azo dyestuff**	3	Janus blue, diazine blue, indoine blue, Janus dark blue, naphthindone, &c.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—**Triphenylmethane class**	2	Night blue, Victoria blue, setocyanine, setoglaucine, turquoise blue, &c.
Decolourised. Colour returns on exposure to air :—**Azine, Oxazine, or Thiazine class**	1	Methylene blue, Nile blue, Capri blue, cresyl blue, Meldola's blue, new methylene blue, diphene blue, &c.

RECOGNITION OF DYES ON WOOL OR SILK.
TABLE V.—GREEN COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Branch	Condition	No.	Dyestuffs
Little or no colour is stripped:—Acid, Vat, Mordant, or Salt dyestuff. Boil twice for one minute with dilute ammonia (1 : 100) and a piece of white cotton. Little or no colour is stripped.—Vat, Mordant, or Salt dyestuff. Boil with hydrosulphite AX. Colour changed to orange or orange-brown: Alizarin class	Original colour does not return on exposure to air, but is restored by persulphate. A chrome mordant is present	18	Alizarin cyanine green, alizarin viridine, brilliant alizarin viridine, &c.
	Original colour returns on exposure to air. A mordant is present	17	Cœruleine, alizarin green S, alizarin dark, green W.
Decolourised. Colour is not restored either by air or by persulphate.—Azo or Nitroso class. Test for a mordant	Colour changed to red-violet. The original colour is restored by persulphate. A chrome mordant is present	16	Eriochrome verdone, acid alizarin green.
	Mordant absent:—Salt dyestuff. Confirm by boiling with 5 p.c. sodium acetate and a piece of white cotton	15	Diamine, benzo, diamil, Columbia, chlorazol, naphthamine, &c., greens.
Mordant present. Boil with 5 p.c. sodium acetate and a piece of white cotton for two or three minutes. Cotton is stained.—Salt-mordant dyestuff		14	Diamond green 2S, chrome patent green N, mercerol green, &c.
Cotton remains white. Boil original fibre with conc. hydrochloric acid	Colour of fibre unchanged, or bluer.—Azo class	13	Diamond green B and 3G, chromoxal green, Cyprus green, omega chrome green, eriochrome green H and L, acid chrome green, &c.
	Fibre and solution light brown.—Nitroso class	12	Naphthol green B, gambines, dioxine, chrome green G, &c.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate : Triphenylmethane class. A Cr mordant is present		11	Chromoxane green, chrome green, fast chrome green, &c.
Decolourised. Colour returns on exposure to air. Test for a mordant	Mordant absent.—Indigoid Vat dyestuff. Confirm by extraction with aniline and sublimation test	10	Ciba green G, helindone green G.
	Mordant present.—Oxazine or Thiazine class	9	Alizarin green B and G
Much colour is stripped, but cotton remains white:—Acid dyestuff. Boil with hydrosulphite AX. Fibre is not decolourised, but colour changes.—Anthraquinone group. Colour of reduced fibre is—	Orange, returning with persulphate to grey-green	8	Anthraquinone green, alizarin cyanine green, alizarin brilliant green, fast acid green RH, anthraquinone blue-green.
	Red-violet returning with persulphate to bluish-green	7	Alizarin emeraldol, alizarin direct green.
Decolourised. Colour is not restored either by air or by persulphate :—Azo class		6	Sulphon acid green, mixtures of an azo blue and yellow.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate —Triphenyl-methane class		5	Acid green, light green, guinea green, wool green, Neptune green, alkali fast green, cyanole fast green, erio green, brilliant milling green B, night green, &c.
Decolourised. Colour returns on exposure to air :—Azine, Oxazine, or Thiazine class		4	Azine green S.
Much colour is stripped:—Basic dyestuff. Boil with hydrosulphite AX. Decolourised. Colour does not return on exposure to air, but is restored by persulphate : Triphenyl methane class		3	Malachite green, brilliant green, fast green, setoglaucine, solid green, China green, new fast green, &c.
Decolourised. Original colour returns on exposure to air :—Azine, Oxazine, or Thiazine class		2	Methylene green, Capri green, azine green, fast green M, &c.
Decolourised. A dark violet colour returns on exposure to air :—Safranine Azo dyestuff		1	Janus green, diazine green.

RECOGNITION OF DYES ON WOOL OR SILK.

TABLE VI.—BROWN COLOURS.

Boil twice for one minute with 5 p.c. acetic acid

Much colour is stripped :— Basic dyestuff. Boil with hydrosulphite AX

- Decolourised. A violet colour returns on exposure to air : Safranine azo dyestuff
  - **1** Diazine brown.
- Decolourised. Colour is not restored either by air or by persulphate :— Azo class
  - **2** Bismarck brown, Janus brown, tannin brown.

Little or no colour is stripped.—Acid, Vat, Mordant, or Salt dyestuff. Boil twice for one minute with dilute ammonia (1 : 100)

- Much colour is stripped :—Acid dyestuff. On boiling with hydrosulphite AX, decolourised. Colour is not restored either by air or by persulphate :— Azo class
  - **3** Acid brown, fast brown, resorcin brown, guinea brown, solid brown, sulphon acid brown, Neptune brown, wool brown, &c.
- Decolourised. Colour returns on exposure to air. Boil with 5 p.c. sodium acetate and a piece of white cotton for two minutes
  - Cotton remains white.— Indigoid vat dyestuff
    - **4** Helindone brown, ciba brown, thioindigo brown, &c.
  - Cotton is stained.—Salt dyestuff stilbene class
    - **5** Mikado browns.
- Decolourised. Colour does not return on exposure to air, but is restored by persulphate
  - **6** Chromogen, oxychromine.

Little or no colour is stripped.—Vat, Mordant, or Salt dyestuff. Boil with hydrosulphite AX

- Decolourised. Colour is not restored either by air or by persulphate :— Azo group. Boil with 5 p.c. sodium acetate and a piece of white cotton for two minutes
  - Cotton remains white. Cr is present. Acid-mordant dyestuff
    - **7** Anthracene acid brown, acid alizarin brown, anthracene chromate brown, diamond brown, palatine chrome brown, salicine brown, metachrome brown, mercerol brown, &c. Also manganese brown (Mn in ash).
  - Cotton is stained. Cr may be present. Salt dyestuff
    - **8** Diamine, benzo, diamil, Columbia, Congo, naphthamine, toluylene, Hessian, &c., browns.

Colour of fibre unaltered. Boil with dilute hydrochloric acid (1 : 10)

- Colour is stripped. Cr present
  - **9** Anthragallol, anthracene brown, alizarin brown.
- Colour is not stripped. Cr and Cu present
  - **10** Cutch.

RECOGNITION OF DYES ON WOOL OR SILK.

TABLE VII.—BLACK AND GREY COLOURS.

Boll twice for one minute with 5 p.c. acetic acid

Little or no colour is stripped :—Acid, Mordant, or Salt dyestuff. Boll twice for one minute with aqueous alcoholic ammonia (1 : 100) and a piece of white cotton

Much colour is stripped :— Basic dyestuff	The colour is stripped :— Acid or Salt dyestuff		Little or no colour is stripped :—Mordant dyestuff. Boll for half a minute with dilute hydrochloric acid (1 : 10)							
	The cotton remains white :— Acid dyestuff. On boiling with hydrosulphite AX, the colour is permanently discharged	The cotton is stained :—Salt dyestuff. On boiling with hydrosulphite AX, the colour is permanently discharged	Fibre and solution crimson	Fibre and solution orange to pale brown	Fibre blue or blue-violet, solution crimson, Test for indigo by extraction, evaporation, and sublimation	Unaffected. Treat original fibre with cold conc. sulphuric acid	Fibre unaffected.	Boll with hydrosulphite AX		Colour changed to brown. Original colour returns slowly on exposure to air
							Blue solution	Colourless solution	The colour is discharged. Boll for one minute with 5 p.c. sodium acetate and a piece of white cotton	
									Cotton remains white	Cotton is stained	
1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**
Janus black, diazine black, jute black, methylene grey, new fast grey, &c.	Naphthol black, naphthylamine black, nerol, azo acid black, Palatine black, sulphocyanine black, sulphon black, Biebrich patent black, cresol black, &c.	Union black, Columbia, diamine, dianil, benzo, chlorazol, naphthamine, &c., blacks and fast blacks, direct deep black, direct blue black, &c.	Logwood on Cr.	Logwood on Fe, Bonsor's black.	A ' vatted black ' (indigo and logwood).	Alizarin cyanine black.	Aniline black.	Diamond black PV, PVB, P2B, F, diamond blue black EB, eriochrome black, eriochrome grey, chrome fast black, anthracene chrome black, acid alizarin black, fast chrome black, acid chrome black, &c.	Diamond black FB, FR, NG, GA, 2B, Palatine chrome black, anthracene acid black, alizarine black, monochrome grey, anthracene chromate grey, &c.	Naphthazarine, alizarin blue black SW, W, brilliant alizarin black, alizarin black S, WR, WX, &c.

RECOGNITION OF DYES ON VEGETABLE FIBRES

TABLE VIII.—YELLOW AND ORANGE COLOURS.

Boil with weak ammonia (1 : 100)

Condition (ammonia)	Branch 2	Branch 3	Branch 4	Branch 5	Branch 6	No.	Dyestuff
The colour is not stripped. Boil for a quarter of a minute with saline caustic soda, rinse with cold water, and boil with water and one or two drops of weak formic acid (1 : 100)	A coloured acid extract not precipitable by tannin. Reduce the original dyestuff with hydrosulphite BX	The colour is unaffected or changed in shade, becoming lighter, browner, or bluer. If altered in shade, exposure to air restores the original colour. Apply the lead acetate test	No H₂S is evolved. Boil with soap solution and white mercerised cotton	The white cotton is not stained.—Mordant or vat dyestuff. Boil with 90 p.c. formic acid. Also test ash for metallic mordant	Colour not stripped by formic acid. No mordant in ash :—Vat dyestuff	18	Helindone orange R, helindone yellow 3G, anthraflavone G, algole yellow 3G and R, algole orange R, indanthrene yellow, indanthrene orange RT and golden orange, indanthrene copper, cibanone yellow R and orange R.
					Colour stripped by formic acid. Al or Cr in ash.—Mordant dyestuff	17	Persian berries on Al or Cr mordants, alizarin orange on Al mordant.
				The white cotton is stained.—Thiazol salt dyestuff		16	Chlorophenine, chloramine yellow, diamine fast yellow B, FF, and C, Clayton yellow, thiazol yellow, thioflavine S, &c. Primuline developed with hypochlorite.
			H₂S is evolved :—Sulphide dyestuff			15	Yellows and oranges of the immedial, katigene, cross-dye, pyrogene, thiogene, sulphur, thional, &c., series.
		Decolourised or becomes light yellow. Original colour is not restored by air oxidation.—Azo dyestuff (including the Stilbene class) Boil with soap solution and white mercerised cotton	White cotton is not stained. Boil with pyridine	Colour is not stripped. Cr present in the ash :—Azo mordant dyestuff		14	Chrome orange, alizarin yellow R, GG, &c. diamond flavine, flavazol, &c.
				Colour is stripped :—Insoluble azo colour		13	Metamtranilne orange, nitrotoluidine orange, orange from naphthol AC.
			White cotton is stained :—Salt dyestuff	Fibre after reduction is colourless —Salt azo dyestuff		12	Chrysophenine, chrysamine, carbazol yellow, toluylene yellow and orange, stilbene yellows and oranges, benzo, Congo, diamine, and dianil yellows and oranges, pyramine orange, Pluto orange, &c.
				Fibre after reduction is light yellow and can be diazotised and developed red with betanaphthol.—Primuline azo-colour		11	Primuline developed with phenol or with resorcinol, cotton yellow G and R, oriol yellow, dianil yellow, &c.
	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution.—Basic dyestuff. Transfer to wool and boil with hydrosulphite B	Wool is permanently decolourised :—Azo class				10	Chrysoidine, tannin orange, Janus yellow, azo phosphine, new phosphine, &c.
		Wool is not decolourised. Boil cotton with hydrochloric acid (1 : 20)	Not decolourised. The conc. H₂SO₄ and alcoholic solutions are fluorescent.—Acridine class			9	Phosphine, benzoflavine, acridine yellow, rheonine, orange flavophosphine, &c.
			Decolourised			8	Auramine.
The colour is stripped. Boil with acidified water and small piece of white wool	Colour is transferred to the wool.—Acid dyestuff. Boil wool with hydrosulphite B	The colour is completely destroyed, both solutions and fibre being colourless. Treat original fibre with cold ammonium sulphide	Fibre is not blackened. Boil with hydrosulphite BX	Decolourised		7	Flavinduline.
				Not decolourised. Test for Al in ash	Al absent	6	Thioflavine T, methylene yellow, rhoduline yellow.
					Al present	5	Alizarin yellow A.
			Fibre blackened. Cr present in ash			4	Chrome yellow or chrome orange (lead chromate).
		Permanently decolourised :—Azo class				3	Indian yellow, orange IV., G, &c.
		Not decolourised :—Pyrone or quinoline class				2	Quinoline yellow, eosine orange.
	Colour not transferred to the wool. Sn is present in ash					1	Persian berries on tin mordant.

RECOGNITION OF DYES ON VEGETABLE FIBRES.

TABLE IX.—RED COLOURS.

Boil with weak ammonia (1 . 100)

The colour is not stripped. Boil for ¼ quarter of a minute with saline caustic soda, rinse with cold water, and boil for one minute with water and one or two drops of weak formic acid (1 : 100) Reduce original fibre with hydrosulphite BX		Cr absent:—**Anthracene Vat dyestuff** — Colour but little affected by formic acid	16	Algole red B, indanthrene red, indanthrene claret, ciba scarlet G.
		Cr in ash:—**Anthracene Mordant dyestuff** — Colour unaffected or changed to maroon or brown. Original colour restored on exposure to air.—Anthracene class. Boil with 90 p.c. formic acid. Also test ash for mordant	15	Alizarin, purpurines or alizarin maroon on Cr mordant.
		Colour stripped by formic acid. Al in ash:—**Anthracene Mordant dyestuff**	14	Turkey red, alizarin red, alizarin pink, alizarin maroon.
	A coloured acid extract precipitable by tannin is not obtained.	Colour changed to greenish yellow (not restored to original colour by air), which can be diazotised and developed red with betanaphthol :—**Primuline Azo colour**	13	Primuline developed with betanaphthol or with R-salt.
		No H₂S is evolved. Red vapours on heating :—**Indigoid vat dyestuff**	12	Algole red 5G and scarlet G, algole pink R, ciba red G and scarlet G, ciba bordeaux B, helindone red B and 3B, helindone scarlet S, helindone fast scarlet R, thioindigo red B, thioindigo scarlet, vat red.
		H₂S is evolved Becomes yellow or colour- less Colour returns on exposure to air. Apply to Indigo class. Also heat fibre in dry tube :—**Sulphide dyestuff**	11	Thiogene rubine, &c.
	Decolourised and colour not restored by air or by persulphate :—Azo class. Boil with soap solution and white mercerised cotton	The colour is not stripped Cr in ash :—**Mordant Azo dyestuff** The white cotton is not stained. Boil with pyridine	10	Chrome red, brilliant chrome red, chrome bordeaux, &c.
		The colour is stripped —**Insoluble Azo colour** The white cotton is stained Salt dye- stuff Test ash for Cr and Cu	9	Paranitraniline red, alphanaphthylamine bordeaux, chloranisidine pink, nitroanisidine pink, scarlet and reds from naphthol AC.
		Cr or Cu present :—**Azo Salt dye- stuff after- treated**	8	Diamine fast red F, &c.
		No Cr or Cu present .—**Azo Salt dyestuff**	7	Benzopurpurine, diamine scarlets, diamine reds, benzo fast scarlets, diazo brilliant scarlet, rosanthrenes, Zambesi red, erica, diamine rose, geranine, rosophenine, &c.
	The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution :—**Basic dyestuff** (on tannin or other mordant). Transfer to wool and boil with hydrosulphite AX	Wool decolourised Colour not restored by air or by persul- phate :—**Azo class**	6	Janus red.
		Wool decolourised. Colour does not re- turn on exposure to air, but is restored by persulphate :—**Triphenyl- methane class**	5	Magenta, fuchsine, new fuchsine, isorubine, cerise, grenadine, &c.
		Wool decolourised. Colour returns on exposure to air :—**Azine class**	4	Safranines, rhoduline reds and pink, azine scarlet, induline scarlet, neutral red, &c.
		Wool not decolourised :—**Pyrone class**	3	Rhodamines, rhodines, irisamine, anisoline, rosazein, rhoduline pink, acridine reds, &c.
	The colour is stripped :—Acid dyestuff. Trans- fer to wool and boil with hydro- sulphite AX	Decolourised. Colour not restored by air or persul- phate :—**Azo class**	2	Crocein scarlets, brilliant croceines, Palatine scarlet, fast reds, &c.
		Not decolourised :—**Pyrone class**	1	Eosines, phloxine, erythrosine, rose bengal, &c.

RECOGNITION OF DYES ON VEGETABLE FIBRES.

TABLE X.—PURPLE AND VIOLET COLOURS. (1 : 100)

Boil for a quarter of a minute with saline caustic soda, rinse with cold water (or salt solution), and boil for one minute with water and one or two drops of weak formic acid (1 : 100).

Boil with weak ammonia (1 : 100)

The colour is not stripped.

Coloured acid extract precipitable by tannin is not obtained. Reduce original fibre with hydrosulphite BX

Decolourised or yellowish. Colour restored on exposure to air :—Azine, Oxazine, Thiazine, or Indigoid classes. Apply lead acetate test. Also heat fibre in dry test-tube

Condition	No.	Dyestuff
No H₂S is evolved :—Anthracene Vat dyestuff	20	Indanthrene violet or violanthrene.
H₂S is evolved :—Sulphide dyestuff	19	Thiogene dark red, &c.

The colour is unaffected or only changed in shade, being restored to original on exposure to air :—Pyrone or Anthracene class. Test ash for mordant

Al or Cr is present :— Mordant dyestuff		
The colour on reduction is browner or darker	18	Alizarin cyanine 3R, alizarin bordeaux.
The colour on reduction is unchanged	17	Gallein, alizarin violet, alizarin claret, alizarin cyclamine, alizarin red on Cr mordant.

Mordants are absent. Apply lead acetate test

Cr is absent. Coloured vapours on heating :—Indigoid dyestuff	16	Ciba violet, ciba heliotrope, thioindigo violet, helindone violet.
Cr is present. No coloured vapours on heating :—Mordant Oxazine dyestuff (not falling in group 7)	15	Gallocyanine, modern violet, ultra violet, coreine, &c.

No H₂S is evolved. Test ash for mordant

H₂S is evolved :—Sulphide dyestuff	14	Thiogene violet, katigene violet, hydrone violet, &c.

The colour is not stripped Cr present in ash :—Mordant Azo dyestuff	13	Chrome bordeaux, chrome prune, &c.
The colour is stripped with pyridine. Insoluble Azo colour	12	Benzidine puce.
Colour destroyed, giving yellow solution. Fe present in ash :—Alizarin red on Fe mordant	11	Alizarin purple.

The white cotton is not stained. Boil with hydrochloric acid (1 : 20)

Cr or Cu present :—Azo Salt dyestuff after-treated	10	The undermentioned (col. 9) coppered or chromed.
No Cr or Cu present :—Azo Salt dyestuff	9	Violets of the diamine, benzo, Congo, Hessian, Columbia, chlorazol, chlorantine, dianil, oxamine, and rosanthrene series.

The white cotton is stained. Boil with soap solution and white mercerised cotton

Iron (decolourised slowly). Boil with soap solution and white mercerised cotton

Decolourised and colour not restored by air or persulphate :—Azo class or Alizarin on Iron (decolourised slowly).

The white cotton is not stained. Boil with hydrochloric acid (1 : 20)

The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin

Not precipitated :—Basic dyestuff. Transfer to wool and boil with hydrosulphite AX

Precipitated.— Cr present in ash :—Basic Mordant dyestuff. Boil cotton with hydrosulphite BX		
Decolourised only slowly. Colour does not return in air, but is restored by persulphate :—Triphenylmethane class	8	Chrome violet.
Decolourised. Colour returns on exposure to air :—Oxazine class	7	Gallocyanine, modern violet, ultra violet, coreine, prune, &c.

The colour is stripped :—Basic dyestuff (on tannin or other mordant). Add chromium fluoride reagent to the extract

Decolourised. Colour is not restored by air or persulphate :—Azo class	6	Janus claret red, &c.
Decolourised. Colour does not return in air, but is restored by persulphate :—Triphenylmethane class	5	Methyl violets, ethyl violet, benzyl violet, crystal violet, &c.
Decolourised. Colour returns on exposure to air :—Azine (Oxazine or Thiazine) class	4	Methylene violet, rhoduline violet, iris violet, neutral violet, tannin heliotrope, &c.
Not decolourised :—Pyrone class	3	Anisoline.

The colour is stripped.—Acid dyestuff. The colour transferred to wool is decolourised by hydrosulphite A and restored by persulphate :—Triphenylmethane class

The ammoniacal solution is violet	2	Acid violets, formyl violets, alkali violet, guinea violet, &c.
The ammoniacal solution is colourless, but becomes blue on acidifying	1	Red shades of soluble and alkali blues.

RECOGNITION OF DYES ON VEGETABLE FIBRES

TABLE XL.—BLUE COLOURS.

Boil with weak ammonia (1 : 100)

The colour is not stripped. Boil for a quarter of a minute with saline caustic soda, rinse with cold water (or salt solution), and boil for one minute with water and one or two drops of weak formic acid (1 : 100).

Branching tests	Final condition	No.	Dye identified
Colour unaffected or becomes darker, browner, &c., the original colour being restored on exposure to air :—Anthracene mordant or anthracene vat dyestuff (also Ultramarine). Boil with 90 p.c. formic acid. Reduce original fibre with hydrosulphite BX — **The colour is not much affected. Test ash for Cr**	Cr absent :— **Anthracene vat dyestuff**	18	Indanthrene blues, algole blues.
—	Cr present in ash :—**Alizarin dyestuff** on Cr	17	Alizarin blue, alizarin cyanines or anthracene blues on Cr mordant.
The colour is stripped. Al in ash. Apply lead acetate test	No H₂S evolved :— **Alizarin dyestuff** on Al	16	Alizarin cyanines or anthracene blues on Al mordant, erganone blues.
—	H₂S is evolved	15	Ultramarine.
A coloured acid extract precipitate by tannin is not obtained. — Decolourised or yellowish. Colour is restored on exposure to air :—Azine, Oxazine, Thiazine, or Indigo class. Apply lead acetate test	Colour changed to greenish-yellow, which can be diazotised and developed with betanaphthol :— **Primuline azo colour**	14	Primuline developed with naphthylamine ether.
No H₂S evolved. Heat fibre carefully in dry test-tube	No coloured vapour. Cr in ash :—**Mordant thiazine or oxazine** (not falling in group 6)	13	Brilliant alizarin blue, gallocyanine, gallamine blue, prune, celestine blue, delphine blue, &c.
—	Violet vapours evolved :—**Indigoid dyestuff**	12	Indigo (natural and synthetic), indigo MLB 2B, 4B, 5B, 6B, and T, ciba blue, bromindigo FB.
—	H₂S is evolved :— **Sulphide dyestuff**	11	Blues of the immedial, katigene, thiogene, pyrogene, sulphur, &c., series, hydrone blues.
Decolourised and colour not restored by air or persulphate.—Azo class. Boil with soap solution and white mercerised cotton — **The white cotton is not stained.**	Colour is stripped by boiling pyridine :— **Insoluble azo colour**	10	Dianisidine blue, blue from naphthol AC.
The white cotton is stained :—Salt dyestuff. Test ash for Cr and Cu	Cr or Cu present :— **Azo salt dyestuff** after-treated	9	The undermentioned (col. 8) coppered or chromed.
—	No Cr or Cu present :—**Azo salt dyestuff**	8	Blues of the diamine, benzo, Congo, Columbia, chlorazol, dianil, oxamine, Chicago, &c., series.
The colour is completely or largely stripped. A coloured acid extract, which is precipitated by tannin :—Basic dyestuff (on tannin or other mordant) or Basic mordant dyestuff. Add chromium fluoride reagent to the extract. — **Precipitated. Cr present in ash :—Basic mordant dyestuff. Boil cotton with hydrosulphite BX**	Decolourised slowly. Colour restored only by persulphate :— **Triphenylmethane class**	7	Chrome blue.
—	Decolourised. Colour returns on exposure to air :— **Oxazine class**	6	Gallocyanine, gallamine blue, celestine blue, prune, coreine, ultracyanine, modern cyanine, &c.
Not precipitated.—Basic dyestuff. Transfer to wool and boil with hydrosulphite AX	Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—**Triphenylmethane class**	5	Victoria blue, night blue, turquoise blue, setocyanine, &c.
—	Colour changes to red just before being decolourised. Colour returns violet or blue : **Safranine azo dyestuff**	4	Indoine blue, Janus blue, naphthindone blue, diazine blue, &c.
—	Decolourised. Colour returns on exposure to air :—**Azine, Oxazine, or Thiazine class**	3	Methylene blue, Nile blue, Capri blue, indazine, Basle blue, Moldola's blue, fast blue, cresyl blue, rhoduline blue, nitroso blue, &c.
The colour is stripped :—Acid dyestuff (or Prussian blue)	The extract is colourless and remains so on acidification. FeCl₃ gives a blue precipitate	2	Prussian blue.
—	The extract is colourless, but becomes blue on acidification. Transferred to wool, the blue is decolourised by hydrosulphite A, and restored by persulphate :— *Triphenylmethane class	1	Alkali blues, soluble blues, chlorazol brilliant blue, isamine blue, betamine blue, brilliant dianil blue, brilliant sky blue.

RECOGNITION OF DYES ON VEGETABLE FIBRES.

TABLE XII.—GREEN COLOURS.

Boil with weak ammonia (1 : 100)

The colour is not stripped. Boil for half a minute with saline caustic soda, rinse, and boil twice with weak formic acid. A coloured acid extract precipitable by tannin is not obtained. Reduce original fibre with hydrosulphite BX.

Condition	No.	Dyestuff
Reduced to yellow. Restored by air oxidation :—**Indigoid dyestuff**	20	Ciba green, helindone green.
Reduced colour is blue. Green shade restored by air	19	Algole green.
Reduced colour is dark maroon. Green shade restored by air	18	Indanthrene green or viridanthrene, leucole dark green B.
Reduced colour is brownish-olive. H₂S evolved on applying lead acetate test	17	Indanthrene olive or olivanthrene.
Colour of fibre rather paler, solution brownish-yellow	16	Cœruleine, anthracene green.
Colour of fibre becomes grey, solution red. Ni in ash	15	Alizarin green S on Ni-Mg mordant.
Colour unaffected. Solution colourless. Cr in ash	14	Alizarin green S on Cr mordant.
Reduced colour is brownish-red. Green restored by persulphate, but not by air. Boiling HCl (1 : 20) gives bright green solution	13	Alizarin viridine, brilliant alizarin viridine, alizarin cyanine green.
No H₂S is evolved :—**Mordant Oxazine (or Thiazine)**	12	Gallanilic green, indalizarine, &c.
H₂S is evolved :—**Sulphide dyestuff**	11	Greens of the immedial, katigene, thiogene, pyrogene, cross-dye, sulphur, and thionol series.
The colour is changed to greenish yellow, not restored to green by air, which can be diazotised and developed red with betanaphthol :—**Primuline Azo class**	10	Primuline developed with amidodiphenylamine.
Not decolourised. Cr is present in the ash :—**Mordant Azo dyestuff**	9	Diamond green, &c.
Colour destroyed. Fe is present in the ash :—**Nitroso class**	8	Russian green, fast green O, steam green, Alsace green, gambines, dioxine, &c.
Cr or Cu present :—**Azo Salt dyestuff after-treated**	7	The undermentioned (col. 6) coppered or chromed.
Cr and Cu absent :—**Azo Salt dyestuff**	6	Diamine green, benzo green, Columbia green, chloramine green, &c.
Precipitated. Cr in ash. Fibre decolourised by hydrosulphite BX, the colour not returning in air, but restored by persulphate :—**Triphenylmethane class**	5	Chrome green.
Decolourised. Colour does not return on exposure to air, but is restored by persulphate :—**Triphenylmethane class**	4	Brilliant green, malachite green, methyl green, Victoria green, setoglaucine, new fast green, &c.
Colour becomes red just before being decolourised. Colour returns violet or green on exposure to air :—**Safranine Azo class**	3	Janus green, diazine green, &c.
Decolourised. Colour returns on exposure to air :—**Azine, Oxazine, or Thiazine class**	2	Fast green M, methylene green, azine green, Capri green, &c.
The colour transferred to wool is decolourised by hydrosulphite A and restored by persulphate :—**Triphenylmethane class**	—	Acid greens, guinea green, Neptune green, naphthalene green, agalme, green.

Intermediate column headings:

- No Cr or Ni present in ash :—**Anthracene Vat dyestuff**
- The ash contains Cr or Ni :—**Anthracene Mordant dyestuff**
- Reduced colour is brown. Green shade returns on exposure to air. Boil with hydrochloric acid (1 : 20)
- Decolourised. Colour returns on exposure to air.—**Azine, Oxazine, or Thiazine class**
- The white cotton is not stained. Boil with hydrochloric acid (1 : 20)
- Decolourised and colour not restored by air.—**Azo or Nitroso class**. Boil with soap solution and white mercerised cotton
- The white cotton is stained.—**Salt dyestuff.** Test ash for Cr and Cu

Left (vertical) headings:

The colour is completely or largely stripped, giving a coloured acid extract, which is precipitated by tannin solution :—**Basic dyestuff** (or tannin or other mordant) or **Basic Mordant dyestuff**. Add chromium fluoride to the extract.

Not precipitated :—**Basic dye-stuff.** Transfer to wool and boil with hydrosulphite AX

The colour is stripped :—Acid dyestuff.

RECOGNITION OF DYES ON VEGETABLE FIBRES

TABLE XIII.—BROWN COLOURS.

	Result
Cr and Cu absent :—Anthracene vat dyestuff, &c.	**15** Indanthrene maroon, algole brown, leucole browns, cibanone brown, paramine brown (p-phenylene diamine oxidised on fibre).
No H₂S is evolved. Test ash for Cr and Cu — Mordant dyestuff. Boil with HCl (1 : 20). Solution brown, fibre unaffected	**14** Cutch.
Not stripped or only slightly. Boil with dilute caustic soda (10 p.c.). Fibre and solution dull violet	**13** Alizarin orange on Cr mordant, alizarin red or purpurin on Cr.
Completely stripped	**12** Anthragallol, anthracene brown, alizarine brown.
H₂S is evolved :—Sulphide dyestuff	**11** Immedial cutch, cross-dye brown, katigene browns, pyrogene browns, thiogene browns, &c.
Decolourised and original colour restored by air :—Indigoid class	**10** Helindone brown G, ciba brown, thioindigo brown.
The shade is changed to greenish yellow, which can be diazotised and developed red with beta-naphthol :—Primuline azo-colour	**9** Primuline developed with metaphenylene diamine, terra-cotta, &c.
The colour is not stripped :—Mineral colour. Treat with sodium bisulphite in the cold. Not decolourised	**8** Iron buff, khaki (oxides of Cr and Fe).
Decolourised	**7** Manganese bronze.
The colour is stripped—Insoluble azo-colour. Test ash for Cu. Cu present	**6** Paranitraniline cutch (para red coppered).
Cu absent	**5** Para brown (chrysoidine and paranitraniline), benzidine or toluidine brown.
The white cotton is stained :—Salt dyestuff. Test ash for Cr and Cu. Cr or Cu present :—Azo salt dyestuff after-treated	**4** The undermentioned (col. 3) coppered or chromed.
Cr and Cu absent :—Azo salt dyestuff	**3** Browns of the diamine, benzo, Congo, dianil, chlorazol, Columbia, Hessian, oxamine, and toluylene series.
The colour is stripped, giving acid extract which is precipitated by tannin solution :—Basic dyestuff. The dyestuff transferred to wool is permanently decolourised by hydrosulphite AX :—Azo class	**2** Bismarck brown, Janus brown, tannin brown, &c.
The colour is stripped :—Acid dyestuff. Transferred to wool it is permanently decolourised by hydrosulphite AX :—Azo class	**1** Fast brown, naphthylamine brown, acid brown, &c.

Column headings (left to right):

The colour is not stripped. Boil with weak ammonia (1 : 100)

Boil for half a minute with saline caustic soda, rinse, and boil twice with weak formic acid (1 : 100)

A coloured acid extract precipitable by tannin is not obtained. Reduce original fibre with hydrosulphite BX

Decolourised and colour not restored on exposure to air or by per-sulphate :—Azo class and Mineral colours. Boil with soap solution and white mercerised cotton

The white cotton is not stained. Boil with pyridine

Unaltered or changed in shade, becoming darker, paler, yellower, &c. Apply lead acetate test

Cr or Cu (or both) present :—Mordant dyestuff. Boil with HCl (1 : 20)

RECOGNITION OF DYES ON VEGETABLE FIBRES

TABLE XIV.—BLACK AND GREY COLOURS.

Boil with weak ammonia (1 : 100)

The colour is not stripped. — Boil with dilute hydrochloric acid (1 : 5)

Boil for one minute with saline caustic soda, rinse, and boil with water and dilute hydrochloric acid (1 : 20)

The colour is not stripped (or only slightly). — A coloured acid extract precipitable by tannin is not obtained. — Reduce original fibre with hydrosulphite BX. The colour is unaffected or changed in shade (becoming brown, maroon, &c.)

No.	Test / class	Dye
15	Colour not changed by reduction (or very slightly) :—**Anthracene class.** Test ash for Cr. — Cr absent :—**Anthracene vat dyestuff**	Indanthrene grey, indanthrene black, cibanone black, helindone black.
14	Cr present :—**Anthracene mordant dyestuff**	Alizarin cyanine black, alizarin blue black B.
13	The reduced colour is brown. Only slowly and imperfectly restored to black by air, but at once by persulphate. Cr present in ash.—**Naphthalene mordant dyestuff**	Naphthazarine S, alizarin black S, alizarin blue black SW, naphthomelane.
12	The reduced colour is brown, but is rapidly restored to black on exposure to air.—**Azine, Oxazine, or Thiazine class.** Apply lead acetate test. — No H_2S is evolved. Fibre becomes reddish-brown on boiling with bleaching powder solution 5° Tw.—**An oxidation black**	Aged-aniline black, Prussiate black, one-bath aniline black, steam aniline black, diphenyl black.
11	H_2S is evolved. Fibre becomes colourless or pale buff on boiling with bleaching powder solution 5° Tw —**Sulphide dyestuff**	Blacks of the immedial, katigene, cross-dye, pyrogene, thiogene, thionol, pyrol, sulphur, &c., series.
10	Decoloured and colour restored by air. Gives violet vapours on heating in dry tube - **Indigoid dyestuff**	Ciba grey G and B.
9	The white cotton is not stained. Colour is stripped by boiling pyridine — **Insoluble azo colour**	Azophor black, &c.
8	Decolourised and colour not restored by air or persulphate — **Azo class.** Boil with soap solution and white mercerised cotton. The white cotton is stained. Test ash for Cr and Cu. — Cr or Cu present.— **Azo salt dyestuff after-treated**	The undermentioned (col. 7) coppered or chromed.
7	Cr and Cu absent :— **Azo salt dyestuff**	Blacks of the diamine, oxydiamine, benzo, Columbia, diamil, Pluto, &c., series. Also diaminogen, diazo blacks, &c. (developed or coupled).
6	The colour is largely stripped and the acid extract is precipitated by tannin solution :—**Basic dyestuff.** Transfer to wool and boil with hydrosulphite AX. Colour becomes red just before being decolourised Violet or violet-blue colour returns in air **Safranine azo class.**	Janus black, Janus grey, diazine grey.
5	Decolourised. Colour returns on exposure to air .— **Azine, Oxazine, or Thiazine class.**	Methylene grey, new methylene grey, new fast grey, nigrisine, &c.
4	**The colour is stripped** — Solution red. Cr in ash	Logwood black on chrome mordant, noir reduit
3	Solution orange. Fe in ash	Logwood black on iron mordant.
2	Fibre and solution colourless	Tannate of iron.
1	The colour is stripped :—**Acid dyestuff.** The dyestuff transferred to wool and boiled with hydrosulphite AX is permanently decolourised :—**Azo class.**	Naphthol blacks, naphthylamine blacks, Palatine black, &c.

edition of Vogel's 'Practische Spectralanalyse irdischer Stoffe' (1889), charts were given of the absorption bands of various dyestuff solutions. This work was greatly extended in 'Formánek's Spectralanalytischer Nachweis Künstlicher organischen Farbstoffe' (1900), which contains a systematic scheme for the spectroscopic identification of upward of 350 distinct dyestuffs. In a later publication (1905) entitled 'Qualitative Spectralanalyse anorganischen und organischen Körper,' Formánek has extended his data to include the natural colouring matters, and, in conjunction with E. Grandmougin, has republished his tables as 'Untersuchung und Nachweis organischen Farbstoffe auf spectroscopischen Wege.'

The value of spectroscopic tests for the identification of dyestuffs on the fibre is limited to those dyestuffs which can be removed without change by suitable solvents.

Spectroscopic examination of dyed fibres has not yielded useful results.　　W. M. G.

NOTE.—Green's scheme of identification of dyes and the annexed Tables are printed by permission of Prof. A. G. Green and Messrs. Chas. Griffin & Co., Ltd

DYER'S BROOM, *Genista tinctoria* (Linn.) (*Dyer's broom, Dyer's greenweed*; *Genêt, Genestrole, Trentanel*, Fr. ; *Ginster*, Ger) is found in the pastures, thickets, and waste places throughout Central and Southern Europe, across Russian Asia to the Baikal, and northward to Southern Sweden. It is frequent in the greater part of England, but rare in Ireland and Scotland. The fact that it contains a yellow colouring matter is recorded by numerous writers, and the following embody the principal references to the dyeing and general properties of the plant : Bancroft (Philosophy of Permanent Colours, 1813, 2, 108) ; Gmelin (Handbook of Chemistry, 16, 517) ; Berthollet (On Dyeing, 1824, 2, 242) ; Gonfreville (L'Art de la Teinture des Laines, 501) ; Leuchs (Farben u. Farbekunde, 1846, 2, 309), and Schutzenberger (Traité des Matières Colorantes, 1867, 4, 422).

To isolate the colouring matters, a hot aqueous extract of the plant is treated with lead acetate solution, and the pale yellow viscous precipitate is collected and decomposed by means of boiling dilute sulphuric acid. The clear liquid decanted from the lead sulphate deposits on cooling a dull yellow powder ; this is filtered off, dissolved in a little alcohol, and the solution poured into a large volume of ether, causing the separation of a dark-coloured resinous impurity. The clear liquid is evaporated, yielding a yellow crystalline residue, which consists of two substances. To separate these, advantage is taken of the fact that, with sulphuric acid in the presence of acetic acid, one only of these compounds gives an insoluble sulphate. This is collected and decomposed with water and the product crystallised from dilute alcohol. It is obtained as yellow needles, and was found to be identical with the *luteolin* of weld (*Reseda luteola*) (Perkin and Newbury, Chem. Soc. Trans. 1899, 75, 830).

Genistein $C_{14}H_{10}O_5$, the second colouring matter of dyer's broom, is present in the mother liquors obtained during the purification of the luteolin, and also in considerable quantity in the filtrate from the lead precipitate, from which

it is most readily isolated. To the boiling liquid ammonia is added, causing the separation of a lemon-yellow precipitate, which is collected and decomposed with boiling dilute sulphuric acid. The clear liquid is extracted with ether, and the extract evaporated, leaving a brownish crystalline mass. It is purified by crystallisation from acetic acid, and by conversion into the acetyl derivative.

Genistein crystallises in long colourless needles ; m.p. 291°–293° (Perkin and Horsfall, Chem. Soc. Trans. 1900, 77, 1312) ; soluble in alkalis with a pale yellow colouration. Alcoholic ferric chloride gives a dull-red violet colouration, and alcoholic basic lead acetate a lemon-yellow precipitate.

Triacetylgenistein $C_{14}H_7O_5(C_2H_3O)_3$, colourless needles, m.p. 197°–201° ; and *tetrabromgenistein* $C_{14}H_6Br_4O_5$, colourless needles, m.p. above 290°, have been described.

On digestion with boiling 50 p.c. potassium hydroxide, genistein gives *phloroglucinol* and *p-hydroxyphenylacetic acid.*

By methylation with methyl iodide in the usual manner, genistein dimethyl ether and methylgenistein dimethyl ether are produced.

Genistein dimethyl ether $C_{14}H_8O_3(OCH_3)_2$ forms colourless leaflets, melts at 137°–139°, and gives the *monacetyl* compound

$$C_{14}H_7O_3(C_2H_3O)(OCH_3)_2$$

minute colourless needles, m.p. 202°–204°. When decomposed with alcoholic potash, it forms *methoxyphenylacetic acid* and *phloroglucinol-monomethyl ether* (identified by means of its disazobenzene derivative).

Methylgenistein dimethyl ether

$$CH_3 \cdot C_{14}H_7O_3(OCH_3)_2$$

melts at 202° ; and the *acetyl* derivative

$$CH_3 \cdot C_{14}H_6O_3(C_2H_3O)(OCH_3)_2$$

forms colourless needles, m.p. 212°–214°. With alcoholic potash it gives *methoxyphenylacetic acid* and probably *methylphloroglucinol-monomethyl ether.*

Genistein diethyl ether $C_{14}H_8O_3(OC_2H_5)_2$ forms colourless needles, m.p. 132°–134° ; whereas *acetylgenistein diethyl ether*

$$C_{14}H_7O_3(C_2H_3O)(OC_2H_5)_2$$

melts at 168°–170°. Alcoholic potash gives p-*ethoxyphenylacetic acid.*

According to Perkin and Horsfall, genistein may be a *trihydroxyphenylketocumaran*:—
Genistein is a feeble colouring matter, and upon woollen cloth gives, with chromium mordant, a pale greenish-yellow ; with aluminium mordant, a very pale yellow ; and with iron mordant, a chocolate-brown shade.

Dyeing Properties of Dyer's Broom.—In this respect there is a close resemblance between dyer's broom and weld. The dyeing power of the former is distinctly the weaker of the two ; otherwise the only point of difference worthy of mention is that shown by the iron mordant, which, in the case of dyer's broom, gives a duller and more drab-coloured shade.

Luteolin is also present in the *Digitalis purpurea* (digito-flavone) (Fleischer and Fromm, Ber. 1899, 32, 1184; v. Kostanecki and Diller, *ibid.* 1901, 34, 3577), and in the flowers of *Antirrhinum majus* (Wheldale and Bassett, Bio-Chem. J. *l.c.*).
A. G. P.

DYMAL. Trade name for 'didymium' salicylate [Nd Pr]·[C₆H₄(OH)·CO₂]₇. A reddish-white substance, used as a dusting powder, having non-irritant and antiseptic properties.

DYNAMAGNITE, DYNAMITE v. EXPLOSIVES.

DYSANALYTE. A cubic or pseudo-cubic mineral consisting of titano-columbate of calcium with some ferrous oxide, cerium earths (up to 5 p.c.), and sodium. The amount of Cb₂O₅ given in various analyses ranges from nil to 26 p.c., and the mineral has sometimes been asserted to be identical with perofskite (CaTiO₃); the difficulties presented in the analysis of this mineral are, however, implied by its name, from δυσανάλυτος, 'hard to undo' It occurs as small black cubes in contact-metamorphic limestone at Sasbach in the Kaiserstuhl Mountains, Baden, and in metamorphic sandstone at Magnet Cove, Arkansas. L. J. S.

DYSCRASITE (antimonial silver). Antimonide of silver Ag₆Sb (Ag 84·3 p.c.) to Ag₃Sb (Ag 72·9 p.c.), occurring as silver-white masses with metallic lustre, but often with a dull yellowish or black tarnish. The material is sectile· H.=3½-4. Orthorhombic crystals, twinned to simulate hexagonal forms, are rare and not distinctly developed. According to T. Liebisch (1910), two compounds are represented, namely, cubic Ag₆Sb, with sp.gr. 10 05, and orthorhombic Ag₃Sb, with sp.gr. 9·63-9·82. The mineral is found in silver mines at Wolfach in Baden (where it is the chief ore), Andreasberg in the Harz, Allemont in France, and the Cobalt district in Ontario. L. J. S.

DYSODILE. A soft laminated carbonaceous substance of a yellowish-grey or green colour burning with a luminous flame, and a smell resembling that of burning caoutchouc. Found in Sicily and in Bavaria (Fricklinger, Jahrb. Min. 1875, 760; also Church, Chem. News, 34, 156; Potonié, Chem. Zentr. 1907, ii. 555).

DYSPROSIUM. Sym. Dy. At. wt. 162·5 (162·52 Kremers, Hopkins, and Engle, J. Amer.

Chem. Soc. 1918, 40, 598) (Urbain and Demenitroux, Compt. rend. 1906, 143, 598; Hinrichs, *ibid.* 1143). From erbia—one of the fractions obtained from ytterbite—Cleve separated an earth which he called 'holmia'; and from this material Lecoq de Boisbaudran isolated a simpler constituent, *dysprosia*, characterised by a well-marked absorption spectrum showing bands in the ultra-violet as well as in the visible region of the spectrum (Compt. rend. 1886, 102, 100). This oxide, one of the most basic constituents of holmia, was concentrated by precipitations with potassium sulphate and ammonia. Further fractionation of the nitrates and double nitrates gave a product rich in terbium and dysprosium (Urbain, Compt. rend. 1904, 139, 736; 1905, 141, 521). The latter is separated from terbium by fractional crystallisation of the ethyl sulphates, terbium and yttrium being concentrated in the least soluble fraction, whilst dysprosium accumulates in the middle fraction (Urbain, Ann. Chim. Phys. 1900, [7] 19, 184; Compt. rend. 1906, 142, 785).

Dysprosium material of very high purity may be obtained by fractional crystallisation of the rare-earth bromates, followed by fractional crystallisation of the ethyl sulphates (Engle and Balke).

Dysprosium is separated from yttrium by crystallisation of the nitrate with the addition of bismuth nitrate.

Dysprosium forms a white *oxide* Dy₂O₃, but no peroxide. Its salts have a faint greenish-yellow tint: *chloride* DyCl₃,6H₂O; *nitrate* Dy(NO₃)₃,5H₂O, melting at 88° in its water of crystallisation, very similar to bismuth nitrate (Urbain and Jantsch, Compt. rend. 1908, 146, 127); *sulphate* Dy₂(SO₄)₃,8H₂O, brilliant yellowish crystals, stable at 110°, and completely dehydrated at 360°. For other salts, v. Jantsch and Ohl, Ber. 1911, 44, 1274.

Dysprosium stands first in the list of paramagnetic elements, its oxide Dy₂O₃ being 12·8 times more magnetic than ferric oxide. The high values for the magnetic susceptibility of the rare earths (yttria, erbia, &c.) fractionated by Cleve and Nilson are probably due to the presence of dysprosium (Urbain, Compt. rend. 1908, 146, 922). G. T. M.

E

EARTHNUT OIL v. ARACHIS OIL.

EAU DE COLOGNE v. PERFUMES.

EAU DE JAVELLE. Solution of sodium hypochlorite (v. *Bleach liquor*, art. CHLORINE).

EAU DE LUCE. *Aqua luciæ.* A milky liquid containing oil of amber, alcohol, and ammonia (v. AMBER, OIL OF).

EBONITE. *Sulphurised caoutchouc* (v. RUBBER).

EBULLIOSCOPE. An instrument for determining the strength of spirits of wine by means of its boiling-point.

ECBOLINE v. ERGOT.

ECGAINE. N-benzoylhydroxypropylnovec-

gonidene ester. A compound allied to cocaine and of the structure

$$CH_2 \cdot CH—CH \cdot CO_2Et$$
$$| \quad\quad |$$
$$NH \quad CH$$
$$| \quad\quad ||$$
$$CH_2 \cdot CH—CH$$
A crystalline base, more active than cocaine in its anæsthetic properties, is non-toxic and can be readily sterilised (Braun and Müller, Ber. 1918, 235; Chem. Werke Grenzbach, D. R. P. 301139).

ECGONINE v. COCAINE AND THE COCA ALKALOIDS.

ECHITAMINE, ECHITENINE *v.* DITA BARK.

ECHUJIIN *v.* DIGITALIS.

E. C. POWDER *v.* EXPLOSIVES.

EDESTIN. A crystalline proteid substance found in the seeds of hemp, sunflower, and castor-bean, capable of uniting with acids to form salts (Osborne, J. Amer. Chem. Soc. 24, 39).

EDIBLE OILS AND FATS. Under this term are comprised those oils and fats which serve as food. Most of the edible oils and fats, such as olive oil, cod liver oil, suet, lard, butter-fat, cacao butter, goose fat, &c , are immediately fit for consumption, if ' rendered ' with sufficient care. Hence they rarely need undergo a process of technical purification, except simple filtration, before they are placed on the market. This applies, however, only to the freshly (' first ') rendered products, as contact with putrescible organic matter rapidly causes hydrolysis of the oils and fats, so that, *e.g* , lard or olive oil which has been allowed to remain in contact for some little time with the organic tissues from which they have been derived, readily become rancid, and therefore unfit for food in their original state This applies with especial force to cod liver oil.

The large demand made on the market by the rapidly growing consumption of oils and fats has, however, led to the employment of second and even third ' renderings,' in the case of animal fats, and second or third ' expressions ' in the case of vegetable oils and fats. Such products contain, as a rule, notable amounts of free fatty acids, and small quantities of extractive substances, all of which must be removed before the oils and fats become suitable for food purposes. The processes applied to the purification and decolourisation are treated as deep secrets. It may, however, be stated that most of the processes are based on physical methods of refining (*see* OILS AND FATS).

Chemicals involving the use of mineral acids must be altogether excluded from the purview, of the refiner, since the mineral acids, however carefully they may be removed by subsequent washing, impart an objectionable flavour to the products, thus rendering them useless for edible purposes. Alkalis or alkaline earths are not so objectionable, and are, therefore, used commercially for the removal of free fatty acids. (A notable example of this kind is furnished by the usual method of refining cotton-seed oil.) The alkalis and alkaline salts chiefly employed in practice are caustic soda, sodium carbonate, sodium silicate, lime, and magnesia. Baryta has also been proposed (and patented), but its poisonous properties would prohibit its use.

Whereas all animal oils and fats, when freshly prepared, are suitable for food, this holds good only in a somewhat restricted sense of vegetable oils and fats. If the vegetable oils and fats are free from objectionable substances they may hold in solution or may have dissolved from the vegetable matter from which they have been obtained by expression or boiling out, they are suitable for edible purposes, and are so used to a very considerable extent.

We know, however, that a number of oils which contain non-fatty toxic or injurious substances, such as tung oil, calophyllum oil, curcas oil, croton oil In the case of castor oil, the fatty acids themselves are injurious to health ; hence

castor oil is unusable as a foodstuff. Experience has also shown that the fats belonging to the Chaulmoogra group are injurious to health. All these oils must, therefore, be excluded from the list of edible oils.

Oils which are regarded as palatable in one part of the world are not used as food in other parts. Thus, whereas rape oil and linseed oil find a ready market for edible purposes in India, these oils are at present used in exceptional cases only as table oils in Western Europe. They are replaced in richer countries by cotton-seed oil, sesamé oil, arachis oil, poppy-seed oil, and olive oil. The increased consumption of the available edible oils and fats has created, during the last decades, a new and growing industry.

Amongst the most important developments in this industry is the preparation of coco-nut oil and palm-kernel oils for edible purposes (*see* COCO-NUT OIL and PALM-KERNEL OIL). Mixtures of several edible oils are now largely prepared as ' table oils ' to replace olive oil. Amongst these substitutes the most important are : arachis oil, sesamé oil, cotton-seed oil, and to some extent also soya-bean oil. Mixtures of edible vegetable and animal oils and fats are chiefly represented by the ' suet substitutes,' which are prepared by mixing tallow with cotton-seed oil, and by ' lard substitutes,' which represent a mixture of animal fats with cotton-seed oil, maize oil, &c. Until a few years ago, ' compound lard ' contained frequently no lard whatever, but, according to legislation in the United States, ' lard compounds ' or ' lard substitutes ' must now contain at least 50 p.c. of lard (*see* LARD SUBSTITUTES).

Another development of the industry has been the introduction of hardened or hydrogenated oils, which are now extensively used as constituents of margarine (*see* HYDROGENATED OILS).

The manufacture and sale of edible oils and fats has assumed such considerable importance that legislation has stepped in to protect the public against fraudulent practices both as regards the commercial description of a ' blended ' fat and the absence of injurious substances (*see* MARGARINE).

The changes in the character of fats during cooking have been described by Masters and Smith (Analyst, 1914, 39, 347).   J. L.

EDINOL. Trade name for *p*-amino-saligenin hydrochloride. Used as a photographic developer.

EDULCORATION. The act of washing insoluble matter so as to remove any soluble impurity.

EFFLORESCENCE. This term is applied to two or three different phenomena, characterised by the formation of a loose pulverulent deposit on the surface of a solid body.

1. Crystallised salts are said to effloresce when they lose their water of crystallisation and fall to powder, *e.g.* normal sodium carbonate.

2. The formation of a pulverulent crystalline deposit on the surface of a porous body, in consequence of the crystallisation of a salt existing in solution within its pores, or formed from materials existing therein, is also called efflorescence ; *e.g.* the crystallisation of potassium nitrate on the surface of the earth or in caves, as

in India, or on saltpetre plantations ; of sodium sulphate and carbonate on walls ; of alum on alum-slate ; of ferrous sulphate on iron pyrites, &c. In all these cases the solution of the salt is drawn by capillary action to the surface of the solid body, and there crystallises in consequence of the evaporation of the water.

3. The term ' efflorescence ' is likewise applied to the effect which sometimes takes place when a saline solution is left to evaporate slowly in an open vessel. The solid salt separates in dendritic crystals just where the surface of the liquid touches the side of the vessel, and the solution, rising by capillarity between these crystals, forms a fresh crystallisation just above the first layer ; and this process is continually repeated till the crystallisation thus formed extends over the edge of the vessel, and sometimes down to the table on which it stands. Sal-ammoniac and other ammonia salts often effloresce in this manner. The effect may be prevented to a certain extent by greasing the edge of the vessel, or better, by quickly boiling the solution, or evaporating it by heat from above.

EGG. The egg of the common fowl, *Gallus Bankiva*, consists of four principal parts : the *shell* ; the *white* ; the *yolk* or *vitellum* ; the *white yolk* or *germinal cell* ; and the membranes separating these parts. The usual weight of an egg is 40–60 grams ; of this the shell and shell membrane form 5–8 grams ; the yolk, 12–18 grams ; and the white, 23–34 grams.

The shell has the composition :

Calcium carbonate	. . .	89·6 p.c.
Phosphates of lime and magnesia		5·7 „
Organic matter and sulphur	.	4 7 „

The colouring matter of egg-shells is a bile pigment (Liebermann, Ber. 11, 606).

The *shell membrane* or *membrana putaminis* separating the white from the shell is double, the two parts being in contact over the greater part of the inner surface of the shell, but separated by an air-space at the broad end of the egg. These membranes are composed of a proteid substance allied to keratin (Liebermann). Abderhalden and Strauss have examined the products of hydrolysis of *ovokeratin*, and find them to be, from 100 grams of substance : 3·9 grams glycine ; 3·5 grams alanine ; 1·1 gram amino-valeric acid ; 7·4 grams leucine ; 4·0 grams proline ; 8·1 grams glutamic acid ; and 1·1 gram aspartic acid (Zeitsch. physiol. Chem. 1906, 48, 530).

The white is a faintly yellow albuminous fluid enclosed in large cells of thin membrane. The fluid has sp.gr. 1·045, and is really mobile, though it appears viscous because of its confinement by the cell walls. It has an alkaline reaction. Kojo (Zeitsch. physiol. Chem. 1911, 75, 1) gives the following analysis :

Water	.	.	.	.	87·71 p.c.
Ash	.	.	.	.	0·4 „
Organic solids	.	.	.	11·89 „
Total nitrogen	.	.	.	1·75 „
Dextrose	.	.	.	.	0·55 „

The organic solids consist mainly of proteins, a small amount of dextrose, and traces of fats, lecithin, and cholesterol. Salkowski showed that glucosamine was also present (Biochem. Zeitsch. 1911, 32, 335).

The protein substances of egg white are all gluco-proteids, and in their solution and precipitation properties are similar to globulins, albumins, or proteoses (*v.* art. PROTEINS).

Ovoglobulin separates from egg white partly on dilution with water, and completely if the solution be saturated with magnesium sulphate or ammonium sulphate. By repeated solution in water and reprecipitation, part becomes insoluble (Langstein, Hofmeister's Beitrage, 1), and it is probably a mixture of several globulins (Corin and Berard, Bull. Acad. Belg. [3] 15, 643). The globulins form about 6·7 p.c. of the total proteids of egg white (Dillner, Hammarstein's Text-book Physiol. Chem. 430).

Ovalbumin is the chief proteid constituent of egg-white. It is obtained crystalline by precipitating the globulins with ammonium sulphate, as above, and allowing the filtrate to evaporate. (For details of methods, *see* Hofmeister, Zeitsch. physiol. Chem. 16, 187 ; Osborne and Campbell, J. Amer. Chem. Soc. 1900, 22, 422 ; Rosenkrantz, J. Russ. Phys. Chem. Soc. 1906, 38, 2 ; and Mayer, Compt. rend. 1906, 143, 515.)

Pure ovalbumin crystallises in large, well-formed needles. A 2·5 p.c. solution in water becomes turbid at 60°, and at 64° yields a flocculent coagulum The addition of sodium chloride to the solution raises the temperature of coagulation (Osborne and Campbell, *l.c.* ; Starke, Pflüger's Archiv. 12, 18).

The composition of ovalbumin is :

C	H	N	S	P	O
52·75	7·10	15·51	1·62	0 12	22·90 p.c.

(Osborne and Campbell, *l.c.* 441 ; in agreement with Hopkins, J. Physiol. 25, 306 ; and Hammarsten, Zeitsch. physiol. Chem. 9, 304).

Many attempts have been made to assign a formula to ovalbumin. Latham (Biochem. J. 1908, 3, 207 *et seq*) gives it a molecular weight of 5473, and the formula $C_{240}H_{397}N_{65}O_{75}S_3$, but this must be regarded as an approximation only.

It has been characterised by determining the various amino-acids yielded on hydrolysis with hydrochloric acid of sp.gr. 1·19 (*v.* art. PROTEINS). 100 grams ovalbumin yield : alanine, 2·1 grams ; leucine, 20·0 grams ; phenyl-alanine, 4·4 grams ; tyrosine, 1·1 gram ; cystine, 0·3 gram ; proline, 2·3 grams ; aspartic acid, 1·5 grams ; and glutamic acid, 8·0 grams (Abderhalden and Pregl, Zeitsch. physiol. Chem. 1905, 46, 24 ; Osborne, Jones, and Leavenworth, Amer. J. Physiol. 1909, 24, 252 ; Levene and Beatty, Biochem. Zeitsch. 1907, 4, 305).

The specific rotation of pure albumin is given as −31° (Willcock, J. Physiol. 1908, 37, 27), −30·70° (Hopkins, ibid. 25, 306), and −29·31° (Osborne and Campbell, *l.c.*).

The precipitation of albumin by acids and salts is a completely reversible reaction (Galeotti, Zeitsch. physiol. Chem. 1905, 44, 461), and follows the law of mass action (Ostwald, Chem. Soc. Abstr. 1908, i. 375 ; Gerrini, Zeitsch. physiol. Chem. 1906, 47, 287).

Conalbumin. Only about one-half of the proteid of egg white can be obtained as crystallised ovalbumin ; the other fractions have a higher rotation and sulphur content. By heating these fractions at 65°, *conalbumin is*

obtained as a coagulum, which, when dried at 110°, has the following composition :—

C	H	N	S	O
52·25	6·99	16·11	1·70	22·95 p.c.

Its specific rotation is about −36° (Osborne and Campbell, *l.c.*; Panormoff, Chem. Zentr. 1898, 11, 487).

Ovomucoid is found in the residue after all proteids coagulated by heat have been removed from egg white (Neumeister, Zeitsch. Biol. 1890, 27, 369; Mörner, Zeitsch physiol. Chem. 1893, 18, 525). It forms about 10 p.c. of the proteids of egg white. It is not precipitated from solution by mineral acids or organic acids (except phosphotungstic and tannic acids) or by metallic salts.

The *inorganic constituents* of egg-white in 1000 parts are : Potash, 276–285 parts ; soda, 235–239 parts ; lime, 18–29 parts ; magnesia, 16–32 parts ; iron oxide, 4·4–5·5 parts ; chlorine, 238–205 parts ; phosphoric acid, 32–48 parts ; sulphuric acid, 13–26 parts ; silica, 3–20 parts ; carbon dioxide, 97–116 parts (Poleck and Weber, Hammarsten's Physiol. Chem. 1904, 432). Traces of fluorine have also been found (Nicklés, Compt rend 43, 885).

The yolk or yellow is contained within a membrane composed of a proteid allied to keratin (Liebermann, Pflüger's Archiv. 43). It is a viscous, opaque, yellow, alkaline emulsion having a mild taste, and consists chiefly of water, fats, and colouring matter, together with vitellin, lecithin, cholesterol, &c. Müller and Masuyama (Zeitsch. f. Biol. 1900, 39, 542) have found a diastatic enzyme in the yolk ; the presence of purine bases has been detected by Mesernitzki (Biochem. Zentr. 1, 739) ; and of creatinin by Salkowski (*l.c.*).

1000 parts of the yolk contain approximately : water, 480 parts ; fats, 228·4 parts ; proteid (vitellin), 156·3 parts ; lecithin, 107·2 parts ; cholesterol, 17·5 parts ; insoluble salts, 6·12 parts ; soluble salts, 3·53 parts.

According to Poleck, the ash of yolk of eggs contains, in 1000 parts : soda, 51·2–65·7 parts ; potash, 80·5–89·3 parts ; lime, 122·1–132·1 parts ; magnesia, 20·7–21·1 parts ; iron oxide, 11·9–14·5 parts ; phosphoric acid, 638·1–667·0 parts ; silicic acid, 5·5–14·0 parts.

The *fat* forms about 30 p.c. of the yolk, and may be extracted with ether. It is a mixture of solid and liquid fat, and contains 0·6 p.c. phosphorus, equivalent to 15·04 p.c. lecithin ; 61·5 p.c. of neutral fat ; and 23·2 p.c. free acids. The neutral fat contains glycerol and acid in such proportions as prove it to consist of *triglycerides* only (Thorpe, Arch. Nedér. Sci. Exact. Nat. 1901, 6, 155). On saponification it yields 40 p.c. oleic acid ; 38·04 p.c. palmitic acid ; and 15·21 p.c. stearic acid (Paladino, Biochem. Zeitsch. 1909, 17, 356).

Barbieri, by extracting yolks with carbon disulphide, obtained tristearin and triolein (Compt. rend. 1907, 145, 133), besides. cholesterol ; while MacLean has isolated pure tripalmitin from egg-fat (Biochem. J. 1909, 4, 168).

Lecithin (*v.* LECITHIN) is present both free and in combination with protein (Hanasse, Biochem. Ze'tsch. 1906, 1, 246). Commercial lecithins are usually prepared from eggs, and show a high choline content. Trier identified

β-aminoethyl alcohol in egg lecithin, isolating it as its gold chloride compound (Zeitsch. physiol. Chem. 76, 496). Lecithin is best prepared from dried egg yolks by Bergell's method (Ber. 1900, 2584). The extract prepared by boiling with 96 p.c. alcohol for 6 hours, is cooled to 0° and precipitated with an alcoholic · solution of cadmium chloride. The precipitate is filtered off, washed with 96 p.c. alcohol, dried in air, and extracted with ether. The residue is boiled with eight times its volume of 80 p.c. alcohol, and a concentrated solution of ammonium carbonate is added until the solution is free from cadmium. The filtered solution is cooled to −10°, and the precipitate is dissolved in chloroform, precipitated with acetone, and dried in *vacuò* over sulphuric acid.

After hydrogenation of egg lecithin, Paal and Oehme isolated stearic and palmitic acids, and suggest that linolic and palmitic acids are originally present (Ber. 1913, 1297).

Barbieri (Gazz. chim. ital. 1917, [1],1) stands alone among a host of investigators in his failure to isolate lecithin from egg yolk. He affirms that the phosphorus of egg yolk is present as inorganic phosphates, that the choline exists only as a degradation product of ovochromin, and that glycerol and fatty acids exist as constituents of fat, and not combined as lecithin.

Cholesterol is present in the yolk to the extent of about 1 p.c. (Juckenack, Zeitsch. Nahr. Genussm. 1899, 1905 ; Benecke, Bied. Zentr. 1881, 568). According to Serano and Palozzi (Chem. Zentr. 1911, ii. 772), it occurs as its oleic and palmitic esters.

Lutein, the colouring matter, was described by Maly (Chem. Zentr. 1881, 485) as a mixture of two substances : vitello-lutein, which is yellow and soluble in petroleum ; and vitello-rubrin, a red body soluble in carbon disulphide. The mixture is an orange-red amorphous substance, which is not affected by alkalis, and can therefore be isolated by hydrolysing the fats. C. A. Schunk (Proc. Roy. Soc. 1904, 170), as the result of spectroscopic examination, identified the yellow pigment of the hen's yolk with the L. xanthophyll, which he has isolated from grass. The characteristic spectroscopic behaviour of the lutein has been suggested as a test of the purity of commercial dried egg yolk (Lewin, Miethe, and Stenger, Pflüger's Archiv. 1908, 585). Willstätter and Escher (Zeitsch. physiol. Chem. 76, 214) isolated the pigment from the yolks of 6000 eggs, and obtained it in crystalline form, and showed it belonged to the xanthophyll group of pigments ; they showed also that a carotin-like pigment was present. Palmer (J. Biol. Chem. 23, 261) showed that the pigments of egg yolk were increased by feeding with rations rich in xanthophyll, yellow corn being particularly suitable for this purpose as a winter ration. The point is of importance to the poultry trade, since eggs with highly-coloured yolks are in great request.

Vitellin, the protein constituent of the yolk, is separated by mixing the yolks with brine, in which the protein is soluble, and extracting the fat, &c., with ether. It has the properties of a globulin, and, on dialysis or dilution of the solution, is precipitated. as a white granular substance. A solution coagulates at 70°–75°.

Vitellin thus obtained is a mixture of compounds of protein matter with lecithin, containing from 15–30 p.c. of the latter, called *lecithin-nucleovitellins*. The lecithin thus combined is not removed by ether, but is completely removed by alcohol, leaving an insoluble proteid, *nucleovitellin*, of constant composition, which, on digesting with pepsin, yields paranuclein.

It is probable that all these proteins are compounds of vitellin with phosphoric acid H_3PO_4, or some very simple organo-phosphoric acid. The composition of vitellin, free from phosphoric acid, is :

C	H	N	S	O
52·71	7·46	16·64	1·05	22·14 p c.

(Osborne and Campbell, J. Amer. Chem. Soc. 1900, 22, 413).

Plimmer states that another distinct protein 'livetin,' can be obtained from the yolk (Chem. Soc. Trans. 1908, 1500).

Berthelot and André determined the heat of combustion of egg yolk to be 8124 calories per gram (Compt. rend. 110, 925).

The germinal vesicle, or **white yolk,** forms a layer between the yolk and the yolk membrane, with a process extending to the centre of the yolk. It is enclosed in a membrane, and contains proteins, lecithin, and a nuclein rich in phosphorus (Meischer. Chem. Soc. Trans. 1871, 24, 746).

The space between the shell membranes at the broad end of the egg contains a mixture of oxygen, nitrogen, and carbon dioxide, richer in oxygen than the surrounding air (Hufner, Du Bois Reymond's Archiv. de Physiol. 1892, Phys. Abth. 54).

Eggs contain, on the average, about 4·6 mgms. of ferric oxide. This amount is increased by feeding the hens with foods rich in iron, and ' iron-eggs ' thus obtained have been recommended for therapeutic use, but are very costly (Hartung, Zeitsch. f. Biol. 1902, 43, 195 ; Hofmann, Zeitsch, anal. Chem. 1901, 40, 450).

Bertrand states that arsenic is normally present in the egg to the extent of $\frac{1}{500}$ mgm. (Compt. rend. 1903, 136, 1083), and that 1 mgm. boron occurs in 1 kgm. dried egg (Compt. rend. 1913, 156, 2027). •

Development.—During incubation the egg respires, giving off carbon dioxide and water, and absorbing oxygen. If this process be stopped by placing the egg in an inert gas, or by rendering the shell impervious to gases, the development of the chick ceases. The respiration is slight for the first four days of incubation, and then increases until, at the ninth day, the respiration of the egg is equal to that of a fowl, weight for weight. This respiration involves combustion of the fat of the egg, and a steady loss in weight (Pott, Landw. Versuchs. Stat. 23, 203 ; Chem. Soc. Abstr. 1879, 474).

Levene states that the quantity of xanthine bases and nuclein compounds increases with the growth of the embryo (Amer. J. Physiol. 1900, 3, xii.).

In egg-white the ratio albumin : ovomucoid of egg is constant during incubation (Bywaters and Roue, J. Physiol. 46, Proc. 33). After 3 days α-lactic acid was found (Anno, Zeitsch. physiol. Chem. 80, 237). In new-laid eggs the cholesterol is free, but gradual esterification

takes place, until at the time of hatching 40 p.c. is in ester form (J. Biol. Chem. 21, 23).

All the phosphorus in the chick is derived from the yolk and white, and, until the last few days of incubation, no lime is taken from the shell (Voit, Zeitsch. f. Biol. 13, 518 ; Pott, l.c.). At the end of incubation, the shell may supply some of the lime required (Carpiaux, Bull. Acad. Roy. Belg. 1908, 283 ; see also Plimmer and Scott, J. Physiol. 1909, 38, 247).

The freezing-point of fresh eggs is 0·427°–0·480°, and rises slightly as incubation proceeds, corresponding to a rise of osmotic pressure from 5·5 atmospheres to 7·3 atmospheres (Atkins, Biochem. J. 1909, 480).

The chief *uses of eggs* are as an article of food and in the tanning industry. As the supply of new-laid eggs varies with the season, recourse is had to some means of preserving a proportion of those that come into the market at the time of greatest production.

The following is a list of some processes for preserving whole eggs, which have been patented.

Saturating with carbon dioxide (Lake, Eng. Pat. 1653, 1888) ; treating with formaldehyde vapour (Loft, Eng. Pat. 19721, 1915 ; Corden, Eng. Pat. 15206, 1914) ; wrapping air-tight in rubber-coated paper (Jessen, Eng. Pat. 15580, 1891) ; coating with gelatin (Mills, Eng. Pat. 17717, 1891 ; Farquhar and North, Eng. Pat. 15128, 1892 ; Coakley, Eng. Pat. 18816, 1899) ; with gelatinous starch solution (Schultz, Eng. Pat. 1328, 1902) ; with drying oils, wax, or varnish, with or without previous treatment with antiseptics (Stukes, U.S. Pat. 649899 ; Barlow, Eng. Pat. 11054, 1902 ; Lorne, Eng. Pat. 18439, 1901, and 9898, 1901 ; Davis and Metz, Eng. Pat. 105840, 1916) ; with boric acid (Markham, Eng. Pat. 3513, 1895) ; with lime (McArdle, Eng. Pat. 3592, 1892 ; Wilson and Wilson, Eng. Pat. 15461, 1899) ; with sulphuric acid (Reinhardt, Eng. Pat. 18130, 1898 ; Marks, Eng. Pat. 12867, 1903) ; with liquid petroleum (Henderson, Eng. Pat. 101337, 1916) ; and with water-glass (Stead, Eng. Pat. 4910, 1882 ; Rylander, Eng. Pat. 23523, 1901).

The following methods (J. Soc. Arts. 1898, 46, 390 ; J. Soc. Chem. Ind. 1898, 261) were found to keep over 90 p.c. of the eggs in good condition for 8 months : (1) varnishing with vaseline ; (2) keeping in milk of lime ; and (3) keeping in water-glass solution. Of these the last method is the one least open to objection, and is that chiefly used. Eggs preserved in water-glass have a tendency to burst when boiled, but this can be prevented by piercing the shell with a needle.

A Chinese preparation, ' Pidan,' is made from duck's eggs by coating them with a paste obtained by stirring into an infusion of 1¼ lbs. strong black tea, 9 lbs. lime, 4½ lbs. salt, and a bushel of wood ashes. After 5 months they are coated further with rice hulls. The changes which take place were investigated by Blunt and Wang (J. Biol. Chem. 28, 125), who deduced that decomposition of both the egg proteins and lipins had taken place. The values for ash, for total and organic phosphorus and especially for ammoniacal nitrogen, are high.

The contents of eggs may be preserved by heating at 185°F. with a strong solution of a sugar (glucose, maltose, dextrose, &c.), until

the product contains 40–60 p.c. of sugar. It is readily miscible with water, milk, &c., and will keep for some months without deterioration (Fordred, Eng. Pat. 15762, 1894 ; Goodlett, U.S. Pat. 692268).

An important method of preserving the whites and yolks of eggs consists in drying the mixture in a current of air at 37°–40° during 18 hours, powdering the product, and again exposing to dry air. The powder is packed in tins, or can be pressed into tablets, and is quite soluble in water (Foschi, Fr. Pat. 369967, 1906). A similar product is obtained by drying on a hot roller at a temperature above 212°F. (Hatmaker, Eng. Pat. 28, 1905 ; *see also* Eng. Pat. 8743, 1903, for apparatus).

Substitutes for eggs in baking are made from albumin and casein obtained from skimmed milk, sometimes mixed with a proportion of dried egg ; or from maize meal containing sodium bicarbonate and artificial colouring matter (Beythien and Waters, Zeitsch. Nahr. Genussm. 1906, 11, 272 ; Bernstein, Eng. Pat 14336 and 29189 of 1897). An emulsion of sunflower or other oil with blood serum and lecithin has been suggested (Eng. Pat. 100135, 1915).

The eggs used for the treatment of leather, especially the finer sorts of glove leather, are preserved in the liquid state by the addition of salt and borax (Jean, Mon. Sci 1892, 6, 561) Analyses of this material, '*eggio*,' show that it contains 2–5 p.c. more water and 3½–6 p.c. less fatty acid than fresh egg yolk (Boyer, J. Soc. Chem. Ind. 1892, 447) Bein has pointed out that the addition of salt to yolks materially reduces the amount of fat (Bied. Zentr. 21, 138) Rotten eggs could well be used for this purpose, as Cech has found that the available oil is not much diminished in amount, and can be extracted by pressure (J. pr. Chem. [2] 22, 338).

Oil of egg, obtained by extracting yolks with ether, or, better, chloroform, forms about 10 p c. of the egg, and is used in pharmacy in the preparation of ointments and emulsions ; in the leather industry and in tempera painting (Lupus, D. R. P. 187211). It has no medicinal value (Paladino and Toso, Analyst, 1896, 21, 161) It has the following properties : m.p 22°–22·5° ; sp.gr. at 15°, 0·9144 ; acid number, 1·2 ; saponification number, 190·2 ; ether number, 189·0 ; iodine number, 72·1 ; Hehner's number, 95·16 ; Reichert-Meissl number, 0·4 (Kitt, Chem. Zeit. 1897, 21, 303).

Detection, estimation, and analysis.—The presence or absence of egg yolk in pastry can be determined by examination of the fat, there being a great difference in composition and properties between the fat of wheat and of the egg (Spaeth, Zeitsch. Nahr. Genussm. 1896, 10, 171). The phosphorus of the yolk being present chiefly as lecithin, the yolk may be estimated by igniting with sodium carbonate and nitre, determining the phosphoric acid in the residue. 1·129 grams phosphoric acid represent 100 grams yolk (Bein, Ber. 23, 423). The addition of alkali is necessary to prevent loss of phosphoric acid during ignition (Juckenack, *l.c.*). The amount of egg present in pastry, &c., may be determined by the amount of cholesterol present (Cappenberg, Chem. Zeit. 1909, 33, 985). (For methods for the determination of the con-

stituents of egg yolk for commercial purposes, *see* J. Soc. Chem. Ind. 1906, 829.)

EGG ALBUMIN *v.* PROTEINS.

EGG FRUIT. The fruit of *Solanum melongena* (Linn.). A plant of tropical and sub-tropical countries. König gives, as the mean of three analyses—

Water	Nitrogenous matter	Soluble carbohydrates	Fat	Fibre	Ash
93·2	1·1	0·1	3·9	1·2	0·5

An American analysis (Bull. 28, U.S. Dept. of Agric.) shows a somewhat larger amount of carbohydrates (5·1 p.c.), but is similar in other respects.

This plant is sometimes called *Aubergine*. The fruit is used in much the same way as the tomato.   H. I.

EGOLS. A class of antiseptics consisting of the potassium mercury salts of *o*-nitrophenolsulphonic acid, the individual members being termed '*phenegol*,' '*cresegol*,' &c., depending on the phenol from which they are derived. They are reddish-brown powders, readily soluble in water, and are strongly bactericidal (Gautrelet, Compt rend. 129, [2] 113 ; J. Soc. Chem. Ind. 1899, 854) (*v.* SYNTHETIC DRUGS).

EGYPTIAN BLUE. This is a blue colouring matter which was used by the Romans in the first few centuries of the Christian era, but ceased to be manufactured about the time of the invasion of the barbarians. It figures in several beautiful frescoes in the Vatican, and has also been found at Pompeii. Fouqué discovered the composition to be that of a double silicate of calcium and copper $CaO,CuO,4SiO_2$, devoid even of traces of alkali. The substance is crystalline, and is hardly attacked by any chemical reagents, which explains the perfect state of its preservation in the paintings for which it was employed 1900 years ago. It may be prepared at a bright-red heat, but this temperature must not be exceeded, as it is then decomposed into cuprous oxide, *wollastonite*, and a clear light-green glass. The higher the temperature, the more of the latter is formed, and, finally, wollastonite disappears entirely. By the old method of preparation, described by Vitruvius, fine sand and soda are intimately mixed with copper filings, then moistened with water, formed into cakes, and the latter dried. The cakes are then fused in an earthen pot until the blue colour is produced. Fouqué found this method practicable, but used potassium sulphate in preference to soda as a flux. It was not possible to replace chalk or lime by magnesia. The ancient Romans employed a large excess of silica, whilst Fouqué employed more basic mixtures, finally purifying the product with hydrochloric acid. The exquisite colour of this mineral body, the fact that it is absolutely unaffected by moisture, light, and most chemical reagents, as well as the facility and the low price of production, render it desirable that its manufacture should be again resumed (F. Fouqué, Compt. rend. 108, 325–327 ; and J. Soc. Chem. Ind. 8, 291). The conditions of its production have been studied by Laurie, McLintock, and Miles (Proc. Roy. Soc. 1914, A, 89, 418). The French ultramarine works of Deschamps Frères reproduced Egyptian blue by fusing in an ultramarine furnace a mixture of quartz (50 parts),

chalk (21 parts), copper oxide (24·4 parts), and sodium carbonate (4·6 parts), all in the finest powder, and completely free from iron. The product, washed with hydrochloric acid and hot water, had the composition corresponding to Fouqué's analysis, and was in all respects similar to the material used by the Romans (Bock, Zeitsch. angew. Chem. 1916, 29, i. 228).

EIKONOGEN. Sodium salt of 1-amino-β-naphthol-6-sulphonic acid. Used as a photographic developer.

EKSANTALAL $C_{12}'H_{18}O$. Obtained on oxidation by ozone of the sesquiterpene primary alcohol a-santalol $C_{15}H_{24}O$, which, together with the isomeric β-santalol, constitutes 'santalol,' the oil resulting from the hydrolysis of the hydrogen phthalate made from the oil obtained by distilling sandalwood with steam (Semmler, Ber. 43, 1893).

It is dextro-rotatory ($a_D +13·5°$); b.p. $100°-110°$, under 10 mm.; sp.gr. 0·9846 at $20°/20$; n_D, 1·48519.

It gives an oxime, which yields the corresponding nitrile and amine, and gives eksantalol on reduction (Semmler, Ber 41, 1488).

Heated with acetic anhydride and sodium acetate, it forms *enol*-eksantalal acetate

$$C_{12}H_{17}O·CO·CH_3$$
which, on oxidation with potassium permanganate, yields noreksantalic acid $C_{11}H_{16}O_2$ (Semmler, Ber 43, 1722–1725), the methyl ester of which, on reduction by sodium and alcohol, yields noreksantalol $C_{11}H_{18}O$; and this on oxidation in benzene solution with potassium dichromate and dilute sulphuric acid, gives *noreksantalal* $C_{11}H_{16}O$, b.p. $92°–94°/11$ mm ; sp gr. $20°/20°$ 0·9964, n_D 1·48301, $a_D -30·8°$. The *enol*-noreksantalal acetate gives, on oxidation by potassium permanganate, *teresantalic* acid $C_{10}H_{12}O_2$ (Semmler and Zaar, Ber. 43, 1890).

In all three series, containing 10, 11, and 12 carbon atoms respectively, the same tricyclic system is present as exists in a-santalol ; and Semmler (Ber. 43, 1893–1898) assigns to these bodies constitutions based upon the camphene or camphor type, and a-santalol and eksantalal are structurally represented as below :

a-Santalol.

Eksantalal.
EKTOGEN. Trade name for a mixture of zinc dioxide with zinc oxide and carbonate, used as a surgical dressing.

ELÆOMARGARIC ACID $C_{19}H_{32}O_2$. An acid, melting at 48°, obtained by the saponification of eläocococa oil (Japanese wood oil) with

alcoholic potash, and decomposing the *trielæomargarin* thus formed. The glyceride when first formed is liquid, but on exposure to light gradually solidifies. Isomeric with eläostearic acid, eläoleic acid, and linoleic acid. On exposing an alcoholic solution to light, plates of eläostearic acid, m.p. 71°, are precipitated (Cloëz, Bull. Soc. chim. 1876, 26, 286 ; 1877, 28, 24) ; traces of iodine or sulphur also bring about this change (Maquenne, Compt. rend. 135, 696). Oxidation with potassium permanganate gives rise to azelaic acid, sativic acid, and dihydroxystearic acid (Kametaka, J. Soc. Chem Ind. 1903, 1138 ; 1908, 1120 ; Kit, Chem. Soc. Abstr. 1905, i. 10 ; Maquenne, *l.c.*). Linolic acid also on oxidation yields sativic acid, and on bromination, linolic acid and elaomargaric acid yield the same tetrabromide. Elaostearic acid and linoleic acid yield the same diozonide (Majima, Ber. 1900, 674). Elaomargaric acid and elaostearic acid are converted into elaoleic acid when heated at 180° in sealed tubes (Cloëz, J. 1878, 38).

ELÆOPTENE. The volatile portion of an essential oil, used in contradistinction to the *stearoptene* or solid portion.

ELAÏDIC ACID $C_{18}H_{34}O_2$. A solid stereoisomeric modification of oleic acid, obtained by the action of nitrous acid upon olive oil, saponifying the glyceride (elaidin) so formed, and decomposing the salt by hydrochloric or sulphuric acid. May also be obtained by the action of nitrous acid or of nitric acid (sp.gr. 1·2) (Edmed, Chem. Soc Proc. 1899, 190) upon oleic acid, or by decomposing barium oleate with fuming nitric acid ; m.p. 52° (Saytzeff, Chem. Soc. Abst. 1893, 551). b p. 287 5°–288° at 100 mm. (Krafft and Mordlinger, Ber 1889, 819). Soluble in alcohol and ether. Solutions have an acid reaction. The melted acid gradually absorbs oxygen from the air, and becomes permanently liquid. It may be distilled unchanged under diminished pressure. Heated with potassium hydroxide, it is converted into acetate and palmitate of potassium with evolution of hydrogen.

Elaidic acid dissolved in benzene, toluene, ligroin, or chloroform, and mixed with caustic soda and shaken, gives a brilliant phosphorescence (Radziszewski, Annalen, 203, 305). Hydriodic acid forms an addition compound (iodostearic acid) with elaidic acid (Farb. vorm. Fried. Bayer & Co. D. R. P. 180087; Chem. Soc. Abstr. 1907, i. 380), which, on treatment with alcoholic potash, yields oleic and *iso*-oleic acids (Lebedeff, *ibid.* 1893, 550). On reduction with nickel or copper and hydrogen at 280°–300°, elaidic acid is converted into stearic acid (Sabatier and Mailhe, Ann. Chim. Phys. [8] 4, 319). Treated with dilute solution of potassium permanganate in presence of potash, it is converted into a dihydroxy acid, which differs from the corresponding compound obtained from oleic acid by its lower melting-point (99·5°), and its greater solubility in alcohol and ether, and also into polargonic, azelaic, and oxalic acids (Saytzeff, Ber. 1886, 21 ; Edmed, Chem. Soc. Trans. 1898, 627) ; oxidation with sulphuric acid, however, gives rise to the same dihydroxystearic acid as is obtained from oleic acid under the same conditions (Tscherbakoff and Saytzeff, J. pr. Chem., 1898, 27).

Elaidin, a solid isomeride of olein, is obtained by the action of nitrous acid upon olein,

and is probably a triglyceride $C_{57}H_{104}O_6$. It melts at 36°; is nearly insoluble in alcohol, readily soluble in ether. The *Unguentum oxygenatum* and *U. citrinum* of the pharmacopœias, prepared by the action of nitric acid upon hog's lard, contain impure elaïdin.

ELAIDIN v. ELAÏDIC ACID.

ELALDEHYDE v. ALDEHYDE.

ELARSON. Trade name for strontium chloroarsenobehenolate.

ELATERIN v. ELATERIUM.

ELATERITE. *Elastic bitumen, Mineral caoutchouc.* A fossil resin, somewhat resembling asphalt, found at Castleton in Derbyshire, in France, Switzerland, &c. It is a soft, flexible, elastic, and readily inflammable substance, with a resinous lustre and a dark-brown colour. It is mainly used as an insulator for electric cables. It is rapidly decomposed by strong nitric acid. When boiled with alcohol and alcoholic potassium hydroxide it behaves like beeswax. One sample gave an acid value of 4 9, and saponification value of 56·9, and contained 88·9 p.c. of unsaponifiable matter.

ELATERIUM. The sediment from the juice of the fruit of the *Ecballium elaterium* (Richard), or squirting cucumber. Elaterium is a drastic purgative.

It, and elaterin derived from it, were excluded from the B.P. in 1914. The latter substance is still official in the United States (*Elaterinum*, U.S.P.). Good specimens of elaterium when extracted with chloroform yield 25 p.c. of elaterin, which by recrystallisation is obtained in minute shining six-sided plates. The dose of elaterin is $\frac{1}{16}$ to $\frac{1}{5}$ of a grain, and to it is ascribed the whole of the physiological activity of elaterium. Elaterin is a neutral bitter compound, insoluble in hot or cold water. It is readily soluble in cold alcohol, sparingly in ether. If sulphuric acid be added to a solution of elaterin in melted phenol, a crimson colour is produced which changes to scarlet (Lindo, Chem. News, 37, 35 ; Johannson, Zeitsch. anal. Chem. 24, 154).

On hydrolysis with alcoholic potash, elaterin furnishes acetic acid and an amorphous compound, *elateridin*. Further action of alkali gives *elateric acid*, also amorphous, and melting at 73°–75° (Berg, Bull. Soc. chim. [iii.] 35, 435).

Elaterium of English origin, examined by Power and Moore (Pharm. J. [iv.] 29, 501), was found to contain 5·3 p.c. of moisture and 6·7 p.c. of ash. By a suitable method of extraction, a colourless crystalline product, m.p. 217°,220°, was obtained, corresponding with the elaterin of the pharmacopœias. This was found to be non-homogeneous, consisting of at least two substances, one, *a-elaterin*, melting at 230° with decomposition, and lævo-rotatory, whilst the other, *β-elaterin*, has a lower melting-point, and is dextro-rotatory. Both have the same empirical composition, but the former is physiologically inert, whilst the latter shows marked physiological activity. Examination of commercial elaterin showed that it consists mainly of varying proportions of these two substances, which probably accounts for the marked difference in medicinal value of different samples. a-Elaterin has also been found in colocynth, the dried fruit of *Citrullus colocynthis* (Schraeder) (Power and Moore, Chem. Soc. Trans. 97, 99), and has

been further investigated by Moore (*ibid.* 97, 1797).

According to Berg (Bull. Soc. chim. [iii.] 17, 85 ; [iv.] 7, 385), elaterin does not exist readyformed in the fruit, but is produced after the rupture of the tissues by the action of an enzyme *elaterase* on a glucoside present. The latter consists of a brittle, amorphous powder, and gives the same reactions as elaterin with sulphuric acid and phenol. Power and Moore (Chem. Soc. Trans. 95, 1985), however, on examination of the fresh fruit, failed to confirm this.

G. B.

ELBON. Trade name for cinnamoyl-*p*-hydroxyphenylurea.

ELDERBERRY. The fruit of *Sambucus nigra* (Linn.). The only analysis quoted by König gives, as the composition of the fruit—

Water	Crude fibre	Pentosans
81·9	6·6	1·2

The berries are used for the preparation of a wine and of 'elderberry syrup,' an old-fashioned cordial. From the wine, a brandy is sometimes distilled, which according to analyses by Arnthor and Zink, quoted by König, contains 39·2 p.c. of alcohol (by weight) and has a sp.gr. of 0·836. According to de Sanctis (Gazz. chim. ital. 1895, 25, 49), elder leaves and stems contain conine. Malmejac (J. Pharm. Chim. 1901, 14, 17) attributes the diuretic and purgative action of the bark of the elder to an alkaloid, *sambucine*, a deliquescent bitter substance, yielding the usual alkaloid reactions. He also found elder bark to contain tannin, a resin resembling scammony and a yellowish-red oil possessing a strong odour of elder. Elder pith contains both xylan and araban (Browne and Tollens, Ber. 1902, 35, 1457). The oil extractable from the juice of red elderberries (*S. racemosa*) by ether, is light yellow in colour, has a sp.gr. of 0·9072, solidifies at −8°, and melts at 0° ; contains 6·65 p.c. of free acid (as oleic acid), 0·66 p.c. of unsaponifiable matter, has a saponification number 209·3, iodine number 81·4, and Reichert-Meissl value of 1·54 (Byers and Hopkins, J. Amer. Chem. Soc. 1902, 24, 771).

The leaves of the elder contain a cyanogenetic glucoside, which, under the influence of emulsin, yields dextrose, benzaldehyde, and hydrogen cyanide ; the yield of the last mentioned amounts to 0·126 gram per kilogram of fresh leaves (Guignard, Compt. rend. 1905, 141, 16 ; Bourquelot and Danjou, *ibid.* 59). This glucoside, which has been named *sambunigrin* $C_{14}H_{17}O_6N$, crystallises from ethyl acetate in long, colourless needles, melting at 151°–152°, is readily soluble in water or alcohol, but nearly insoluble in ether (Bourquelot and Danjou, Compt. rend. 1905, 141, 598).

According to Ravenna and Tonegutti (Chem. Zentr. 1910, i. 544) the enzyme which decomposes the glucoside in the plant is not soluble in water. The hydrocyanic acid is present in larger quantities than has hitherto been believed, and is most abundant in the stalks. H. I.

ELECTRARGOL. Trade name for a form of colloidal silver.

ELECTRIRIDOL. Colloidal iridium.

ELECTRO-DEPOSITION and **ELECTRO-PLATING.** Electrolytic processes are now used to a considerable extent in the precipitation

of metals in a reguline form, available for many commercial purposes. Thus the common and more easily corroded metals are coated with thin films of electro-deposited metal of a more permanent and less oxidisable character, in the process of electroplating; for the reproduction of engraved surfaces, type, &c., in electro-deposited copper, electrolysis is applied in electrotyping; and in the deposition of a pure metal from an impure form or a mixture of metals, the principles of electrolysis are applied in the process of electrolytic refining and in chemical analysis.

An electric current passed through solutions of metallic salts brings about decomposition of a particular type, accompanied by the deposition or evolution of the products, or others which may have been formed as the result of secondary changes. When copper sulphate solution is electrolysed with a platinum anode, and any cathode, not ordinarily attacked by this salt, copper is deposited at the cathode, and oxygen and sulphuric acid are formed at the anode, thus:

$$Cu \leftarrow Cu\,SO_4 \rightarrow SO_4 + H_2O = H_2SO_4 + O$$

Deposited on cathode.   Formed at anode.
Other metallic compounds follow a similar course. The primary products consist of charged atoms or radicals. These are termed *ions*, and in the process of electrolysis migrate to the electrodes, those to the anode being called the *anions*, and those to the cathode *cathions*. Anions consist of the acidic group of the salt, while the cathions comprise hydrogen, the metals, and basic radicals. At the electrodes, the electrical charges are neutralised, and the substance appears in the nascent form, subsequently being deposited or evolved. Elementary anions, such as chlorine, bromine, and iodine may enter into subsequent secondary changes, while others, such as NO_3, SO_4, $C_2H_3O_2$, &c., react with water, giving generally the corresponding acid, and liberating oxygen. With soluble anodes—those attacked by the anion—solution of the metal takes place, and thus, in a copper solution, a copper anode supplies metal under the best conditions as rapidly as metal is deposited. The strength of the solution is thus maintained, a condition necessary for continuous deposition as required for plating and refining purposes.

The deposition of metals follows the usual law of chemical equivalents as enunciated by Faraday in 1835. The ampere-hour is thus associated with a definite amount of metal, which cannot be exceeded, but may not be attained owing to failure in realising the best conditions. The quantities of metals deposited by the coulomb, ampere-hour, and 746 ampere-hours, are shown in the table on next column.

These amounts, however, can only be deposited when the cathode is surrounded by a considerable amount of strong electrolyte, and only under this condition can the facts of electrolysis be applied, as in the voltameter, to the determination of the number of coulombs passing through a circuit. While for most industrial purposes it is not necessary for the theoretical amount of metal to be deposited per ampere-hour, yet the most satisfactory deposits are,

Metal	Chemical equivalent	Mgs. per coulomb	Grams per ampere-hour	Ozs. (av.) per 746 ampere-hours
Copper (cupric)	31·8	0·329	1·182	31·0
„ (cuprous)	63·6	0·658	2·364	62·0
Gold (auric)	65·7	0·680	2·440	58·6(Troy)
„ (aurous)	197·0	2·040	7·320	176·0 „
Iron	28·0	0·290	1·040	27·3
Lead	103·5	1·070	3·870	101·0
Nickel	29·3	0·302	1·085	28·5
Silver	108·0	1·118	4·025	96·5(Troy)
Tin (stannous)	59·0	0·610	2·190	57·5
„ (stannic)	29·5	0·305	1·095	28·7
Zinc	32·5	0·336	1·210	31·8

in many cases, obtained when this condition is most nearly attained. Failing the full amount of metal per ampere-hour, hydrogen is deposited, and this often leads to a dark powdery deposit unsuitable for most industrial purposes. Such deposits, caused usually by excessive current, are said to be 'burnt.' In some solutions—for example, those of copper, iron, or nickel sulphate —this inferior deposit seems to result from the simultaneously deposited hydrogen due to a weak electrolyte. In other examples, that of the alkaline or cyanide copper bath, it would seem (from the fact that much hydrogen may be deposited without 'burning') more probably due to the deposition of traces of basic compounds with the metal (Bancroft, Trans. Amer. Electrochem. Soc. vi. [ii.] 27). This view is supported by the fact that the presence of substances in the solution, which are good solvents for such basic compounds, prevents 'burning' to a considerable extent. Thus, in the alkaline copper-bath, 'burning' is reduced, and the quality of the deposit improved by the addition of such salts as sodium bisulphite and potassium cyanide. In other examples, notably those of tin and lead, the deposit is much improved by the addition of a trace of a colloid, such as glue or gelatine.

Migration of Ions. It is well known that ions migrate to their respective plates with definite speeds under unit potential gradient. If deposition proceeds more rapidly than this rate of migration, the cathode liquid becomes impoverished of its metal, and this involves a falling off in the ampere-hour yield. The deficiency of metal around the cathode is counteracted to a limited extent by the ordinary process of diffusion, but there is a limit to the rate at which metal may be satisfactorily deposited, unless special steps are taken to make up for this slow migration. Methods of circulation and stirring are based on this fact, and also on the further fact that the heavier solution formed around the anode falls to the bottom of the solution, and, owing to its superior conductance, gives rise to the conduction of an undue proportion of the current and consequently thicker deposits on the portion of the cathode in this heavier layer; hence a limit to the rate at which deposition may be safely allowed to proceed is set, and the time required to deposit a given amount of metal varies correspondingly.

E.M.F. for deposition. With an insoluble anode, a definite minimum E.M.F. is required to maintain electrolysis. Thus, when copper sulphate is decomposed with a platinum anode, the total change is as follows :—

$$CuSO_4 + H_2O = Cu + O + H_2SO_4$$
This, as a chemical change, is endothermic, and electrolytically it demands a minimum E.M.F. of about 1·25 volts for its continuance. When a copper anode is used, no change in the composition of the solution occurs. Energy changes at both electrodes are equal and of opposite character, and hence a much smaller E.M.F., viz. that required to overcome the ohmic resistance of the solution, is required. With efficient anode solution and a good conducting electrolyte, such as is obtained in an acidified copper sulphate solution, a P.D. of about 0·3–0·5 volt will maintain a fair rate of deposition. In the case of nickel, where there is usually inefficient anode solution and a poorly conducting electrolyte, a much higher P.D. is required, partly on account of the greater stability of nickel compounds. Figures given, therefore, for P.D.'s at bath terminals are of a very elastic character, depending upon the efficiency of anode solution, strength and temperature of the solution, distance between electrodes, presence or otherwise of conducting substances in the solution, and current density required ; while the conditions controlling the allowable current density at the cathode are chiefly the strength of the electrolyte and its motion.

The **deposition of copper** may be accomplished by simple immersion methods, resulting in a chemical exchange with the more positive metal plated ; thus :

$$\left.\begin{matrix}Zn\\Fe\end{matrix}\right\} + CuSO_4 = \left.\begin{matrix}Zn\\Fe\end{matrix}\right\}SO_4 + Cu$$
The process is but little used, and then only for very cheap work. Deposits on a surface which is undergoing simultaneous corrosion, cannot be sufficiently adherent to withstand the frictional processes of polishing and burnishing.

The single-cell process, practised at one time, involves the generation of current and the deposition of metal in the same apparatus. The process is illustrated in the Daniell cell, in which, if the copper cylinder is replaced by any conducting substance, copper is deposited.

For the deposition of copper on brass and similar electro-negative metals, and on black-leaded or metallised non-conducting surfaces of wax, guttapercha, plaster, earthenware, &c., the following solution is of wide application :—

Bluestone (CuSO₄, 5H₂O) . .	1½–2 lbs.
Oil of vitriol	¼–½ lb.
Water	to 1 gallon

The composition is variable. Strong solutions admit of more rapid deposition without 'burning,' while the acid imparts conductance. From such a solution deposition can be carried on at the rate of 40 amperes per square foot without stirring, while, with a properly stirred electrolyte, this current density may be increased up to 250 or 300 amperes per square foot.

Previous to deposition, brass is cleaned first in potash (5–10 p.c.) to remove grease. It is then passed through aquafortis to remove scale

of oxide, or tarnish, and, after rinsing, is scoured with pumice or ordinary sand or scratch-brushed. After finally rinsing, it is immersed in the solution, and should be covered immediately. The deposit is pink, though dull. When of sufficient thickness, the work is removed, rinsed, and the dull surface improved by scratch-brushing or polishing.

For deposition upon non-conducting substances such as wax, guttapercha, &c., the following methods may be used :—

(1) *Wax* and *guttapercha.* Thorough yet careful brushing with the finest plumbago causes sufficient to be retained to render the surface conductive. Such surfaces when suspended in the copper solution, receive a deposit beginning at the metal connection, and gradually spreading over the whole surface, the thickness of the deposit not being exactly uniform.

(2) *Plaster of Paris* and *unglazed earthenware* may be rendered conductive by first soaking in linseed oil and allowing to dry. They are thus rendered impervious to the solution; and the skin of dried oil will now retain blacklead, when this substance is applied by gentle brushing, sufficient to impart the necessary conductance.

(3) *Flowers, feathers,* and other delicate objects which will not withstand the pressure of even gentle brushing, may be treated to produce a fine layer of some metal or sulphide on the surface by simple chemical means. A usual method is to paint them or immerse them in a weak solution of phosphorus in carbon disulphide, and, after drying, a brief immersion in silver nitrate solution leads to the precipitation of silver, which imparts the necessary conductance. Again, the object to be treated may first be immersed in silver nitrate solution, and subsequently exposed to sulphuretted hydrogen, which produces a layer of silver sulphide, sufficient to cause the immediate deposition of copper at all points.

A more successful method for wax and guttapercha involves covering these substances with copper by simple precipitation. The substance, usually as a mould or impression of a surface to be reproduced in electrotype copper, is first blackleaded and is then laid face upwards in a solution of copper sulphate. Iron filings are then sprinkled on the surface. The filings in contact with the blackleaded surface produce innumerable voltaic couples, which bring about the deposition of copper quickly and completely. The mould is then rinsed to detach the filings, and placed in the bath, when copper is at once deposited uniformly over the whole surface.

On positive metals such as iron, zinc, tin, Britannia metal, pewter, &c., copper cannot be successfully deposited from the acid sulphate solution on account of the ease with which these metals turn out the copper by simple immersion, and are, moreover, corroded by the acid. A more stable and more satisfactory compound for this class of work is the double cyanide of copper and potassium (CuCN·KCN). Solutions of this compound are usually prepared by (1) dissolving the carbonate in a solution of potassium cyanide ; (2) precipitating the sulphate with ammonia, dissolving the precipitate in excess of ammonia, and decolourising the blue solution with potassium cyanide. Many other

methods are available and are in use. The strength of such solutions may be varied between wide limits up to 4 ozs. (or even more) of metal per gallon. An excess of potassium cyanide is essential, owing to the formation of insoluble single copper cyanide (CuCN) at the anode. The course of electrolysis in such double cyanide solutions (including those of zinc, silver, and gold) is very different from that of the salts of the, mineral acids. In the case of copper, the reaction may be simply represented as follows :—.

Anode		Cathode
	CuCN·KCN	
$\leftarrow$	Cu(CN)$_2$·K$^+$	$\rightarrow$

then :

$$Cu(CN)_2 + Cu = 2CuCN \quad K + CuCN \cdot KCN = Cu + 2KCN$$
(Insoluble)   (deposited)
The copper in the salt thus migrates as a complex ion to the anode, and there forms an insoluble compound. This, unless removed, offers considerable resistance, and increases the difficulty of maintaining a normal current Sufficient potassium cyanide for its removal is formed at the cathode, and can be best brought to the anode by stirring, which facilitates the process of deposition by keeping the anode clean. The solution of the anode deposit is more usually accomplished by using an excess of potassium cyanide called 'free cyanide.' From such a solution copper is not deposited upon iron, tin, Britannia metal, pewter, &c., by simple immersion, and only very slightly on zinc. The solution is conveniently used warm, and yields a deposit of copper accompanied by hydrogen, which, as a rule, does not seriously interfere with the physical character of the deposit. The deposit is, under the best qualitative conditions, smoother than that from the sulphate solution, and once the positive metal has been coated in this solution, it may be removed, and, after thorough rinsing, introduced into the sulphate solution for a thicker deposit. The cyanide solution, when strong, and used within certain limits of current density, yields twice as much copper per ampere-hour (viz. 2·36 grams) as the sulphate, the cyanide compound being the monovalent cuprous salt.

Applications of copper deposition.—The metal is most extensively deposited as a covering for more positive and more corrodible metals, and as a preliminary deposit before coating with the more expensive metals. Deposits of copper on iron may then be burnished or polished and the surface improved by metal-colouring, when, by chemical processes, the surface is covered with a uniform film of oxide or sulphide by immersion in solutions producing these compounds, such as the salts of copper and soluble sulphides. Uniform and pleasing effects are readily obtained, and may be rendered more permanent by subsequent lacquering. The metal is also deposited on a considerable scale in the electrotyping process, thin, but rigid reproductions of type, engraved plates and blocks being made in electro-deposited copper, and subsequently strengthened by 'backing' with a lead-antimony alloy, which is then planed down to the required thickness.

Analytically, copper deposition is applied in the separation of this metal from more positive metals in an acid solution with a platinum anode. From a solution of brass in nitric acid, the copper may be most completely deposited without interfering with the zinc. The copper deposit made on a platinum dish or suitable electrode is then weighed, and the zinc obtained by either a chemical or a further electrolytic method (v. ANALYSIS). On a commercial scale, the deposition of copper has been applied by Cowper-Coles to the production of parabolic mirrors for lighthouse work, and to the production of sheet, wire, and tubes. The manufacture of deposited tubes of large diameter has been successfully carried on by Elmore Bros., who arrange an agate burnisher to travel backwards and forwards along the tube during deposition, thereby producing a compact deposit of good mechanical properties. Tubes up to 16 feet long by 8 feet diameter, and weighing more than 3 tons, have been produced by this method. More usually, however, tubes are of smaller dimensions, and are subsequently drawn down or opened longitudinally for the production of sheets. Copper is deposited on a most extensive scale in the refining process, possibly as much as three-quarters of the total output of the metal annually being refined in this manner, using a solution of the sulphate with thick anodes of the crude metal. The crude metal contains up to 1·0 p.c. of impurities. The deposited metal is almost entirely free from impurity. Positive impurities pass into the solution, and are retained there by the application of the principle used in electrolytic analysis. Electro-negative impurities, as silver and gold, pass as chloride and metal respectively into the mud at the bottom of the tank, from which they may be recovered. Tin, antimony, arsenic, and bismuth are prevented from being deposited by a careful control of the conditions, and the sum-total of impurities in the refined metal is usually less than 0·05 p.c.

Deposition of silver. Silver, being an electro-negative metal, is readily deposited by simple immersion. The process is applied commercially under the name of 'whitening.' Solutions for this purpose contain a small proportion of a silver compound, such as chloride or cyanide, dissolved in cream of tartar, sodium chloride, or similar solvent. The deposition on properly prepared work is a case of simple replacement, and only very thin deposits are obtainable by this means. The same materials may also be used in the form of pastes, and rubbed on the prepared work with a wet rag, this method finding application in silvering clock and instrument dials.

Electro-deposition is most frequently practised. For this purpose the nitrate solution is unsuitable on account of its instability, being serviceable only as a voltameter electrolyte where the very electro-negative metal platinum is used. For silvering on more positive metals, those which usually require silver plating, a solution of the double cyanide of silver and potassium is used. This may be prepared from the metal as follows :—

(a) The metal is converted into nitrate, and precipitated with potassium cyanide. When precipitation is just complete, the clear liquid is decanted and the precipitate washed and

subsequently dissolved in more cyanide solution, a further supply of cyanide being added for 'free cyanide.'

(b) Precipitation may be effected by common salt, and the washed chloride dissolved in excess of potassium cyanide.

(c) A silver plate may be made the anode in a 5 p.c. solution of potassium cyanide, using a small copper or carbon cathode contained in some of the solution in a porous cell. The silver dissolves electrolytically, and the process can be continued until sufficient silver has passed into the solution and a good deposit is obtainable from it.

The solution is used cold, and yields a dull deposit of the metal, which may subsequently be scratch-brushed, burnished, and polished. The addition of a small proportion of carbon disulphide (1 oz. in 250 gallons) completely alters the character of the deposit from dull to bright. "Bright plating" is, therefore, much practised. The silver compound in the solution being somewhat unstable, special precautions are necessary before placing work in the solution for deposition. Copper, brass, and nickel silver may be plated directly, though previous to deposition it is common practice to pass such work through a solution of mercury cyanide. This solution can be prepared by treating a soluble mercuric compound with excess of potassium cyanide, or by dissolving the oxide in cyanide. A usual strength is 1 oz. of metal per gallon. From such a 'quicking,' solution a bright deposit of mercury is obtained on brass, copper, and nickel silver by simple immersion, with the advantages that the more negative metal mercury is less oxidisable than copper, &c., and prevents simple immersion deposition of silver when the work is put into the bath, and possibly promotes the adhesion of the subsequently electrolytically deposited silver, by amalgamation. More positive metals, like iron and zinc, are first coppered in the alkaline bath, and subsequently treated as copper. With the lead alloys it is usual to pass them straight from the cleansing processes through a separate silver solution, from which a rapid deposit is first made. This is termed 'striking,' after which the work is transferred to the main solution to complete the deposition.

The current density permissible is controlled largely by the metal content of the solution, Excessive current produces a light-grey, dark-grey, or black deposit, which, being powdery, is unable to withstand the processes of burnishing and polishing.

Silver anodes should be of fine metal, preferably annealed, and, therefore, more susceptible to solution. Their behaviour is an indication of the condition of the solution. If a dull deposit collects upon them, with a falling off in the current, more free cyanide is required to dissolve the insoluble single cyanide which forms upon them. On the other hand, excessive free cyanide unduly promotes the solution of the anode, limits the permissible current density at the cathode, lowers the cathode efficiency, and promotes simple immersion deposition on work which is not 'quicked.' The amount of free cyanide present can easily be determined in this and other cyanide solutions by titration with standard silver nitrate.

The deposition of gold is practised considerably on account of the pleasing colour and permanence of the deposit. Deposition is easy owing to the strong electro-negative character of the metal, and for electro-gilding, as with electro-silvering, cyanide solutions are used. Gold may be applied to metallic surfaces by three methods, viz.: (1) mercurial gilding; (2) simple immersion; and (3) the electrolytic method. Mercurial gilding is used for heavy deposits of gold. An amalgam of gold is first prepared by pouring mercury on to hot gold. Excess of mercury is squeezed through chamois leather, and the pasty amalgam preserved in balls under water. It is applied to the prepared metallic surface with a wire brush, which has first been wetted with a weak solution of mercuric nitrate. This is rubbed on the amalgam and then on to the work, depositing a layer of amalgam. When a uniform coating is obtained, the mercury is expelled in a muffle, and the process repeated for thicker deposits. The dull surface is improved by scratch-brushing. This process is still largely employed.

Simple immersion methods are followed, for mere films of metal, in solutions of very varied composition. A moderately strong solution of sodium pyrophosphate is prepared (5–10 p.c.), and gold chloride added a little at a time. The warm solution at once gives up its metal, but the deposits can, in any case, only be very thin, though they may be thickened somewhat by 'quicking' in a mercury solution and re-immersing in the gold solution.

Gilding with the separate current is largely practised, using a solution prepared by the following or similar methods :—

(1) Making a gold sheet the anode in a cyanide solution (4 ozs. per gallon), using a cathode contained in a porous cell. The process is continued until sufficient metal is lost from the anode or until the solution yields a good deposit.

(2) Precipitating gold chloride with ammonia, avoiding excess, and dissolving the washed precipitate in potassium cyanide solution.

The metal content may vary from a few pennyweights to a few ounces per gallon. The solution is used warm with a gold anode, which is electrolytically corroded, or by a less desirable, though common, method of using an insoluble platinum anode and making frequent small additions of gold chloride. The colour of the deposit varies considerably with the conditions, chiefly that of current. Other conditions, such as temperature, size of anode, distance between electrodes, metal content, also apparently affect the colour: but these varying conditions primarily influence the current. Cold and weak solutions give a pale colour, which may be improved by warming. Excessive current produces darker and foxy deposits, which are, however, improved by scratch-brushing. More satisfactory deposition proceeds when the work is kept in motion. The colour of the deposit is heightened somewhat by a preliminary coating of copper, while a deposit of silver has the reverse effect, though occasionally required. The colour is modified also by the addition of copper and silver cyanides to the solution. Thick deposits are most satisfactorily obtained by occasional scratch-brushing and 'quicking.'

The deposition of nickel is now very largely applied on account of the hardness of the deposit and its permanence, together with the exceptional lustre which can be imparted to it by polishing. The solution most commonly employed is :

Nickel ammonium sulphate	12 ozs.
Water	1 gallon

The conditions which affect the electro-deposition from this solution have been studied by Bennett, Kenny, and Dugliss (J. Phys. Chem. 1914, 18, 373 ; Bennet, Rose, and Tinkler, *ibid.* 1915, 19, 564 ; Hammond, Trans. Amer. Electrochem. Soc. 1916, 30, 103). To this solution, additions are frequently made to increase the conductance, sal-ammoniac or common salt being used. Owing to the fact that no free mineral acid is permissible, and the tendency also to the formation of nickel hydroxide at the cathode, small additions of acids, such as citric, boric, or acetic, are made with varying success. The only modification in the above solution which adds any appreciable advantage, is that of nickel sulphate, which is so much more soluble than the double salt, and from which, therefore, much stronger and therefore better, conducting solutions can be prepared. For thick deposits, Langbein recommends the use of 3 lbs. of nickel sulphate per gallon, with the addition of ethyl sulphate or magnesium ethyl sulphate. On account of the greater stability of nickel compounds and the poor solution of the anodes, and also the absence of free mineral acid, a distinctly higher E.M F. is required than for copper deposition, viz. 5–6 volts for 'striking,' that is, rapidly coating the work with nickel, and then 2–3 volts for depositing the bulk of the metal. The absence of free acid necessitates especial care in the preliminary cleansing processes, most work being finally passed through a weak solution of cyanide (5 p.c.), and quickly and thoroughly rinsed before being put into the vat. The nickel-plating solution is usually worked cold, and is conveniently contained in lead-lined vats. Anodes may be of cast or rolled metal, the cast being much superior, as its porosity assists its corrosion under the influence of the current. Rolled metal is but little attacked by the anion SO_4, and, failing the solution of the anode, sulphuric acid is produced and oxygen evolved ; thus :

$$SO_4 + H_2O = H_2SO_4 + O$$
This acidity is to be avoided, and with it there is a diminution in the metal content of the solution which is similarly undesirable. Cast anodes are therefore much more largely used, more uniform conditions being maintained with them. On account of the high E.M.F. used, some hydrogen is evolved at the cathode, though the current efficiency should not ordinarily fall below 90 p.c. Occasional motion of the work is desirable in order to disengage any bubbles which may collect. Once deposition has commenced, the work should not be exposed more than momentarily, otherwise an imperceptibly thin film of oxide will form and almost entirely prevent the adhesion of further deposited metal. In fact, it is considered impossible to successfully deposit nickel on such a surface or on a previous deposit. On this account, previously nickelled work should be entirely freed from its nickel, and, while this may be done by acid solutions, common practice follows the method of polishing, at the same time preparing the surface for the new deposit. Copper and brass work is nickelled directly after the usual cleaning operations, whilst positive metals like zinc and Britannia metal require a previous deposit of copper from the cyanide bath. According to Canac and Tasilly (Compt. rend. 1914, 158, 119), aluminium is readily plated with a durable coating of nickel by first plunging the metal in a boiling potassium hydroxide solution, scrubbing it with milk of lime, followed by steeping in a 0·2 p.c. solution of potassium cyanide for some minutes, after which it is transferred to a bath of 500 grams of hydrochloric acid and 1 gram of iron in 500 c.c. of water. Between each bath it is well washed with water, and then plated electrolytically in a solution of nickel chloride. The success of the plating apparently depends on the use of the ferruginous bath. Iron and steel may be nickelled without coppering, the polished surface being first rendered somewhat dull by scouring with finest pumice. The deposit should be kept bright, and this is attained by a current density not exceeding 5 amperes per square foot. Higher current densities produce dull deposits, tending to become powdery on the edges. The nickel deposit is very hard, and the final lustre is obtained by 'finishing' with Sheffield lime, which produces a highly lustrous surface. In addition to the extensive cycle and motor industry, nickel-plating is applied considerably for small machine parts and instrument work and for 'facing' stereotypes, the deposit being much more durable than the stereotype metal.

The deposition of iron is carried out on lines similar to those for nickel, solutions of ferrous sulphate or ferrous ammonium sulphate being used. These must be entirely free from mineral acid, more so than in the case of nickel, and water should be well boiled before being used, to expel air and prevent the oxidation of ferrous to ferric compounds. Ferric compounds under electrolysis yield little metal, being first reduced to ferrous at the cathode. The process is not much used beyond the application in 'steel-facing' engraved plates. The iron deposit obtained is free from carbon, but is very hard. Anodes of the softest wrought iron containing a minimum of carbon are desirable, and require occasional scouring to remove the layer of insoluble carbon. The deposition of iron has also been used for thicker deposits, which have subsequently been removed and examined to investigate the properties of pure iron, and to more successfully determine the effect of impurities. For 'steel facing,' the engraved plates are cleaned, any scouring being done with only a light brush. The plate is then hung in the bath and covered quickly by 'striking.' Deposition is then continued more slowly for 10–15 minutes. The deposit is very hard and withstands the printing process much better than copper. When the deposit shows signs of wear by the exposure of copper, the metal is simply and readily removed by immersion for a short time in a 5–10 p.c. sulphuric acid. By voltaic

action the iron is soon dissolved from the plate, and, after a light scouring with a fibre brush and subsequent rinsing, the plate is again immersed in the solution to receive a further coating of iron, thus considerably lengthening its life. For a review of the work done in the commercial electro-deposition of **cadmium,** see Mathers and Marble, Trans. Amer. Electrochem. Soc. 1914, 25, 297 et seq.

Of several **cobalt** solutions the following yield the *best results : (1) crystallised cobalt ammonium sulphate, 200 grams per litre of water ; (2) cobalt sulphate, 312 grams ; sodium chloride, 19·6 grams ; boric acid, nearly to saturation ; water, 1000 c.c. From these solutions, cobalt plates on brass, iron, steel, copper, tin, nickel-silver, lead, and Britannia metal, the coating being firm, adherent, hard, and uniform. When polished, the surface, although brilliantly white, has a slight bluish tint. Compared with nickel-plating, the plating with solution (1) is four times, and with solution (2) fifteen times, more rapid, but the voltage required is greater than that used for most nickel-plating baths. Since cobalt is harder than nickel, a much thinner coating of cobalt will offer the same protective coating as a greater weight of nickel deposit ; thick deposits of cobalt are superior in appearance and character to those of nickel (Kalmus, Harper, and Savell, J. Ind. Eng. Chem. 1915, 7, 379 ; Chem. Soc Abst. 1915, 107, ii. 465).

Deposition of alloys. (1) *Brass.* From mixed solutions of zinc and copper sulphates with the addition of acid, copper can be completely deposited free from zinc, this principle being applied in electrolytic analysis and also in refining. With salts more alike in stability, this condition being attained in the double cyanide solutions, the two metals are deposited simultaneously in proportions varying with conditions. The cyanides are invariably used for this purpose, the zinc and copper compounds being used in about the same quantity. The mixed solution may be prepared in many ways, of which the following are in common use :—

(a) Treating solutions of the mixed sulphates with excess of ammonia and adding about 30 p.c. more cyanide (KCN) than is required to decolourise the blue solution.

(b) Preparing a solution of potassium cyanide (1–1½ lbs. per gallon) and saturating about three-quarters of it with the mixed carbonates of zinc and copper, subsequently adding the remaining solution for 'free cyanide.'

The solution may be used warm or cold. If cold, a higher concentration is desirable, and also a smaller proportion of zinc compound. If warm, the zinc compound should be increased and the solution may be safely diluted. Brass anodes are used, which, in a warm solution with a fair proportion of free cyanide, dissolve under the influence of the current. Lack of free cyanide gives rise to the formation of a deposit of the two single compounds on the anode, adding resistance and reducing the current, and thus altering the colour of the deposit. The colour and composition of the deposit vary with several conditions. In general, the conditions which demand a higher E.M.F. give rise to a lighter deposit containing more zinc, whilst those which reduce the resistance of the solution tend to the production of redder deposits containing more copper. Thus more yellow deposits are produced in cold dilute solutions with little free cyanide, whilst the copper in the deposit is increased when the solution is strengthened or warmed, or more free KCN added. The composition of the deposit is controlled also by the proportion of the two metals in the solution, and the fact that from cyanide solutions copper and zinc are ordinarily deposited in the proportion of 63·6 of copper : 32·5 of zinc accounts approximately for the 2 : 1 proportion in deposited yellow brass. The colour of the deposit is lightened by the addition of ammonia or ammonium carbonate, these substances assisting the solution of the zinc compound, which is less soluble than the copper compound, and preventing the formation of basic compounds.

The methods of deposition of brass follow on the same lines as those of copper from the cyanide solution.

(2) Other alloys are deposited to only a very limited extent. The choice of solutions depends upon the ease of mixture of solutions from which the constituents can be separately deposited Thus for bronze, the sulphate, chloride and cyanide solutions, are unsuitable. A satisfactory mixture can be made from the double oxalates of the two metals with ammonium oxalate, the solution being worked warm with a bronze anode. Similarly, a solution from which nickel silver may be deposited may be prepared by mixing the separate double cyanides of copper, zinc, and nickel with potassium cyanide, or by dissolving the alloy in nitric acid, precipitating the mixed carbonates and dissolving the mixture in cyanide. The deposition of these alloys is subject to the same conditions as for brass, attention being paid to those conditions which facilitate the deposition of the more positive constituents, viz. tin, zinc, and nickel

The *electrodeposition of zinc* has of late years been extensively carried on. As a protective coating for iron and steel an electro deposit has great advantages over the ordinary process of galvanising. The sulphate solution is commonly used. In some cases zinc anodes are employed and these to a large extent maintain a constant composition of solution. Other processes employ insoluble anodes, resulting in the formation of sulphuric acid equivalent in quantity to the zinc deposited. The deposition of zinc from such acid solutions demands special conditions, and for general plating purposes the free acid thus formed is neutralised by filtering the liquid through zinc dust. From neutral solutions there is the tendency for the formation of basic compounds leading to the growth of mossy deposits. Such addition agents as glucose beta-naphthol, &c., lead to a considerable improvement in the character of the deposit.

Another extending application of zinc deposition is found in the recovery of zinc from liquors produced by treating certain zinc ores with weak sulphuric acid. The zinc is usually present to the extent of 6–10 p.c. By electrolysis this is reduced considerably, and the acid solution formed by the use of insoluble anodes is then used for extracting the zinc compounds from a further quantity of ore. The process has been applied largely at Anaconda.

Deposition of tin may be successfully carried out from a number of solutions. The chloride yields a beautiful crystalline deposit, but reguline deposits may be obtained from solutions of the stannite, stannate, or double oxalate with ammonium, with ease. They are prepared as follows :—

(1) The hydrate is precipitated from stannous chloride with alkali, and the precipitate dissolved in excess of alkali. .

(2) By converting the metal to hydrated oxide with nitric acid, and dissolving the washed oxide in alkali.

(3) By adding a solution of ammonium oxalate to tin chloride. A white precipitate first forms, and this is soluble in excess.

Solutions containing from 1 to 2 ozs. of metal per gallon are of convenient strength. From these solutions tin may be obtained as a reguline deposit within certain limits of current density Excessive current produces a grey spongy deposit, which may, however, be considerably improved by the addition of a small amount of glue or gelatine, thereby extending the limit of allowable current Solutions of moderate strength yield metal quantitatively, and the anode suffers normal corrosion, maintaining the strength of the electrolyte. The dull white deposit is improved by gentle scratch-brushing with a soft brush. Tin may also be deposited without the current by using an oxalic acid solution to which tin chloride is added The metal is deposited by simple immersion, and the process may be improved by the addition of grain tin with the work, which facilitates deposition by local voltaic action, while tin passes into the solution. The process is hastened by immersing the small work in zinc trays, the zinc passing into the solution as an anode. In this case the solution must be replenished with tin chloride, and rejected when any large amount of zinc has accumulated in it

The **deposition of lead** may be similarly effected from alkaline solutions, which yield reguline deposits, whilst the acetate produces the well-known crystalline deposit. The process has but little application, but more recently the deposition of the metal has been successfully applied by Betts to the refining of the metal The electrolyte is a solution of lead fluosilicate, which may be made by dissolving the oxide or carbonate in the acid. With unrefined anodes the lead passes into solution, whilst silver is retained in the anode mud. Good reguline deposits are obtained by the addition of glue or gelatine in small amount.

More recently, lead perchlorate has been successfully used. Perchloric acid is prepared from the sodium salt with a slight excess of hydrochloric acid. Insoluble sodium chloride is filtered off and the acid liquid evaporated down to 135° C. until excess of hydrochloric acid is expelled. The perchloric acid solution is diluted and neutralised with litharge, a small proportion of the acid being set aside to add to the lead perchlorate solution, so that lead and free acid are present to the extent of about 5 p.c. each. Very satisfactory deposits are obtained from this solution, especially with the addition of peptone in the proportion of 0·05 p.c., and deposits of considerable thickness may thus be produced. With moderate current densities deposition proceeds almost quantitatively, and this with the high chemical equivalent of lead has suggested its use for voltmeter purposes.

A feature of lead deposition is the production of lead peroxide at the anode. This has long been known, and the production of coloured rings and films was first observed by Nobili, in 1826. Thus in a solution of lead acetate, or of litharge in alkali, and a polished anode of nickel or iron, coloured rings are obtained if a wire cathode is held close to the anode. The colours are due to the gradually varying thickness of the film, which brings about interference in the light falling upon them. With anodes of other shapes the colours follow the shape of the anode, though they pass off into a more or less rounded form. These colours are called 'metallochromes.' With excessive current a dull-brown deposit of lead peroxide is at once formed.

Anodic deposition of lead peroxide is also applied in the estimation of small amounts of lead in certain alloys from solutions containing nitric acid.

The **deposition of platinum** is carried out from a solution of the chloride in sodium phosphate. A platinum anode is insoluble and the solution needs the addition of the platinum compound. A brown colour sometimes occurs owing to some of the metal passing into the colloidal form.

Palladium may be successfully deposited from a solution of its double chloride, and the process has been applied by Cowper-Coles for producing a non-corrodible covering for electrolytically deposited parabolic mirrors in copper.

Cobalt deposition follows on lines similar to those for nickel; **mercury**, which may be deposited from the nitrate solution, has been applied to the construction of electrolytic meters, in which a small and definite fraction of the total current is shunted through a cell in which mercury is deposited, the weight of the mercury deposit automatically recording the current passing through the meter, and at constant potential difference the energy absorbed in the circuit.   S. F.

ELECTRUM v. NICKEL.

ELEMI v. OLEO-RESINS.

ELEMI, ESSENTIAL OILS OF, v. OLEORESINS.

ELEMICIN (3 : 4 : 5-trimethoxyallylbenzene). A constituent of the essential oil of elemi has been synthesised by Mauthner (Annalen, 1917, 414, 250) by condensing allyl bromide and pyrogallol-2 : 6-dimethyl ether, which yields 2 : 6-dimethoxyphenyl allyl ether (I.), which, by heating at 220° is converted into 2 : 6-dimethoxy-4-allylphenol (II.) ; this, on methylation, yields elemicin (III.) :—

(I) •   (II)   (III)
ELEMOL, $C_{15}H_{26}O$, a naturally-occurring monocyclic sesquiterpene alcohol found in Manilla elemi oil; b.p. 152°–156°/17 mm.; D^{20} 0·9411; n_D 1·5030; a_D–5°. Forms a benzoate; b.p. 214°–218°/10 mm.; D^{20} 1·0287; n_D 1·5378; a_D–6°. Elemol, when reduced by means of formic acid, sodium hydrogen sulphate, or zinc-dust, yields *Elemene* $C_{15}H_{24}$; b.p. 115°–117°/10 mm.; D^{20} 0·8797; n_D 1·4971.

Elemol is the first monocyclic sesquiterpene alcohol to be found in Nature or to be obtained artificially (Semmler and Liao, Ber. 1916, 49, 794).

ELIQUATION or **LIQUATION.** A metallurgical term to denote the operation of separating substances by taking advantage of their different fusibilities.

ELLAGIC ACID. Ellagic acid, $C_{14}H_6O_8$, is obtained from numerous tannin matters which contain an ellagitannin by boiling the aqueous extract with dilute sulphuric acid. In many cases it is found in the free state, due probably to the hydrolysis, by fermentation, of the ellagitannin or ellagic acid glucoside originally present, and such a fermentation frequently occurs when aqueous extracts of the tannin matters are allowed to stand for some time.

Divi-divi (*Cæsalpinia coriaria* [Willd.]) (Lowe, Zeitsch. anal. Chem. 1876, 14, 40), myrobalans (*Terminalia chebula* [Ratz.]) (Löwe, *ibid.*), algarobilla (*Cæsalpinia brevifolia*) (Zölfiel, Beilstein, 2, 1085), and valonia (*Quercus aegilops* [Linn.]) yield considerable quantities of ellagic acid, and are the best natural sources of this material. It has also been isolated from oak galls (Chevreul, Ann. Chim. Phys. 1828, [2] 9, 329); oak bark (Etti, Montash 1880, 1, 226); the bark of *Picea excelsa* (Link.) (Strohmer, *ibid.* 1881, 2, 539); pomegranate rind (Rembold, Annalen, 1867, 143, 288); *Quebracho colorado* (Perkin and Gunnel, Chem. Soc. Trans. 1896, 69, 1307); *Arctostaphylos uva-ursi* (Spreng) and *Coriaria myrtifolia* (Linn.) (Perkin, *ibid.* 1900, 77, 424); *Hæmatoxylon campeachianum* (Linn.) (Perkin, *ibid.* 1897, 71, 1137); the fruit of *Cæsalpinia digyna* (Rottl) (Nierenstein, Chem. Zeit. 1909, 87); and the bark of *Terminalia catoppa* (Linn.) (*ibid.*). In fact, ellagic acid probably always occurs, if only in minute quantity, in all plant products which contain gallotannin. Most interesting are the Oriental bezoar stones, concretions which are found in the stomachs of goats and other animals, and consist largely of ellagic acid. These originate, without doubt, from the fact that the animal has fed upon plants in which some quantity of an ellagitannin is present.

Ellagic acid was first discovered by Chevreul (Ann. Chim. Phys. *l.c.*) in oak galls, and more closely examined by Braconnot (*ibid.* 9, 187). According to Pélouze, it possessed the composition $C_7H_4O_4$ (*ibid.* 54, 356); whereas Merklein and Wöhler (Ann. Chem. Pharm. 55, 129), who isolated it from bezoar stones and termed it 'bezoaric acid,' showed that its true formula is $C_{14}H_6O_8$.

The precipitate of crude ellagic acid, which is produced by boiling the tannin extract with dilute mineral acid, is purified by washing with alcohol and subsequent recrystallisation. A similar procedure is also satisfactory with the deposits so frequently produced by fermentation and alluded to above. Ellagic acid is most readily crystallised from pyridine (Perkin and Nierenstein, Chem. Soc. Trans. 87, 1416), and the product, which is either a pyridine compound or contains pyridine of crystallisation, is washed with alcohol.

Löwe (Zeitsch. Chem. 1868, 4, 653) was the first to prepare ellagic acid synthetically by oxidising gallic acid with arsenic acid, and this was subsequently accomplished by Ernst and Zwenger (Annalen, 1871, 159, 32) by heating ethyl gallate with sodium carbonate solution in the presence of air, and by Griessmayer (*ibid.* 1871, 160, 55) by heating gallic acid with water and iodine. It is readily produced by oxidising gallic acid dissolved in acetic acid by means of potassium persulphate and sulphuric acid (Perkin and Nierenstein, *l.c.*), and together with flavellagic acid by the addition of potassium persulphate to a solution of gallic acid in sulphuric acid (Perkin, *ibid.* 1906, 89, 251). Under similar conditions, gallotannin produces ellagic acid (Nierenstein, Ber. 1908, 41, 3015; and 1909, 42, 353), and it can also be prepared by boiling the tannin with hydrogen peroxide solution (*ibid.* 1907, 40, 917). Herzig and Bronneck obtained good results by passing air through an ammoniacal solution of gallic acid ethyl ester, and also of gallotannin (Monatsh. 1908, 29); whereas Sisley (Bull. Soc. chim. 1909, [4] 5, 727) prepared ellagic acid from tannin by means of alcoholic potassium hydroxide solution. According to Rupe, a 60 p.c. yield is produced when gallic acid in sulphuric acid solution is oxidised with sodium nitrite (Chemie d. naturl. Farbstoffe, 1909, 2 162).

Ellagic acid crystallised from pyridine forms prismatic needles, which are converted by alcohol into a pale yellow crystalline powder; but when purified by means of its acetyl derivative, the product is almost colourless (Perkin and Nierenstein). It is very sparingly soluble in all the usual solvents, dissolves in alkaline solutions with a pale yellow colour, and from these liquids, when diluted with hot alcohol, is deposited on acidifying in a crystalline condition. When heated it does not melt below 360°; and sublimes at higher temperatures with considerable carbonisation. With nitric acid containing nitrous acid and subsequent dilution, it gives a blood-red colouration (Griessmayer's reaction), and this property, considered at one time to be characteristic, is known to be also possessed by flavellagic acid (Perkin).

According to Merklein and Wöhler (*l.c.*), the alkaline solution of ellagic acid becomes reddish-yellow on exposure to air, and deposits black crystals of potassium glaucomelanate

$$K_2C_{12}H_{14}O_7$$

When boiled with phenylhydrazine in alcoholic solution, or when carefully heated with phenylhydrazine, ellagic acid forms the product $C_6H_5NH·NH_2,C_{14}H_8O_8$, which crystallises in yellow needles, and is readily reconverted into ellagic acid. Ellagic acid gives similar compounds with aniline and quinoline (Goldschmiedt, Monatsh. 1905, 26, 1139).

Tetraacetylellagic acid, $C_{14}H_2O_8(C_2H_3O)_4$, (Barth and Goldschmiedt, Ber. 1878, 11, 846; Schiff, *ibid.* 1879, 12, 1534; Zölffel, Arch.

Pharm. 229, 123), colourless needles, m.p. 343°-346° (Perkin and Nierenstein); *tetrabenzoylellagic acid* $C_{14}H_2O_8(C_7H_5O)_4$, colourless needles (Goldschmiedt and Jahoda, Monatsh. 1892, 13, 151), m.p. 332°-333° (Perkin); *ellagic acid monomethyl ether* $C_{14}H_6O_7(OCH_3)$, yellow crystalline powder (Goldschmiedt, Monatsh. 1905, 26, 1139); *diacetylellagic acid monomethyl ether* $C_{14}H_3O_7(OCH_3)(C_2H_3O)_2$, crystalline powder (Goldschmiedt); *ellagic acid dimethyl ether* $C_{14}H_4O_8(OCH_3)_2$, crystalline powder (Goldschmiedt); and *ellagic acid tetramethyl ether* $C_{14}H_2O_4(OCH_3)_4$, colourless microscopic needles (Goldschmiedt; Herzig and Pollak, Monatsh. 1908, 29, 263), have been described.

Ellagic acid gives the following salts: $KC_{14}H_5O_8$, minute yellow needles (Perkin and Wilson, Chem. Soc. Trans 1903, 83, 134); $K_2C_{14}H_4O_8$, prisms (Merklein and Wohler; Perkin and Wilson): $K_2C_{14}H_4O_8$,KOH, microscopic prisms (Merklein and Wöhler);

$$Na_2C_{14}H_4O_8$$

crystalline powder; $NaC_{14}H_5O_8$,H_2O, yellow needles (Ernst and Zwenger, Annalen, 1871, 159, 32).

The tinctorial properties of ellagic acid are somewhat feeble, but in 1887 it was placed on the market by Messrs. Meister, Lucius, and Brüning, under the name of 'Alizarin Yellow in paste,' and was recommended as yielding, with chromium mordants, greenish-yellow shades of considerable permanence.

Rembold (Annalen, 1867, 143, 288) states that when ellagic acid is treated with sodium amalgam, it gives γ-*hexahydroxydiphenyl*

$$C_{12}H_4(OH)_6$$

three distinct *rufohydroellagic acids* $C_{14}H_{10}O_8$, $C_{14}H_{10}O_7$, $C_{14}H_{10}O_9$, and *glaucohydroellagic acid*; but, according to Nierenstein (Ber 1908, 41, 1649), this latter compound is in reality the pentahydroxydiphenylmethylolid referred to later. By the action of boiling potassium hydroxide solution (Barth and Goldschmiedt, Ber. 1879, 12, 1242), ellagic acid gives *hexahydroxydiphenylenketone* (?) $C_{13}H_4O_7$, by fusion with potassium hydroxide β-*hexahydroxydiphenyl*, and by fusion with sodium hydroxide γ-*hexahydroxydiphenyl*, together with some of the β- compound.

When ellagic acid is distilled with zinc-dust *fluorene* is produced (Rembold, Ber. 8, 1494; Barth and Goldschmiedt, *ibid.* 11, 846; *cf.* also Graebe, *ibid.* 1903, 36, 212).

As a result of their investigation, Barth and Goldschmiedt (*ibid.* 1879, 12, 153) suggested that ellagic acid could be represented by one of the two following formulæ:—

(1) CO $\langle$ C$_6$′(OH)$_3$ / C$_6$′(OH)$_2$ / O / CO

(2) CO $\langle$ C$_6$′(OH)$_2$ / C$_6$′(OH)$_2$ / O / COOH
and of these the first was preferable.

Whereas such a constitution requires the presence of five hydroxyl groups, Schiff (Ber. 1879, 12, 1534) considered that acetylellagic acid was $C_{14}H_3(C_2H_3O)_4O_8$, and this was subsequently corroborated by Zölffel (Arch.

Pharm. 229, 123). Schiff, at the same time, proposed two formulæ for ellagic acid:

(1) CO $\langle$ O $\rangle$ C$_6$H(OH)$_2$ / CO $\langle$ O $\rangle$ C$_6$H(OH)$_2$

(2) O $\vert$ CO $\langle$ C$_6$H(OH)$_2$ / CO $\vert$ O $\rangle$ C$_6$H(OH)$_2$
the latter of which is identical with that preferred by Graebe (*l.c.*). In a later investigation, Goldschmiedt and Jahoda (Monatsh. 13, 49), as the result of their preparation of tetrabenzoylellagic acid, were satisfied of the existence in ellagic acid of but four hydroxyls, and consequently adopted their second formula.

Graebe (Ber. 1903, 36, 214), among other criticisms, pointed out that a substance having this constitution, and which may be more clearly written as follows (1):—
would yield, on distillation with zinc-dust, not fluorene, but an isomeric hydrocarbon (2), if this, indeed, were capable of existence. In the same paper this author announced the interesting fact that diphenylmethylolid
on distillation with zinc-dust, gives not only diphenyl and methyldiphenyl, but also *fluorene*; and in a theoretical discussion of the subject, suggested that Schiff's second formula (given above) most probably represents the true constitution of this substance.

The subject was reinvestigated somewhat later by Perkin and Nierenstein (*l c.*), who, on digesting ellagic acid with boiling potassium hydroxide solution, obtained Barth and Goldschmiedt's so-called hexahydroxydiphenyleneketone $C_{13}H_8O_7$. From this substance a *pentaacetyl* derivative $C_{13}H_2O_7(C_2H_3O)_5$, prismatic needles, m p. 224°-226°, and a pentabenzoyl derivative, $C_{13}H_3O_7(C_7H_5O)_5$, plates, m.p. 257°-259°, were prepared. As, moreover, zinc-dust distillation gave fluorene, there could be little doubt that this compound was in reality *pentahydroxydiphenylmethylolid*, as, indeed, was surmised by Graebe:
From their results, together with a study of other similar compounds, Perkin and Nierenstein considered that Schiff's formula, and which can be more clearly written thus:
is a correct representation of the constitution of ellagic acid.

Finally, Herzig and Pollak (Monatsh. 1908, 29, 263), by a study of the methylation products of ellagic acid, obtained results further corroborating this constitution.

When Goldschmiedt's tetramethylellagic acid is digested with alcoholic potash and methyl iodide, *diphenyl*-1 : 2 : 3 : 6 : 7 : 8-*hexamethoxy*-5 : 10-*di-carboxylic methyl ester* (m.p. 109°–111°) :

(1)
is obtained, together with a small quantity of *diphenylmethylolid*-2 : 3 : 6 : 7 : 8 - *pentamethoxy*-5-*carboxylic acid methyl ester* (2), m.p. 187°–189° :

(2)
By means of alcoholic potash, these compounds (1) and (2) yield respectively *diphenyl*-1 : 2 : 3 : 6 : 7 : 8-*hexamethoxy*-5 : 10-*dicarboxylic acid* (3), m.p. 238°–240°, and *diphenyl*-2 : 3 : 6 : 7 : 8-*pentamethoxy*-1-*hydroxy*-5 : 10-*dicarboxylic acid* (4), m.p. 200°–203° :

(3)

(4)
Ellagic acid is probably not a tanning material in the true sense of the term, but is of considerable importance nevertheless in the tanning process. Thus the ellagitannic acid absorbed by the hide is at least in part converted into ellagic acid, and the deposit thus formed adds weight and bloom to the finished article.

Other members of this group have been prepared from *m*-hydroxybenzoic acid, *p*-hydroxybenzoic acid, proto-catechuic acid, sym. dihydroxybenzoic acid, gallic acid, and from ellagic acid itself. An account of these is given below.

FLAVELLAGIC ACID.

Flavellagic acid $C_{14}H_6O_9$ is obtained in conjunction with ellagic acid when gallic acid is oxidised with potassium persulphate and strong sulphuric acid. By the employment of a dilute acid, flavellagic acid almost free from ellagic acid can be produced, and for this purpose the following process is recommended (A. G. Perkin, Chem. Soc. Trans. 1906, 89, 251) : 20 grams of gallic acid are treated with 160 c.c. of 96 p.c. sulphuric acid, 66 c.c. of water added, and the hot solution thus obtained is cooled to 50°, and maintained at this temperature during the gradual addition of 40 grams of potassium persulphate. A. G. Perkin and F. M. Perkin (Chem. Soc. Trans. 1908, 93, 1194) have obtained the same compound by the electrolytic oxidation of gallic acid in the presence of sulphuric acid,

and more recently Bleuler and Perkin (*ibid.* 1916, 109, 530) have prepared it by heating gallic acid at 110°–120° with arsenic and sulphuric acids.

Flavellagic acid crystallises from pyridine in small yellow prismatic needles which contain pyridine, and do not melt below 360°. With nitric acid containing nitrous acid and subsequent dilution, it gives the blood-red colouration (Griessmayer reaction), which is also produced by ellagic acid. Dilute alkalis dissolve it with a yellowish-green colouration, and by distillation with zinc-dust *fluorene* is produced. *Acetyl-flavellagic acid* $C_{14}HO_9(C_2H_3O)_5$, colourless needles, melts at 317°–319°, and *benzoylflavellagic acid* $C_{14}HO_9(C_7H_5O)_5$, prismatic needles, melts at 287°–289°. Flavellagic acid dyes mordanted woollen cloth shades somewhat resembling but stronger than those produced by ellagic acid.

Chromium.	Aluminium.	Tin.	Iron.
Yellowish-olive.	Pale greenish-yellow.	Pale yellow.	Dark olive-brown.

By the action of boiling 50 p.c. potassium hydroxide solution, flavellagic acid gives *hexahydroxydiphenylmethylolid*
colourless needles (m.p. above 300°). This compound dissolves in solutions of the alkali hydroxides with an orange-yellow tint, and this, on dilution with water and exposure to air, develops a strong bluish-violet colouration. The *acetyl* derivative $C_{13}H_2O_8(C_2H_3O)_6$, colourless prismatic needles, melts at 232°–234°. Flavellagic acid is hydroxyellagic acid, and possesses the following constitution :—
(*cf.* Herzig and Tscherne, Monatsh. 1908, 29, 281).

Flavellagic acid gives with diazomethane the *methyl ether* $C_{14}HO_4(OMe)_5$, m.p. 245° ; and this is converted by methyl iodide and potassium hydroxide into *methyl*-3 : 4 : 5 : 6 : 2′ : 3′ : 4′-*heptamethoxydiphenyl*-2 : 6′-*dicarboxylate*

$$C_{12}H(OMe)_7(CO_2Me)_2$$

m.p. 83°–87°. The latter, on hydrolysis with potassium hydroxide, yields the *acid*

$$C_{12}H(OMe)_7(CO_2H)_2$$

m.p. 163°–167°, in the anhydrous condition. From water it crystallises with $1H_2O$ and then melts at 95°–100° (decomp.) (M. von Bronneck, Monatsh. 1908, 29, 281).

When gallic acid 3 : 4-dimethylether, or gallic acid trimethylether is oxidised by means of potassium persulphate and sulphuric acid at 45° (Herzig and Schmidinger, Monatsh. 1910, 31, 918), *flavellagic acid tetramethylether*
yellow needles, m.p. 270°-271°, is produced, the acetyl derivative of which melts at 270°-271°. By means of methyl sulphate and potassium hydroxide, the heptamethoxy compound is obtained.

CŒRULEOELLAGIC ACID.

Cœruleoellagic acid is prepared by heating ellagic or flavellagic acid (1 part) with sulphuric acid (monohydrate'10 parts) to 200° and allowing the temperature to fall to 185°-190° and remain there for 30 minutes. The product isolated by pouring into water is purified by conversion into its acetyl derivative, and this is subsequently hydrolysed by means of sulphuric acid in the presence of acetic acid. It may also be obtained by the oxidation of ellagic or flavellagic acids (1 part) in sulphuric acid solution (10 parts) with arsenic acid (1 part) at 100°-130° (Perkin, Chem. Soc. Trans. 1916, 109, 529).

Cœruleoellagic acid, $C_{14}H_8O_{10}$, separates from hot pyridine in small pale yellow prismatic needles which melt above 360° and are very sparingly soluble n the usual solvents Concentrated solutions of the alkali hydroxides dissolve it with a greenish-yellow colour, which on dilution become green and finally of a blue colour, and these changes appear to arise from oxidation. Sodium and potassium carbonate solutions also give blue liquids. On distillation with zinc-dust fluorene is produced

Acetylcœruleoellagic acid, $C_{14}O_{10}(C_2H_3O)_6$, colourless needles, m.p. 330°-332°, and *benzoyl-cœruleoellagic acid* $C_{14}H_{10}(C_7H_5O)_6$, m.p. 343°-345°, have been prepared The latter is more sparingly soluble in benzoic anhydride than the corresponding derivative of flavellagic acid, and this property provides a means for the separation of the two substances.

By digestion with 50 p.c. potassium hydroxide solution diluted with its own volume of alcohol, cœruleoellagic acid gives a compound $C_{12}H_{10}O_8$, evidently *octohydroxydiphenyl*. This consists of an almost colourless crystalline powder, soluble in dilute potassium hydroxide solution, with a reddish-violet colouration which becomes brown on exposure to air. The *acetyl* derivative $C_{12}H_2O_8(C_2H_3O)_8$, forms colourless needles melting at 177°-178°.

The constitution assigned to cœruleoellagic acid is as follows :—
a formula which represents it as either a dihydroxy-ellagic or hydroxy flavellagic acid.

Cœruleoellagic acid possesses well-marked dyeing properties of a similar character, though more strongly developed than those of ellagic and flavellagic acids, and may have practical utility. Owing to its sparing solubility it gives the best results in the paste form. The following shades are obtained by the employment of mordanted woollen cloth :—

Chromium.	Aluminium.	Tin.	Iron.
Deep olive-yellow.	Greenish-yellow.	Dull yellow.	Greenish-black.

In the case of the aluminium mordant the employment of chalk in the dye-bath exerts a detrimental effect.

CATELLAGIC ACID.

Schiff (Ber. 12, 2590) on heating protocatechuic acid with arsenic acid, obtained a substance which he named *catellagic acid*, and to this he assigned the formula $C_{14}H_{10}O_7$ or $C_{14}H_8O_7$. Perkin and Nierenstein (Chem. Soc. Trans. 1905, 87, 1417) obtained a similar substance by the oxidation of protocatechuic acid, and also parahydroxybenzoic acid with potassium persulphate and sulphuric acid. According to the latter authors, catellagic acid $C_{14}H_8O_6$ crystallises from pyridine in colourless needles, which melt above 360°, and sublime with but moderate carbonisation at higher temperatures. Solutions of the alkali hydroxides dissolve it with a pale yellow colour, and with nitric acid it gives a magenta coloured liquid. *Diacetyl-catellagic acid*, colourless prismatic needles, melts at 322°-324°.

Catellagic acid, by distillation with zinc-dust, gives *fluorene*, and is closely related to ellagic acid. Its constitution (Perkin and Nierenstein) may be expressed as follows :—
From the oxidation products of parahydroxybenzoic acid, Perkin and Nierenstein isolated, in addition to catellagic acid, a second compound $C_{14}H_8O_6$, colourless needles, m.p. above 360°. This, which gives the diacetyl derivative $C_{14}H_6O_6(C_2H_3O)_2$, colourless needles, m.p. 267°-268°, and by distillation with zinc-dust fluorene, possesses the formula :
and evidently originates from the interaction of one molecule of protocatechuic acid and one of parahydroxybenzoic acid.

METELLAGIC ACID.

Metellagic acid (Perkin and Nierenstein, Chem. Soc. Trans. 1905, 87, 1425) is obtained in small amount together with other substances by oxidising metahydroxybenzoic acid in sulphuric acid solution with potassium persulphate at about 30°. The product is fractionally crystallised from acetic acid, the second crop acetylated, the acetyl derivative thus obtained purified by repeated crystallisation from acetic anhydride and hydrolysed with sulphuric acid in the usual manner.

Metellagic acid $C_{14}H_8O_8$ crystallises from acetic acid in colourless needles which readily sublime at high temperatures. With caustic alkaline solutions it behaves similarly to catellagic acid giving a yellow colour which is discharged on heating. Distilled with zinc-dust a small quantity of a crystalline hydrocarbon is produced which appears to be identical with fluorene. *Acetylmetellagic acid* $C_{14}H_4O_8(C_2H_3O)$ crystallises in colourless leaflets, m.p. 269°-271°.

The reactions of metellagic acid are in harmony with those required by a member of the ellagic acid series, and the following formula assigned to it is probably correct :—
In the mother liquors obtained during the purification of acetyl metellagic acid, a second acetyl compound, m.p. 237°–243°, was isolated. Thus on hydrolysis gave a substance crystallising in glistening yellow needles, the nature of which has not been ascertained.

By the oxidation of suitable hydroxybenzoic acids, a series of hydroxydiphenyldimethyloid derivatives have thus been prepared, viz. :—

Metellagic acid $C_{16}H_8O_4(OH)$
Catellagic acid $C_{15}H_4O_4(OH)_2$
Resoflavine $C_{14}H_2O_4(OH)_3$
Ellagic acid $C_{14}H_2O_4(OH)_4$
Flavellagic acid $C_{14}HO_4(OH)_5$
Cœruleoellagic acid $C_{14}O_4(OH)_6$

A. G. P.

ELLAGITANNIC ACID. A tanning principle present in divi-divi (Löwe, Frdl. 14, 35); in algarobilla (Zölffel, Arch. Pharm. 229, 123); in myrobalans (Lowe, *l.c.* 44; Zölffel, *l.c.*); and probably to some extent in all plant products which contain a gallotannin (*v.* ELLAGIC ACID).

According to Lowe, the molecule of ellagitannic acid contains 5 hydroxyl groups replaced by acetyl. It gives precipitates with gelatin, albumen, alkaloids, tartar emetic, and a nearly black precipitate with ferric acetate. Its alcoholic solution gives, with lead acetate, a yellow precipitate.

Zölffel (*l.c.*) considered it a sugar-free tannic acid of the formula

$C_6H_2(OH)_3COO \cdot C_6H_2(OH)_2COOH$
whereas Perkin and Nierenstein (*l.c.*) suggested it to be a glucoside or a condensation product of two molecules of gallotannin.

Nierenstein (Ber. 1910, 43, 1267) has obtained it in a pure state by repeated treatment of the crude substance from myrobalans with alkali and ethyl chloroformate, and then decomposing with pyridine according to Fischer's method; and gives its formula as

$C_{26}H_{28}O_{19}, 3H_2O$
It crystallises from a mixture of pyridine and acetic acid in pale-yellow plates, which, after sintering at 300°–306°, melt at 329°–336° $[a]_D^{17} + 18·02°$. So obtained, it readily yields ellagic acid with dilute sulphuric acid, but is not decomposed by 10 p.c. sodium carbonate solution. As it is hydrolysed by emulsin to luteoic acid, Nierenstein considers it to be a glucoside of this compound (*v.* TANNINS).　　　A. G. P.

ELUTRIATION. The separation of the lighter from the heavier particles of a powder by washing and decantation.

EMANIUM *v.* ACTINIUM.

EMBARIN. Trade name for sodium mercuri-salicylsulphonate.

EMBELIC ACID. The active constituent of the fruit of the Indian plant *Embelia ribes*

(Burm.) (nat. ord. Myrsineæ). Employed as an anthelmintic.

EMBOLITE. Native silver chlorobromide containing chlorine and bromine in indefinite proportions. It is the commonest of the horn-silvers or cerargyrites (*q.v.*), occurring as compact horn-like masses or as small, indistinct cubic crystals of a greenish-grey colour. Frequently a small amount of iodine is also present, and the formula is Ag(Cl,Br,I); the colour of this iodembolite variety is usually greenish-yellow to orange-yellow. Large quantities have been mined with other ores of silver in Chile, Mexico, and Broken Hill in New South Wales. (*V.* Prior and Spencer, Min. Mag. 1902, 13, 174.)

L. J. S.

EMERALD *v.* BERYL, and GLUCINUM.

EMERALD GREEN. *Hydrated chromium sesquioxide* (*v.* CHROMIUM); also applied to *Schweinfurth green* (*v.* art. ARSENIC; also PIGMENTS).

EMERALD-NICKEL *v.* ZARATITE.

EMERALD, ORIENTAL, *v.* CORUNDUM.

EMERY. (*Émeri*, Fr.; *Smirgel, Schmirgel*, Ger.) An impure variety of corundum. It is, however, more of the nature of a rock, rather than a simple mineral, consisting essentially of a fine-grained aggregate of corundum (50–60 p.c.) and magnetite (30–40 p.c.). Several other minerals are also present in smaller and variable amounts. Hæmatite and limonite are present as alteration products of the magnetite; and others, such as diaspore, margarite (emerylite), muscovite, kyanite, have probably been derived from the corundum. In addition, there may also be tourmaline, chloritoid, biotite, staurolite, rutile, idocrase, pyrites, iron-spinel (hercynite), &c. The material is dull black, dark grey, or bluish-black, and has much the appearance of a fine-grained iron-ore; sp.gr. 3·75–4·31. It is massive and opaque, breaking with a more or less regular fracture, and is magnetic. The abrading power (measured by the amount of glass abraded by a given weight of emery in a certain time) ranges from 65 to 32, as compared with sapphire at 100. These values are only roughly proportional to the amount of alumina (corundum) present in the mixture, depending also to some degree on the texture of the material.

The analyses on next page are of material from Naxos, I–IV (I and II, the extremes as regards the amount of alumina of seven analyses by Oser, quoted by S. A. Papavasiliou, 1913; III and IV, by E. Ludwig, quoted by G. Tschermak, 1894); Asia Minor, V, by R. Kramer, 1907; VI, Peekskill, New York, by G. H. Williams, 1887. Several older analyses have been published by J. L. Smith (Amer. J. Sci. 1850, 1851, 1866), and by R. Jagnaux (Bull. Soc. Min. France, 1884).

Analysis III corresponds with the mineral composition : corundum 52·4, magnetite 32·1, tourmaline 11·5, muscovite 2, margarite 2 p.c.; and IV with : corundum 50, magnetite 33, tourmaline 9, chloritoid 4, muscovite 3, calcite 1 p.c.

The only sources of supply are Greece, Asiatic Turkey, and the United States. The deposits in the island of Naxos in the Grecian archipelago have been known since remote times. Here, on the north-east side of the

island, the emery occurs as irregular beds and lenticular masses in crystalline limestone (marble), associated with crystalline schists and intruded by granite. Large isolated blocks also occur weathered out on the surface. The methods of mining are very primitive, and resort is made to the old method of fire-setting, the surface of the rock being heated by fires and suddenly cooled by water to develop cracks. The production is the monopoly of the Greek government, and amounts to about 10,000 tons per annum. Emery also occurs on the neighbouring islands of Irakha, Sikinos, Paros, and Amurgos, but these deposits are not worked. (On the Naxos deposits, v W. H. Cottrell, Foreign Office Rep., Miscell. Ser. No. 368, London, 1895; G. Tschermak, Min. Petr. Mitt. 1894, xiv. 311; S. A. Papavasiliou, Zeits. Deutsch. Geol. Gesell. 1913, lxv. 1-123.)

The important deposits in western Asia Minor, around Smyrna, were discovered by J. Lawrence Smith in 1847. Here also the emery occurs as lenticular bodies in bluish crystalline limestone, associated with mica-schist, gneiss, and granite; and as loose blocks weathered out in the reddish surface soil. The principal mines are situated on the Gume Dagh or Messogis Mountain in the Aidin district (E. of Ephesus and S.E. of Smyrna). Others are near Mausa (the ancient Magnesia), near Kula and Adula (N. of Ala-Shehr=Philadelphia), and on the neighbouring islands of Samos and Nikaria. The output of 20,000 to 30,000 tons per annum is shipped from Smyrna. (On the Asia Minor deposits, v. J. L. Smith, Amer. J. Sci. 1850, 1851; and Original Researches in Mineralogy and Chemistry, 1884; R. Krämer, Kleinasiatische Schmirgelvorkommnisse Inaug.-Diss. Leipzig, Berlin, 1907.)

In the United States, deposits have been worked at Peekskill in Westchester Co., New York, occurring here as segregations in gabbro; and in amphibolite-schist at Chester in Hampden Co., Massachusetts. The annual output amounts to only about 1000 tons, and that from Chester has now fallen off. (On the United States occurrence, v. G. P. Merrill, The Non-Metallic Minerals, 2nd edit. New York, 1910.)

An abrasive material mined at Wildenreuth and other places in Bavaria under the name of emery (Schmirgel, Ger.) is really a mixture of garnet and quartz. In the trade the name emery has also been applied to the refuse from cutting gems and from gem-washings.

¹ Also Cr₂O₃ trace.   ² Also P₂O₅ trace, S 0·01.

In the preparation of the material for the market, after being carefully hand-picked at the mine, it is crushed under stamps and sorted into various grades of fineness through wire sieves. The finest 'flour of emery' is prepared by washing and elutriation. Emery powder is used by lapidaries and stone workers; for polishing plate glass and grinding lenses. In the form of emery paper, emery cloth, and emery sticks, the powder is fixed by means of glue. For emery wheels the powder is mixed with a cementing material, such as shellac, sodium silicate, or vulcanite; or it is baked with loam or kaolin and thus embedded in terra-cotta or porcelain. Such wheels are much used by lapidaries and dentists, and for grinding and polishing metals, &c. Attempts have been made to use pieces of emery, in place of diamond, in the crowns of rock-drills. (On the technical uses of emery, v. A. Haenig, Der Schmirgel und seine Industrie, Wien, 1910.)   L. J. S.

EMETAMINE v. IPECACUANHA.

EMETINE v. IPECACUANHA.

EMIN RED v. PRIMULINE.

EMODIN v. GLUCOSIDES; RHUBARB; SYNTHETIC DRUGS.

EMPRESSITE. A silver-tellurium mineral AgTe, discovered in the Empress-Josephine mine, Kerber Creek, Colorado, associated with galena and native tellurium. Lustre, metallic; streak, greyish-black; fracture, conchoidal; hardness, 3–3 5; sp.gr. 7·51 (Bradley, Amer. J. Sci. 1914, 38, 163).

EMPYROFORM v. SYNTHETIC DRUGS.

EMULSIN. The term 'emulsin' was applied originally to the enzyme or mixture of enzymes, present in bitter and sweet almonds, which hydrolyses amygdalin to glucose, benzaldehyde, and hydrogen cyanide. The same enzyme was shown subsequently to hydrolyse many natural glucosides as well as the synthetically prepared β-glucosides, though it was entirely without action on the stereoisomeric α-alkylglucosides (Fischer, Zeitsch. physiol. Chem. 1898, 26, 60). The name is now used to comprise all enzymes which hydrolyse β-glucosides. Such enzymes are widely distributed in plants: besides the kernels of fruits, they also occur in the leaves and young twigs of the higher plants, in most mould fungi, especially in Polyporus species parasitic on trees, and in bacteria. Henry and Auld (Proc. Roy. Soc. 1905, B, 76, 568) have identified emulsin as present in yeast.

β-Glucosides are also hydrolysed by certain animal extracts, e.g. intestinal mucous membrane, a fact which is taken to indicate the presence of emulsin.

There are, however, well-marked differences in the number of substances which these various emulsin preparations are able to hydrolyse, and the investigations of Armstrong and others (Chem. Soc. Proc. 1910, 334) indicate, that whilst the leaf enzyme (emulsin) is, as a rule, a specific for the glucoside normally occurring in the particular plant, the seed enzyme, especially that of the almond, is able to attack a number of glucosides. For this reason almond emulsin is considered to be a mixture of several closely related enzymes. According to H. E. and E. F. Armstrong and Horton (Proc. Roy. Soc. 1908. 80, 321), it contains a β-glucase

proper, which attacks β-glucosides; a *cyanase*, which eliminates hydrogen cyanide from amygdalin; an *amygdalase*, splitting off glucose from amygdalin; and a *lactase*, acting on milk sugar (*cf.* Rosenthaler, Arch. Pharm. 1910, 240, 105).

Almond emulsin hydrolyses β-glucosides and also the disaccharides, lactose, gentiobiose, cellose, and melibiose. It further hydrolyses the synthetical β-methylgalactoside. The emulsin of *Aspergillus niger*, on the contrary, has no action on lactose or on β-galactosides. In referring to emulsin, it is therefore advisable to specify the source of the enzyme.

Preparation.—Ground sweet almonds from which the fat has been expressed are macerated with water and a little toluene or chloroform at the ordinary temperature for 12–24 hours. The liquid is expressed through a cloth, protein precipitated with a few drops of acetic acid, and the clear filtrate precipitated with alcohol added 50 c.c. at a time till no further precipitate is formed. The liquid is decanted and the precipitate rapidly washed with absolute alcohol and ether to dehydrate it, and dried in a vacuum. Alternatively the original precipitate may be collected on a filter paper, dried roughly on bibulous paper, and dissolved in water in a closed bottle, to which a little toluene is added. The clear solution so obtained is very active, and retains almost constant activity for many months. It is essential to carry out this preparation as rapidly as possible.

The dried enzyme is a soft, white powder, giving most of the reactions of proteins, but losing these on purification. Its chemical nature has not been the subject of any detailed investigation. Active preparations are to be obtained in commerce.

Emulsin exhibits maximum activity in neutral solution. Alkali stops the action; small quantities of acids usually increase the activity, owing to their effect in neutralising alkaline impurity.

Experiments with emulsin are usually carried out at about 37°; the optimum temperature is 45°. Emulsin is less resistant to destruction by heat in presence of alcohol below 50 p.c., but above this point the reverse is the case, owing to the fact that in stronger alcohols the enzyme is precipitated, and in this condition is more resistant to heat. In sterilising plants containing enzymes it is best to use alcohol of such strength as to produce a liquid containing about 60 p.c. of alcohol (Bourquelot and Bridel, J. Pharm. Chim. 1913, 7, 65).

Emulsin. is detected qualitatively ,by its action on amygdalin, liberating hydrogen cyanide. The activity is tested quantitatively either against amygdalin or salicin, by measuring the amount of sugar formed in a given time.

Emulsin is also able to bring about synthetic change (Armstrong, Proc. Roy. Soc. 1905, B, 76, 592; van't Hoff, Sitzungsber. K. Akad. Wiss. Berlin, 1910, 48, 963). Emulsin exhibits hydrolytic activity in alcoholic solutions. Although unable to hydrolyse salicin in presence of 95 p.c. alcohol, it becomes active in 90 p.c. alcohol, hydrolysis continuing slowly until 37 p.c. of the glucoside has been decomposed. As the strength of the alcohol is diminished equilibrium is more rapidly attained, and a greater proportion of the salicin undergoes hydrolysis (Bour-

quelot and Bridel, Compt. rend. 1912, 154, 944). Similarly, emulsin is inactive when suspended in solutions of glucosides in acetone or ethyl acetate, but becomes able to effect hydrolysis when 10 p.c. of water is added to the acetone or the wet ester is used. When emulsin acts on a solution of glucose in 85 p.c. alcohol, the corresponding β-methyl or β-ethyl glucosides are formed, the same equilibrium point being reached in solutions containing originally glucose or alkyl glucoside. The more dilute the alcohol the greater is the hydrolysis and the less the synthesis (Bourquelot and Bridel, Compt. rend. 1912, 155, 319). The position of the equilibrium is independent of the quantity of emulsin added and of the temperature, but it varies with the strength of the alcohol and with the amount of glucose present. The property of emulsin to facilitate synthesis has been utilised by Bourquelot to prepare a large number of glucosides of the alcohols, including such substances as geraniol and glycol, and also the corresponding galactosides.

The emulsin contained in a number of plant preparations is able to hydrolyse *dl*-benzaldehyde cyanohydrin, and also to synthesise this compound from benzaldehyde and hydrocyanic acid. In some cases the synthesis is asymmetric, and an optically active cyanohydrin is formed (*cf.* Rosenthaler, Arch. Pharm. 1913, 251, 56).

(For a list of the glucosides attacked by emulsin, *v.* GLUCOSIDES.)   E. F. A.

ENAMEL BLUE. *Cobalt blue* (*v.* PIGMENTS).

ENAMELS are vitreous compositions capable of adhering by fusion to the surface of metal or of pottery. The base of the enamel is generally a colourless glass, in which are suspended particles of an opaque metallic oxide or salt, generally stannic oxide. Up to about 900°, tin dioxide exists finely suspended in the enamel, but at a higher temperature combination or solution may occur and opacity is diminished. Titanic oxide has been used in place of stannic oxide, and antimony compounds have been employed. Opacity may also be obtained by the use of arsenious oxide, calcium phosphate, cryolite, or fluorspar. A preparation known as 'artificial cryolite' sometimes replaces the mineral. When bone ash is used, a little nitre may be added to remove the grey colour; the nitre also prevents reduction of the lead. The vitreous base of most enamels is a glass containing much lead, but when the presence of lead is objectionable, as in enamelled vessels for culinary purposes, soda- and potash-glasses should be used. If great fusibility be required, it may be secured by the association of borates with the silicates. Borate enamels are very hard, but are deficient in elasticity, and may be affected by moisture. Colour is imparted to the enamels by the introduction of various compounds, generally metallic oxides, the use of which, in many cases, has been known from remote ages. Percy's analyses of the enamelled bricks of Babylonia (*circa* 700 B.C.) showed that a dense white was obtained by the use of stannic oxide; a rich yellow by means of antimony, apparently in the form of lead antimoniate ('Naples yellow'); and a deep blue by copper, probably introduced as oxide, but existing in the enamel as a copper sodium silicate. The ancient Egyptian blue enamel, or glaze,

contains a definite copper calcium silicate, forming crystals remarkable for their intense pleochroism, to which Fouqué gave the name of *vestorien* (Bull. Soc. Fr. Min. [12] 1889, 36) (*v.* EGYPTIAN BLUE). The ancient Egyptians seem to have been ignorant of the art of enamelling on metal.

The enamelling of pottery is a simple operation, since it consists in the mere fusion of an opaque glaze on to the surface of the ware. But the application of a vitreous body to a metallic surface is less easy, and it is to this process that the term 'enamelling' is sometimes restricted, while the works of art produced by enamelling on metal are themselves known as 'enamels.'

The most ancient enamels found in North-Western Europe are referable to the prehistoric Iron Age, sometimes distinguished as Late Celtic. In these ancient enamels, brilliantly coloured opaque glass is embedded in cells or shallow cavities in bronze : it is probable that the vitreous material was applied as a powder, mixed with a vehicle so as to form a paste, and then heated sufficiently to cause its fusion, and thus secure firm attachment to the metal.

A similar method, known as *champ levé* enamelling, was extensively employed at a much later date in Germany and at Limoges in France —a town which for centuries was the chief centre of artistic enamelling. In this process the design is traced on a plate of copper or bronze, and all the parts to be enamelled are excavated by the graver ; these hollows are then filled with enamel, which is afterwards fused, and the entire surface is finally ground smooth. The design thus appears in permanent colour, each tint being defined by ridges, or separated by areas, of metal which are the elevated parts of the original ground. The exposed metal is sometimes gilt.

Another and probably older method of inlaid enamelling is that known as *cloisonné* work. Here the design is outlined by strips of metal fixed to the metallic base, and the spaces between these bands are filled with enamel, which is then fused and the surface ground down. Each coloured area is, therefore, sharply separated from its neighbour by the edge of the metal fillet. Of this character were the early Byzantine enamels, which were generally executed on plates of gold. The Chinese have for many centuries (at least since the 13th) been extremely skilful in this work, and the Japanese have applied a similar method to the ornamentation of porcelain. The Japanese attach the cloisons to the base with a gummy cement, and even when the ground is a metal, they generally use no solder. In some *cloisonné* work the surface is not ground down, so that the fillets stand in relief above the general surface of the enamel.

The use of transparent enamels for the ornamentation of metalwork was introduced by the Italian goldsmiths of the 13th century, and afterwards became popular in France. The design was generally worked in low relief, or chased on gold or silver, and brilliant translucent enamels were applied in such a way that the varying thickness produced differences of tint. This style is known as *basse-taille*. In certain rare enamels, probably of the 15th century, the pattern is outlined by strips of metal without any foundation, and the spaces in this grating are filled in with coloured transparent enamels ; such *cloisonné* work is termed *plique-à-jour*.

Artistic enamelling has been largely used, not only for inlaid and encrusted work, but for the production of paintings on metal. The painted enamels of Limoges, introduced in the 15th century, were usually executed on slightly convex plates of copper, the subjects being generally in white and grey on a deep-violet ground ; but the process was extended to the decoration of dishes, ewers, and other objects, and various colours were employed, sometimes heightened with gold. In this country, enamel painting was largely practised, by the family of Bone, during the latter part of the 18th and the early years of the following century. While their smaller works, or miniatures, were executed on gold, the larger examples were on plates of copper. The copper plate, having been annealed and cleaned with dilute sulphuric acid, was coated on both sides with white enamel powder ; it was then fired, and the enamelled face ground smooth. This white enamel, which was rendered so opaque by means of stannic oxide as to conceal the metal ground, was imported from Venice in the form of round cakes. The surface to be painted was further prepared by the application of a second coat of enamel, more fusible and transparent than the first ; this material, known to the enameller as 'flux,' was used in the form of rods and beads of white Venetian glass. Upon the fluxed surface, carefully ground smooth, the painting was executed in enamel colours, or powdered glasses mixed with an appropriate vehicle ; and as it was necessary to vitrify each colour separately, a complicated subject would require several successive firings in a muffle, each liable to injure or spoil the work. Recent years have witnessed a great revival in artistic enamelling, with the introduction of various improvements in technical details.

In addition to art enamels, there is a growing demand for coarse work in enamelled sheet-iron for street plates, railway notices, and other advertisements, which are generally executed in blue and white. In applying enamel to metal it is necessary to use a material which will adhere firmly to the base ; at the same time, it must fuse at a temperature lower than that which softens the metal, or melts the solder if any be present ; and the enamel should have a coefficient of expansion by heat as nearly as possible that of the metal ground. It is obviously important that, when enamel is used as a lining for saucepans, stew-pans, and other vessels for culinary purposes, it should be free from all ingredients which are poisonous, or may become so by contact with food. An important industry has been developed in recent years, especially in Germany, Austria-Hungary, and France, in the manufacture of vessels for domestic use, in cast or sheet metal ; soft sheet steel is commonly used for hollow ware.

The object to be enamelled, having been carefully cleaned by pickling in an acid bath, is coated with a thin layer of ground enamel. This primary coating need not be opaque, and generally contains a little cobalt or nickel oxide. A suitable material is obtained, according to P. Randau, by fusing a mixture of flint or quartz 30 parts, borax 25, and felspar 30. This product is then ground with kaolin 10·75 parts, felspar 6,

and magnesia, 1·25 ; the clay tends to lessen the fusibility. The finely powdered ground enamel is mixed with water to a creamy consistency and applied to the ware, slightly heated ; after the coating has dried, the object is fired in a muffle furnace at a temperature rather under 1000°. After this stage of enamelling, the ware is scrubbed to remove scale, and a second coating is applied, this time opaque white. This enamel may be made, according to the same authority, from a mixture of flint 37·5 parts, borax 27·5, tin dioxide 30, soda 15, nitre 10, ammonium carbonate 7·5, and magnesia 7 ; this mixture is fritted and then ground with flint 6·12 parts, tin dioxide 3·66, soda 0·7, and magnesia 0·7. The cover enamel is suspended in water and spread over the ground enamel, and the ware is then carefully fired in a muffle at a lower temperature than that of the first firing. In some cases a third coat of enamel is applied, while in other cases the ground layer is dispensed with, and only a single white coating used. Finally the surface may be decorated by painting or transfer printing in enamel colours, or by photographs. In some enamels, like 'granite ware,' the colour is applied by spraying.

(On enamels, v. Sir H. H. Cunynghame, On the Theory and Practice of Art Enamelling upon Metals, 3rd ed. London, 1906 ; Lewis F. Day, Enamelling, London, 1907 ; Alexander Fisher, The Art of Enamelling upon Metal, London, 1906 ; Philip Eyer, Die Eisenemaillierung, Leipsig, 1907 ; Paul Randau, Die Fabrikation des Emails und das Emailliercn, Vienna, 4th ed 1909 ; Enamels and Enamelling, English translation of P. Randau by Charles Salter, London, 1900 ; Julius Grunwald, translated by Herbert H. Hodgson, The Theory and Practice of Enamelling on Iron and Steel, London, 1909.)   F. W. R.

ENARGITE. Copper sulpharsenate Cu_3AsS_4 or $3Cu_2S\cdot As_2S_5$, occurring as orthorhombic crystals with perfect prismatic cleavages and usually a prismatic habit. The colour is iron-black with a metallic lustre ; sp.gr. 4·44. It is not a common mineral, but in a few copper-mining districts, for example, at Butte in Montana, Morococha in Peru, and in the Sierra de Famatina in Argentina, it is of some importance as an ore of copper.   L. J. S.

ENDIVE. *Cichorium endivia* (Linn.), the blanched leaves are used as a salad or garnish.

According to Konig, their average composition is—

				Other carbohydrates			
Water	Protein	Fat	Sugar	hydrates	Fibre	Ash	
94·1	1·8	0·1	0·8	1·8	0·6	0·8	

There are two chief varieties—with crinkled leaves and with smooth leaves. The former is apparently richer in nitrogen and ash, but poorer in carbohydrates (Dahlen, Landw. Jahrb. 1874, 3, 312, and 4, 614).

An analysis of the ash of endives by Richardson (Annalen, 67, 377) gave the following figures :—

| K_2O | Na_2O | CaO | MgO | SO_3 | P_2O_5 | SiO_2 | Fe_2O_3 |
| 37·9 | 12·1 | 12·0 | 1·8 | 5·2 | 3·0 | 24·6 | 3·4 |

ENSILAGE is a process of preserving green fodder for cattle. The term *silo* is applied to the pit or other depository in which the fodder (*silage*) is contained, and appears to be of Basque derivation, and originally meant a pit for storing grain. This method of preserving grass and other succulent forage crops has been in use for many years in Germany, whence the practice was carried to France, and afterwards to America. Although the German system had been fully described by Johnston, in 1843, in the Transaction of the Highland Agricultural Society (new series, 9), no general notice of it was taken in these islands until 1882, when a report of the British Legation at Washington on ensilage, as practised on Mr. Havemeyer's estate in New Jersey, was published as a blue-book, since which time many silos, of varying forms and construction, have been made in this country The object of all these is to exclude the air from the mass of fodder, allowing only a greater or less fermentation according to the practice of different authorities ; and to this end silos have been formed (1) wholly or partly underground ; (2) in the form of enclosed buildings. Silage has also been largely made by building up the green fodder in the form of an ordinary stack, of which only the top is covered. Whether it be silo or stack, the principal factor is the superposition of a sufficient pressure, either by dead weight or by some mechanical system of screws, levers, or similar appliances. The changes which forage undergoes in the silo are due to fermentation, and, as may be supposed, this action varies considerably with the materials stored and with the condition of storage ; as, for example, green maize undergoes principally lactic fermentation ; whilst in English fodder fermentation produces alcohol which is almost immediately converted into aldehyde. If the air has not been properly expelled from the silo, or if the fodder has been pitted in a very damp condition, the aldehyde becomes quickly converted into acetic acid.

Silage is of two kinds—viz. 'sweet' and 'sour.' Sweet silage is the result of allowing the grass to remain without pressure, and so permitting air to mingle with it until such time as a temperature of 125° to 150° F. is reached by the fermentation process ; sour silage, on the other hand, results when pressure is at once applied, whereupon an acetic or lactic fermentation takes place. It appears that a temperature of about 125° is sufficient to kill the bacteria which produce acid fermentation ; 'if the bacteria are killed and the silo is covered and weighted, the enclosed mass of green fodder will remain sweet, and be practically preserved under the same conditions as fruits, vegetables, or meats are preserved when canned. If this be the case, it will be at once intelligible that by less packing of the fodder when put into the silo, and extending the time of filling until the temperature rises to a point fatal to the bacteria, the resulting silage will be sweet and free from

acidity; whilst sour silage is produced by at once consolidating, covering up, and weighting the grass fodder so as to prevent the temperature rising to the point fatal to the bacteria (A. Voelcker, J. Roy. Agric. Soc. 20).

Two samples of sweet silage showed only a trace of acid, not exceeding in quantity that contained in ordinary fresh meadow grass :—

	Silage made from	
	Clover and rye grass mixed	Meadow grass
Moisture . . .	75·80	74·40
*Albuminoids . . .	2·53	2·56
Sugar and other carbohydrates soluble in water	1 43	2 99
Crude vegetable fibre .	18 31	17·90
Mineral matter (ash) .	1·93	2·15
	100·00	100·00
*Containing nitrogen .	0 40	0·41
Volatile acids (calculated as acetic acid) . . .	0 01	0 04
Non-volatile acids (calculated as lactic acid) . .	0 01	0·02

A sample of sour silage made from grass placed in a heavily weighted silo showed the following composition :—

Water . . .	76·01
Soluble albuminoids .	0 91
Insoluble albuminoids .	1·78
Soluble carbohydrates .	2 87
Crude fibre . .	15 82
Soluble mineral (ash) .	1·63
Insoluble mineral matter (ash)	0·98
	100 00
Total nitrogen . .	0·43
Volatile acids (calculated as acetic acid) . .	0 19
Non-volatile acids (calculated as lactic acid) . .	1·24

This silo was provided with a tap at the bottom from which juice was drawn off from time to time. This drainage had a sp.gr. of 1·022, and contained, per imperial gallon :

	Grains
Albuminoids . . .	1,008·56
Fixed acid (lactic acid) .	516·42
Volatile acids (butyric and acetic acids) . .	476·70
*Carbohydrates and amides	1,528·42
Mineral matters (ash) .	1,768·20
Water . . .	64,701·70
	70,000·00

*Containing non-albuminous nitrogen . . . 35·84

The dry matter (dried at 100°) which was left on evaporation of its drainage contained :

*Albuminoids . . .	20·90
Lactic acid . . .	10·71
†Carbohydrates and amides .	31·73
Mineral matter (ash) . .	36·66
	100·00

*Containing nitrogen . . 3·34
†Containing nitrogen . . 0 51

The subject of changes during ensilage has been very carefully investigated both at Rothamsted by Lawes and Gilbert, and at Woburn by Voelcker. The results obtained present a striking similarity, and it will suffice if one set of tables (those of Dr. Voelcker) is referred to here, although the Experiments on Ensilage conducted at Rothamsted (Lawes and Gilbert) should also be read. The silo to which these figures relate was one made at Woburn in 1886, and was of the character generally termed 'sour.' It was weighted with stones in strong elm boxes to 112 lbs. per square foot, and was unprovided with any drain. The silo was closed on July 3 and opened on December 16, the contents being 'very fair,' although 'not really fine,' meadow grass. The numbers, in a condensed form, are given in the following table.

QUALITY AND COMPOSITION OF THE GRASS PUT INTO SILO, AND OF THE SILAGE PRODUCED.

	Total weight	Water	Volatile acids	Non-volatile acids	Soluble albuminoids	Insoluble albuminoids	Digestible fibre	Woody fibre	Soluble carbohydrates, &c.	Soluble mineral matter	Insoluble mineral matter	Total nitrogen	Albuminoid nitrogen	Non-albuminoid nitrogen
	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.	lbs.
Grass put in silo	32,780	23,108	—	—	47	733	3278	2670	2265	430	249	151	123	28
Silage removed .	30,389	22,035	109	106	197	252	2326	2409	2254	471	230	155	73	82
Loss . . .	2,391	1,073	+109	+106	+150	481	952	261	11	+41	19	+4	50	+54
Loss per 100 lbs. of fresh grass .	7·29	3·27	+0·33	+0·32	+0·46	1·47	2·90	0·79	0·03	+0·12	0·06	+0·01	0·15	+0·16

The main features shown in the table are as follows : The total loss due to fermentation, evaporation, &c., in making the silage was 7·29 p.c. on the fresh grass. Of this, 3½ p.c. consisted of water, so that the loss in dry matter was only about 4 p.c. The loss of total nitrogen when, as here, no drainage was allowed to flow away is very slight ; but the nitrogenous bodies have undergone considerable change from the albu-minoid to the non-albuminoid condition, the fibre has been diminished, insoluble albuminoids have been lessened, and soluble albuminoids increased (Voelcker, J. Roy. Agric. Soc. 23, 410).

Since the nutritive value of food depends to a considerable extent on the albuminoid compounds contained in it, it becomes of importance from the economic point of view to determine the quantity of such compounds in fresh green

food and in silage. Kinch found that 55 p.c. of the total nitrogen present in the silage of grass was of a non-albuminoid nature, whilst in the original grass only 9 p.c. was of this form. In the case of mangold leaves, Kellner found that of the total nitrogen present, 27·8 p.c. in the original leaves, 45·5 p.c. in the silage, and as much as 59·7 p.c. in silage preserved in stoppered jars, was non-albuminoid. Clifford Richardson, examining maize silage, found :

	Per cent. total nitrogen as non-albuminoid
Original stalks . . .	21·2
Silage No. 1 . . .	44·6
„ No. 2 . . .	49·6
Dried fodder . . .	15·6
Silage from young maize .	53·3
„ „ older „ .	47·1

These results with grass, mangolds, and maize show that in ensilage a large portion of the albuminoids is converted into non-albuminoid nitrogenous substances, whilst in the ordinary drying of fodder no such change seems to take place. This is made clear by a reference to Dr. Voelcker's table given above under the heading ' Quality and composition,' &c., where the woody fibre, as indeed the whole of the fibre, has been diminished, insoluble albuminoids are lessened, and the soluble albuminoids increased.

Ensilage is largely practised in Canada and in America for the sake of having a supply of 'green' fodder during the winter months, especially in Canada where the winter is long. In England, since the interest attaching to novelty has waned, it has gradually died out of practice, except as a resource for adoption in unusually wet seasons, when haymaking is impossible or is so long delayed as to threaten loss of the crops. In such circumstances those who possess the simple tackle necessary for putting up silage stacks in the open field have a material advantage over their neighbours. Otherwise, in a country in which roots are easily grown and preserved for winter use, and where the actual period of the year in which vegetation is suspended is comparatively short, it would seem preferable, having regard to the deterioration which occurs in ensilage, especially as regards albuminoids, to adhere to the more ordinary practice of hay-making.

The application of silage as fodder and its practical effects with stock have been carefully investigated both at Rothamsted and Woburn.

(See Report on the Practice of Ensilage at Home and Abroad, Jenkins in J. Roy. Agric Soc., new series, 20 ; On the Chemistry of Ensilage, Voelcker, ibid. ; Experiments on Ensilage conducted at Crawley Mill Farm, Woburn, 1884–5 and 1885–6, Voelcker, ibid. 22 ; Experiments on Ensilage conducted at Crawley Mill Farm, Woburn, 1886–7, Voelcker, ibid. 23 ; articles in the Agricultural Gazette, April 27, 1855 et seq., by Sir J. B. Lawes and Sir Henry Gilbert, reprinted in pamphlet form under the title of Experiments on Ensilage conducted at Rothamsted.)

ENSTATITE. Metasilicate of magnesium, usually with some ferrous oxide isomorphously replacing magnesia, $(Mg,Fe)SiO_3$, and with increasing iron passing into bronzite and hypersthene. It belongs to the orthorhombic series of the pyroxene group, and is of importance as a rock-forming mineral and as a constituent of meteoric stones. Rarely it is clear and transparent and of a rich green colour, when it is used as a gem-stone ; such material is found in the ' blue ground ' of the South African diamond mines. L. J. S.

ENTEROL v. SYNTHETIC DRUGS.

ENZYMES and **ENZYME ACTION** v. FERMENTATION ; BARLEY ; CHEMICAL AFFINITY.

EOSAMINE v. AZO- COLOURING MATTERS.

EOSIN v. TRIPHENYL METHANE COLOURING MATTERS.

EOSOTE v. SYNTHETIC DRUGS.

EPHEDRINE, $C_{10}H_{15}ON$, crystals, m.p. 39°, b.p. 225°, occurs in Ephedra vulgaris. It is a secondary base, furnishes crystalline salts, and on ' exhaustive methylation ' yields eventually trimethylamine and a-phenylallyl alcohol $C_9H_{10}O$. On distillation the hydrochloride furnishes methylamine and propiophenone. When heated with hydrochloric acid, ephedrine undergoes isomerisation to ψ-ephedrine (isoephedrine), crystals, m.p. 117°, which also occurs with it in E. vulgaris. Both bases are poisonous and ephedrine hydrochloride has been used as a mydriatic (Ngai, Chem. Zentr. 1894, i. 470 ; Merck's Bericht, 1893, 13 ; Ladenburg and Oelschlägel, Ber. 1889, 22, 1823 ; Miller, Arch. Pharm. 1902, 240, 481 ; Flaecher, ibid. 1904, 242, 380 ; Schmidt and collaborators, ibid. 1905, 243, 73 ; 1906, 244, 239, 241, 269 ; 1908, 246, 210 ; 1909, 247, 141 ; 1911, 249, 305 ; 1913, 251, 320 ; Apoth. Zeit. 1911, No. 37 ; Fourneau, J. Pharm. Chim. 1904, [vi.] 20, 481 ; Emde, Arch. Pharm. 1907, 245, 662 ; Gadamer, ibid 1908, 246, 566 ; Calliess, Apoth. Zeit. 1910, 25, 677). According to Rabe (Ber. 1911, 44, 824) the ammonium base of ephedrine decomposes into water, trimethylamine and ɑ-phenylpropylene-αβ-oxide, and he regards ephedrine and ψ-ephedrine as optically isomeric β-methylamino-α-phenyl-propane-α-ols $OH·CHPh·CHMe·NHMe$ (cf. Emde, l.c.). This view is shared by Schmidt (Arch. Pharm. 1914, 252, 89 ; 1915, 253, 52), who considers the isomerism due to the difference in the spatial arrangement of the -- CHOH group. Cf. also Eberhard (Arch. Pharm. 1915, 253, 62). ɑ-Ephedrine has been synthesised by Nagai (Eng. Pat. 120936) and shown to differ from Fourneau's products and to be the racemic form of the natural variety (see Chem. Soc. Abst. 1919, i. 92).

The name ephedrine has also been applied by Spehr to a crystalline alkaloid $C_{13}H_{19}ON$, m.p. 112°, obtained from Ephedra monostachya, a drug used as a remedy for syphilis and gout in Bessarabia and Wallachia. Ordinary ephedrine is known commercially as ' ephedrine (Merck) ' and the second species as ' ephedrine (Spehr).'

EPICARIN,

$$HO·C_{10}H_6·CH_2 \diagdown \diagup OH \quad COOH$$
A derivative of β-naphthol used in the treatment of skin diseases. V. SYNTHETIC DRUGS.

EPICHLORHYDRINS a-epichlorhydrin (γ-chlorpropylene oxide) $CH_2·CH·CH_2Cl$ with an O bridge. Prepared by treating glycerol with phosphorus pentachloride or by heating the dichlorhydrins with

hydrochloric acid (Berthelot, Ann. Chim.&Phys. [3]·41, 299) ; by treating a- or β-dichlorhydrin with caustic potash (Reboul, Annalen, Spl. 1, 221 ; Tollens and Münder, Zeitsch. Chem. 1871, 252 ; D. R. P. 239077), or with alkali carbonates or alkaline earth hydroxides (D. R. P. 246242). Glycerol is treated with hydrogen chloride at 120°-130°, and the product distilled *in vacuó*. The fraction boiling at 50°-120°, which contains the dichlorhydrins, is treated with strong caustic potash solution, and the product distilled *in vacuó*. The portion boiling below 75° is washed with water and distilled. The fraction boiling at 118°-119° is crude epichlorhydrin, and may be purified by redistillation *in vacuó* (Fauconnier, Bull. Soc. chim. ii. 50, 212). Mobile liquid with odour resembling that of chloroform ; b.p. 116·6° (corr.) ; sp.gr. 1·2031 at 0°/4° (Thorpe, Chem. Soc. Trans. 1880, 206) ; insoluble in water. With sodium in ethereal solution epichlorhydrin yields allyl alcohol and the diallyl ether of glycerol (Tornoi, Ber. 1888, 1209 ; Kijner, J. Russ. Phys. Chem. Soc. 24, 31) ; by heating with alkyl iodides, chloriodohydrin alkyl ethers are produced (Paal, Ber. 1888, 2971) ; ammonia gas converts it into trichlorhydroxypropylamine (Fauconnier, Compt rend. 107, 115) ; with potash in the presence of an alcohol, it yields the corresponding dialkyl ether of glycerol (Zunino, Atti. Real. Accad. Lincei, 1897, ii. 348 ; 1907, 9, i. 309) ; with phenols and sodium ethoxide, glyceryl diaryl ethers are formed ; whilst with sodium hydroxide, glycide aryl ethers are produced (Boyd and Marle, Chem. Soc. Trans. 1908, 838 ; 1909, 1803 ; Zunino, Atti. Real. Accad. Lincei, 18. i. 254 ; Cohn and Plohn, Ber. 1907, 2597 ; Lindemann, *ibid.* 1891, 2145) ; concentrated nitric acid oxidises it to β-chlorlactic acid ; alcoholic ammonia and ethylsodiomalonate convert it into chlorhydroxypropylmalonamide (Traube and Lehmann, Ber. 1899, 720) It combines with acid chlorides to form dichlorhydrin esters. Haller and March have synthesised ketolactonic acids and other unsaturated compounds by condensing epichlorhydrin with the sodium derivatives of benzoyl acetic esters of acetone dicarboxylic ester and of acetylacetone (Compt. rend. 132, 1459 ; 136, 434 ; 137, 11, 1203). It has also been condensed with aniline (Fauconnier, *ibid.* 106, 605 ; 107, 250) ; with p-toluidine (Cohn and Friedlander, Ber. 1904, 3037) ; with prussic acid (Lespieau, Compt. rend. 127, 965), and with salicylic acid (Lange, D. R. P. 184382 ; Chem. Soc. Abstr. 1906, i. 930). Organomagnesium compounds react with it to form substituted chlorhydrins of the type

$$R·CH{<}^{CH_2OH}_{CH_2Cl}$$
(Riedel, Chem. Zentr. 1907, i. 1607 ; D. R. P. 183361 ; Fourneau and Tiffeneau, Bull. Soc. chim. 1, [4] 1227). Epichlorhydrin has been used as a solvent for resins for photographic purposes (Phot. Korr. 1899, 2).

β-*Epichlorhydrin* (β - *chlorpropylene oxide*)

$$\overset{\text{—O—}}{CH_2·CHCl·CH_2}.$$ Obtained together with the a- compound and other products by treating the chloriodohydrins formed by treating allyl alcohol with iodine monochloride, with dry sodium hydroxide (Bigot, Ann. Chim. Phys. 22,

[6] 468). Liquid ; b.p. 132°-134°. Phosphorus pentachloride converts it into $\beta\gamma$-dichloropropylene, and sodium amalgam into allyl alcohol.

Polymerides. $(C_3H_5OCl)_2$. Obtained in the preparation of pyrazine bases by the distillation of glycerol with ammonium phosphate and ammonium chloride ; by treating the high-boiling fractions with hydrochloric acid, it is obtained crystalline ; m.p. 112°-113° ; b.p. 232°-233°. Readily soluble in hot alcohol, sparingly soluble in water.

$(C_3H_5OCl)_5$. Obtained by treating a-epichlorhydrin with hydrofluoric acid in a platinum dish. Yellow oil, soluble in alcohol, benzene, ether, or acetic acid. Dilute sulphuric acid at 200° converts it into a substance resembling cellulose (Paternò and Olivieri, Gazz. chim. ital. 24, i. 305 ; ii. 541).

Chlorbutylene oxide C_4H_7OCl. Obtained by treating a mixture of butenylglycerol and glacial acetic acid with hydrogen chloride ; b.p. 125·5° (corr.) at 738 mm. ; sp.gr. 1·098 at 15°/0 (Zikes, Monatsh. 6, 352).

EPIDIORITE. A rock consisting essentially of plagioclase-felspar and hornblende, and with a more or less marked schistose structure. It has been formed by the action of pressure-metamorphism on dolerite (*q.v.*), the augite of which has been thereby transformed into hornblende. Rocks of this class are of wide distribution, and being tough and hard they are much quarried for road-mending, for example, in Cornwall. Auriferous quartz-veins are often associated with epidiorites. L. J. S.

EPIDOTE. Basic silicate of calcium, aluminium, and ferric iron, $HCa_2(Al,Fe)_3Si_3O_{13}$, the alumina and ferric oxide replacing one another isomorphously, Fe_2O_3 ranging from 1·6 p.c. (in the clinozoisite variety) to 17 p c. The monoclinic crystals are usually much elongated in the direction perpendicular to the plane of symmetry, the habit thus being prismatic. The colour ranges from green to brown, and is usually a characteristic yellowish-green resembling that of a pistachio-nut, hence the name pistacite sometimes applied to this mineral. Sp gr. 3 3 –3·5 ; H. 6–7. Good crystals are found at many localities, and very fine ones at the Knappenwand in the Untersulzbachthal in Salzburg. These are of a deep green colour and are sometimes cut as gem-stones. Epidote is strongly pleochroic, and when manganese (Mn_2O_3) enters isomorphously into the composition this character becomes still more pronounced. This is seen in the withamite variety from Glencoe, Scotland, and in the cherry-red manganese-epidote (piedmontite) from San Marcel, Piedmont. As a rock-forming mineral epidote is abundant in crystalline schists and metamorphic rocks ; and it is often present in weathered igneous rocks. A rock composed of epidote and quartz is known as *epidosite* or epidote-schist, and sometimes carries gold. Banded epidosites have been used as ornamental stones. L. J. S.

EPINEPHRINE *v.* ADRENALINE ; also SYNTHETIC DRUGS.

EPININE. Trade name for 3.4-Dihydroxy-phenylethylmethylamine. *See* ADRENALINE.

EPIOSINE. Trade name for 1.methyl.4.5-diphenylene imidazole.

EPIRENAN *v.* SYNTHETIC DRUGS.

EPRONAL. Ethylpropylacetylurethane.

EPSOM SALTS. *Magnesium sulphate* (v. MAGNESIUM).

EPSOMITE or Epsom Salts, $MgSO_4,7H_2O$, as a mineral usually occurs as silky white fibres forming efflorescences in limestone caves, mine galleries, &c. Crystals are orthorhombic with spheroidal hemihedrism and a prismatic habit, the prism angle being nearly a right angle (89° 26′). Although good crystals are readily obtained by artificial means, in nature they are of rare occurrence. They have, however, been found in the salt deposits at Stassfurt in Prussia; where also a massive variety (' reichardtite ') ferms thin layers in carnallite. This epsomite is no doubt derived by the hydration of the more abundant kieserite, $MgSO_4,H_2O$. In Albany Co, Wyoming, and on the border of British Columbia and Washington, there are several small lakes containing rich deposits of compact white epsomite. At Epsom in Surrey, from which place the name is derived, the salt occurs only in solution in mineral waters

L. J. S.

ERBIUM or Neo-Erbium Sym. Er. At wt. 167·7. A dark-grey powder; sp.gr. 4·77 at 15° (S. Meyer, Monatsh 1899, 20, 793).

Sources.—Ytterbite (gadolinite), yttrotantalite, euxenite, xenotime.

The oxide of this metal belongs to the group of yttrium earths, forming with dysprosium and thulium the erbium sub-group, the salts of which are distinguished by their colour and by their characteristic absorption spectra in solution.

Separation and purification of the yttrium earths. The following methods have been employed in separating the closely related members of the yttrium earths :

1. *Fractional decomposition of nitrates* (Bahr and Bunsen, Annalen, 1866, 137, 1). The nitrates, heated until nitrous fumes are evolved, leave a vitreous residue of basic nitrates, the solutions of which, in hot water, slowly deposit, on cooling, small pink needles containing the greater proportion of the coloured erbium earths. The crystals are extracted with 3 p.c nitric acid, the solution evaporated, the residue again heated, and the whole series of operations repeated many times. The erbium earths accumulate in the less soluble basic salts, whilst the remaining yttrium earths, and any cerium earths which may be present, accumulate in the final mother liquors, and are not readily freed completely from the erbium earths. Further separation is effected by heating these nitrates from the final mother liquors so strongly that the residue consists of oxides mixed with insoluble basic nitrates. On extraction with water, the erbium compounds remain dissolved, and the operation is repeated till the more soluble yttrium salts no longer show absorption bands.

According to Wichers, Hopkins and Balke (J. Amer. Chem. Soc. 1918, 40, 1615) the nitrate fusion method is very efficient for separating erbium and yttrium and is much better than any of the later methods, although the cobalti-cyanide and the nitrite precipitation methods (v. supra) are both good, the latter being the more practicable and efficient.

2. *Differences in the solubility of the oxides.* —The oxides are mixed with water and treated

with an amount of nitric acid insufficient to convert the oxides into normal nitrates. The mixture becomes hot, and, after cooling, concentrated nitric acid is added until the product assumes a reddish tint. The precipitate is then digested with alcohol, which dissolves the normal nitrate, to the exclusion of the basic nitrates. The latter consists chiefly of erbium salts mixed with some ytterbium and scandium compounds, the more basic yttrium and cerite metals passing into solution. The final separation of erbium from ytterbium and scandium is effected by fractionally precipitating the basic nitrates by adding oxides to the solution of normal nitrates. In this operation ytterbium and scandium are precipitated as basic nitrates, while erbium remains dissolved (v. Drossbach, Ber. 1902, 35, 2826).

3. *Fractional precipitation by alkalis or aniline.*—The addition of ammonia to hot solutions of the salts of the yttrium group occasions the precipitation of basic salts which are easily filtered.

The neutral chloride dissolved in 50 p.c. alcohol is decomposed at 90° with alcoholic aniline, or the hydroxide is treated with aniline hydrochloride in aqueous solution (Drossbach, Ber 1896, 29, 2452 ; Mullmann and Baur, ibid. 1900, 33, 1748 ; 1902, 35, 2382 ; Urbain, Compt. rend. 1901, 132, 136 ; Kruss, Annalen, 1891, 265, 1 ; Zeitsch. anorg. Chem. 1893, 3, 108, 353, 407)

4. *Fractionation with ammonium carbonate and acetic acid* —The hydroxides of the yttrium group are moderately soluble in concentrated aqueous ammonium carbonate, and from this solution the earths may be fractionally precipitated by acetic acid (Dennis and Dales, J Amer. Chem. Soc 1902, 24, 400).

5. *Fractionation of oxalates, acetates, acetylacetonates, ethylsulphates* (Urbain, Ann. Chim. Phys. 1900, [7] 19, 184 ; Marc, Ber. 1902, 35, 2370) ; formates (K. A. Hofmann, ibid. 1908, 41, 308), ferrocyanides (Bohm, Die Darstellung der seltenen Erden) ; bromates (James, J. Amer. Chem Soc. 1908, 30, 182) ; chromates (Kruss and Zoose, Zeitsch. anorg. Chem. 1893, 3, 92).

Various methods of separation of erbium from yttrium have been examined by Willand and James (J. Amer Chem. Soc. 1916, 38, 1198), who find that fractional precipitation with (1) sodium nitrite; (2) with potassium · cobalti-cyanide from a hydrochloric acid solution; (3) with sodium phosphate from a dilute nitric acid solution of the oxides on the whole yield the best results. In all three methods the last fraction was obtained by the addition of oxalic acid to the final liquors.

Erbia (*erbium oxide*) Er_2O_3. A pink powder obtained by heating the oxalate at 575°–845° ; sp.gr. 8·64 ; sp.ht. 0·065. So prepared is apt to retain carbon dioxide.

The salts of erbium have a pink or reddish colour, a sweet, astringent taste, and their solutions exhibit characteristic absorption bands in the red, green, and blue regions of the spectrum. The wave lengths corresponding with the two most prominent bands are as follows : λ 522·5–523·5 and 647·5–651·5.

Unless ionic dissociation is repressed, dilute solutions of the various erbium salts exhibit

identical absorption spectra (Zeitsch. physikal. Chem. 1906, 56, 624 ; v. Purvis, Proc. Camb. Phil. Soc. 1903, 12, 202, 206). The absorption bands undergo displacement when the solutions are placed in a magnetic field (J. Becquerel, Compt. rend. 1907, 145, 1412).

(For accounts of the flame, spark, and arc emission spectra, v. Thalén, ibid. 1880, 91, 326 ; Exner and Haschek, Wien. Akad. Ber. 1899, 108, IIa, 1071, 1123 ; • Eder, Chem. Zentr. 1916, i. 242 ; ibid. ii. 455.) . According to Eder erbium is probably complex.

Erbium salts exhibit signs of radio-activity (Strong, Amer. Chem. J. 1909, 42, 147).

Erbium sulphate $Er_2(SO_4)_3,8H_2O$. Pink monoclinic crystals, separating from aqueous solution at $20°$-$25°$; isomorphous with the corresponding yttrium, praseodymium, and neodymium salts (Kraus, Zeitsch. Cryst 1901, 34, 307).

The double sulphates $Er_2(SO_4)_3,K_2SO_4,4H_2O$ and $Er_2(SO_4)_3,(NH_4)_2SO_4,4H_2O$, are readily soluble in cold water.

Erbium nitrate $Er(NO_3)_3,5H_2O$. Large reddish crystals stable in air. When heated on platinum wire, the nitrate imparts an intense greenish colour to the flame, which, when viewed through the spectroscope, shows bright lines in the yellow-green and orange-blue regions of the spectrum. These bright lines correspond in position with the dark bands of the absorption spectrum.

Erbium formate $Er(CHO_2)_3,2H_2O$. Crystallises from cold aqueous solution.

Erbium oxalate $Er_2(C_2O_4)_3,10H_2O$ (K. A Hofmann, Ber. 1910, 43, 2631) is a reddish, sparingly soluble microcrystalline powder

Erbium platinocyanide $Er_2[Pt(CN)_4]_3,21H_2O$, like the corresponding yttrium salt, crystallises in red prisms with a green metallic reflex. For other salts, see Morgan and James, J. Amer. Chem. Soc. 1914, 36, 10 ; Katz and James, ibid. 1913, 35, 872. G. T. M.

ERECTHIDIS OIL consists of a terpene $C_{10}H_{16}$, which boils at 175°, and at 18·5° has a sp.gr. of 0 838. This body absorbs a molecule of hydrochloric acid without the separation of a crystalline compound. The portion of the oil which boils above 200° also consists of a terpene (Beilstein and Wiegand, Ber. 15, 2854).

EREPSIN v. Enzymes, art. FERMENTATION.

ERGAMINE, ERGOSTEROL, ERGATHI-ONEÏNE, ERGOTIN, ERGOTININE, ERGO-TOXINE v. ERGOT.

ERGOT OF RYE. Spurred rye ; Ergota, B.P. ; U.S.P. Secale cornutum. (Ergot de seigle, Fr. ; Mutterkörn, Ger.) Ergot of rye consists of the dried sclerotium (resting stage) of the fungus Claviceps purpurea (Tulasne) developed from the ovary of the rye (Secale cereale). The grains are dark violet-black, 1–4 centimetres long, slightly curved and tapering at both ends. The same or a closely related fungus occurs on a number of other grasses, wild and cultivated, and on some Cyperaceæ. The first definite mention of ergot which the writer has been able to trace, is in the 1582 edition of Adam Lonicer's Kreuterbuch, cap. ccclxx. p. 285, where its use by midwives is also referred to. From an account by the medical faculty of Marburg, published in 1597, down to the middle of the

19th century, there is a voluminous literature in German and in French, on ergotism ; there seems little doubt, however, that the epidemic ignis sacer of the Middle Ages was also due to the presence of ergot in flour (cf. Ehlers, L'ergotisme, Paris, 1896). Only one outbreak of ergotism in England (due to wheat) has been described (Phil. Trans. Roy. Soc. 1762, 52, 530). The use of ergot by midwives was forbidden in several countries about 1770–1780, but in the second decade of the last century it was definitely introduced into scientific medicine by the American physicians Prescott and Stearns, and now ergot is only important as a drug, being chiefly employed as a stimulant of uterine muscle. In the United States ergot growing on wild grasses (especially on species of Elymus, cf. also Amberg, Schweiz. Woch. Chem. Pharm 1911, 49, 489), has occasionally given rise to extensive poisoning of horses and cattle. Further botanical and historical details are given by Fluckiger and Hanbury, p. 740. Cooke, Brit. Fungi, 772 ; Pharm J. [iii.] 1, 702 ; Parsons, Rep U.S. Commissioner Agriculture, 1880, 136 ; Holmes, Pharm. J. 1886, [iii.] 16, 684 ; Kobert, Historische Studien, Halle, 1889 ; Carruthers, Rep. Roy. Agric. Soc. 1874, [ii.] 10, 443 (with illustrations of ergot on other grasses).

The chief commercial varieties of ergot of rye come from Russia and from Spain. ' Bold ' ergot with large grains, is probably of no special value, because several writers agree that the larger grains have a smaller percentage of alkaloid than the smaller ones. Although they are not official, other ergots, growing on wild grasses, deserve attention as a source of alkaloid. E.g. that on Monilia cærulea has been found to contain as much as 0·81 p c. Festuca ergot contains 0·34 p c. (Pharm. J. 1913, 130). Perhaps ' Diss' ergot on Ampelodesmostenax (Link.), occurring along the coast of Algeria, might thus be utilised (cf. Germaix et Chassang, Rev. méd. et pharm. de l'Afrique du Nord, Alger, 1898, 1, 45, 78, 113, 146, 184 ; also Holmes, Pharm. J. 1886, [iii.] 16, 684). Diss ergot has better keeping properties than ergot of rye, about which the Brussels Conference agreed that it should not be more than one year old and should be preserved entire. The rapid deterioration of ergot seems to be due to oxidation, which is favoured by the presence of the oil. Hence removal of the latter by light petroleum has been recommended. Aymonier (J. Pharm. Chim. 1897, [vi.] 6, 359) suggests coating the ergot •with a dilute ethereal solution of tolu balsam.

The literature on the chemistry of ergot is as voluminous as that on ergotism. The first investigation is recorded by J. G. Model in his Chymische Nebenstunden (Wittenberg, 1771), seven years after von Münchhausen had first recognised the drug as a fungus. Among older writers we need, however, only mention here Tanret (Compt. rend. 1875, 81, 896), who first obtained the crystalline alkaloid ergotinine, and Buchheim (Arch. exp. Path. Pharm. 1874, 3, 1) who, albeit without experimental evidence, expressed the view that the activity of ergot is due to decomposition products of protein. The active principles of ergot have only been obtained pure in recent years. They

are a complex alkaloid and some simpler bases.

Ergotoxine $C_{35}H_{41}O_6N_5$, m.p. 162°-164°, an amorphous alkaloid yielding crystalline salts, of which the *phosphate* $C_{35}H_{41}O_6N_5.H_3PO_4H_2O$, m.p. 187°-188°, is the most readily obtainable (Barger and Carr, Chem. News, 1906, 94, 89; Trans. Chem. Soc. 1907, 91, 337; Barger and Ewins, *ibid.* 1910, 97, 284; 1918, 113, 235). This alkaloid had been obtained in an impure form as 'amorphous ergotinine' by Tanret, and was termed hydroergotinine by Kraft (Arch. Pharm. 1906, 244, 336; 1907, 245, 644), who, without analyses, first recognised it as a hydrate of Tanret's ergotinine.

The alkaloids of ergot are best obtained on a small scale by extracting the powdered drug with ether and shaking the ethereal solution with a weak acid (citric, tartaric). Excess of strongly ionised mineral acids precipitates the salts of the ergot alkaloids, which, on account of their high molecular weight, are semi-colloids. This property led many of the earlier investigators into error, but may be put to account when working on the large scale. The residue left on evaporation of an alcoholic tincture of ergot is extracted with light petroleum, to remove the fat. It is then dissolved in ethyl acetate and shaken with citric acid; sodium bromide solution then precipitates the mixed hydrobromides almost quantitatively. The latter are dissolved in dilute caustic soda, from which ether removes only ergotinine. The caustic soda solution is then neutralised, made alkaline with sodium carbonate and extracted again with ether. The crude ergotoxine left on evaporation, together with that from the mother liquors of the crystallisation of ergotinine (see below), is dissolved in 80 p.c. alcohol and a slight excess of syrupy phosphoric acid in alcohol is added. On standing for a few days the ergotoxine phosphate crystallises in thin needles, which on recrystallisation from 50 parts of 90 p.c. alcohol may be transformed into broad plates. They are soluble in 313 parts of cold and 14 parts of boiling 90 p.c. alcohol. By shaking with cold distilled water a 1 p.c. solution is obtainable, which is strongly opalescent and sets to a thick jelly on the addition of electrolytes. For physiological experiments ergotoxine is best dissolved in dilute sodium hydroxide.

Ergotinine, although not physiologically active, may be considered here. The alkaloid left on evaporation of its ethereal solution (above) readily crystallises from absolute alcohol in needles, m.p. 229° (corr.), and having the composition $C_{35}H_{39}O_5N_5$. It is extremely soluble in cold chloroform, and dissolves in 292 parts of absolute alcohol at 18°; in alcohol $[a]_D = +338°$; the solutions are strongly fluorescent. Prolonged boiling with alcohol lowers the rotation and produces an amorphous decomposition product. Heating in alcoholic solution with slightly more than one equivalent of (phosphoric) acid transforms ergotinine into ergotoxine phosphate which may be crystallised. The same change takes place slowly in cold dilute acetic acid. Conversely ergotoxine is dehydrated to ergotinine by boiling with methyl alcohol or by warming with acetic anhydride.

Both alkaloids give the following colour reaction (Tanret). A solution of 1 m.g. of the alkaloid in ether or in ethyl acetate is allowed to evaporate on the surface of concentrated sulphuric acid (containing oxides of nitrogen). A transitory orange colour is developed changing to violet-blue. Keller (Schweiz. Woch. Chem. Pharm. 1894, 32, 121) has improved this by dissolving 2-3 m.g. of the solid alkaloid in sulphuric acid on a watch glass and stirring in a trace of anhydrous ferric chloride, when an orange colour is produced, changing to deep red and then becoming blue or green at the edges. Alternatively the solution of the alkaloid in glacial acetic acid may be poured on sulphuric acid, without mixing. The test yields a positive result with the crude alkaloid from 1 gram of ergot.

Both alkaloids are sensitive to general alkaloidal precipitants, potassium mercuric iodide giving a faint opalescence with 1 part of alkaloid in 1-2 millions of water. On dry distillation both alkaloids yield a crystalline sublimate in *iso*butyryl formamide $CH(CH_3)_2CO\cdot CO\cdot NH_2$ (Barger and Ewins, *l.c.*). Ergotoxine probably contains a carboxyl group and ergotinine is the corresponding lactone. Both contain one N-methyl group, but no O-methyl group (Barger and Ewins, Chem. Soc. Trans. 1918, 113, 235). Ergotinine does not yield any crystalline salts.

The total alkaloids of ergot (*i.e.* ergotoxine + ergotinine) may be estimated by exhausting the finely powdered drug with light petroleum, mixing it with magnesia, extracting with ether and shaking the ether with dilute acid. After making alkaline with ammonia the alkaloids are again shaken into ether, and estimated gravimetrically (Keller, *l.c.*). For details and results of analysis, see Allen's Comm. Organic Analysis, 1913, vol. vii. p. 21. The alkaloidal content varies roughly from 0·1 to 0·4 p.c., and in Russian and Spanish ergot is generally between 0·2 and 0·3 p.c. König (Apot. Zeitsch. 1912, 27, 879) found 10 samples of German ergot to contain 0·032-0·14 p.c. An approximate idea of the ergotoxine content may be obtained by physiological means (Barger and Dale, Bio-Chem. J. 1907, 2, 240).

In addition to a specific alkaloid, the active principles of ergot comprise a number of simpler bases, derived from the amino-acids of protein by loss of carbon dioxide. Of these β-iminazolylethylamine (from histidine) and *p*-hydroxyphenylethylamine (from tyrosine) are therapeutically the most important. They can be prepared synthetically and are also formed by putrefaction. Their physiological action has been much studied of late and they have been applied practically.

Histamine (β-*iminazolylethylamine* 'β-1,' 4-β-*aminoethylglyoxaline, erganine*)

$$\begin{array}{c} CH=N \\ | \diagdown \\ NH\cdot CH \diagup \end{array} C\cdot CH_3\cdot CH_2\cdot NH_2$$
was obtained first synthetically by Windaus and Vogt (Ber. 1907, 70, 3691) and then by Ackermann (Zeitsch. physiol. Chem. 1910, 65, 504) by the putrefaction of histidine. Its intense physiological activity was not recognised until it was isolated from a commercial dialysed ergot preparation (Barger and Dale, Chem. Soc. Trans.

1910, 97, 2592). Kutscher (Zentralb. Physiol. 1910, 24, 163) isolated it simultaneously from ergot, but did not correctly identify it. The substance is certainly present in ergot as such, but its amount may be increased by such processes as prolonged extraction and dialysis. The base can be obtained directly from histidine by putrefaction (D. R. PP. 2528724, 256116, Hoffmann, La Roche & Co; D. R. P. 250110, F. Bayer & Co.; the yield is inconstant but may reach 60 p.c. or more). It may also be made from histidine by heating with acids (Ewins and Pyman, Trans. Chem. Soc. 1911, 99, 339; yield 25 p.c.). It is best obtained by reduction of the nitrile of iminazolylpropionic acid (Pyman, Trans. Chem. Soc. 1911, 99, 668), which nitrile in its turn is obtained most conveniently from histidine by the action of chloramine-T (Dakin, Biochem. J. 1916, 10, 322), although it may also be synthesised, according to Pyman (l.c.; cf. also Koessler and Hanke, J. Amer. Chem. Soc. 1918, 40, 1706). The most important salts are the phosphate $C_5H_9N_3\cdot 2H_3PO_4$ forming large crystals, and the d·picrate

$$C_6H_9N_3(C_6H_3O_7N_3)_2$$
yellow rhombic leaflets, m.p. 238°–242° (corr.). The free base is readily soluble in water; its solutions give Pauly's histidine reaction with sodium p-diazobenzene sulphonate; a very distinct rose-pink colouration is still obtainable at 1 : 10,000.

Tyramine   (p-Hydroxyphenylethylamine) OH·C₆H₄·CH₂·CH₂NH₂ 'is similarly derived from tyrosine by loss of carbon dioxide. On a small scale it can be obtained by heating tyrosine to 260°–270° under reduced pressure (Schmitt and Nasse, Annalen, 1865, 133, 211; Ehrlich and Pistschimuka, Ber. 1912, 45, 1006, thus obtained a 50 p.c. yield). On a larger scale it is best got by reduction of p-hydroxy-benzylcyanide according to Barger (Trans. Chem. Soc. 1909, 95, 1123), who first isolated it from ergot. It also occurs as a product of putrefaction (Barger and Walpole, J. Physiol. 1909, 38, 343). The free base melts at 161° and boils at 175°–180° and 8 mm. It dissolves in 95 parts of water at 15° and can be extracted from aqueous solutions by shaking many times with ether, more readily by amyl alcohol. It gives Millon's reaction, the most characteristic derivative is the dibenzoyl compound C₂₂H₁₉O₃N, m.p. 170°·

Acetylcholine   .

OH(CH₃)₃N·CH₂·CH₂O·OC·CH₃
occurs in ergot and ergot extracts in varying small amounts. It was isolated by Ewins (Biochem. J. 1914, 8, 44) from a B.P. liquid extract. It is hydrolysed almost at once by rendering its solution alkaline with caustic soda.

Physiological action of the active principles.— Ergotinine is inert, but ergotoxine causes, on intravenous or intramuscular injection, a prolonged rise of blood pressure and contraction of the pregnant uterus. Repeated administration leads to dry gangrene, e.g. of the cock's comb, which is coloured purplish black by small doses, a reaction used at one time for the testing of ergot preparations (for criticism v. Cronyn and Henderson, J. Pharm. exp. Therap. 1909, 1, 231). Ergotoxine is the poisonous principle

responsible for epidemic ergotism (Kobert attributed the two types of this disease to the alkaloid cornutine and the resin sphacelinic acid, but both these substances seem to have been ergotoxine in an impure or modified form; cf. Barger and Dale, Biochem. J., 1907, 2, 240). β-Iminazolylethylamine is one of the most potent of drugs, causing marked contraction of the isolated guinea-pig's uterus in a bath containing 1 : 25,000,000. p-Hydroxyphenylethylamine resembles adrenaline in action, as in structure, but is much less potent; it causes a rather transitory rise of blood pressure. Acetylcholine is not a therapeutically desirable constituent It has a muscarine-like action, inhibiting the heart, and stimulates intestinal muscle (Hunt and Taveau, Hygienic Bulletin, Washington, No. 73, 1911). In most ergot preparations the amount is negligible. For a detailed account of the last three and most of the following bases, see Barger, the Simpler Natural Bases, Longmans, 1914.

In addition to β-iminazolylethylamine, p-hydroxyphenylethylamine and acetylcholine, there have been found in ergot quite a number of other substances of bio-chemical interest, which are not peculiar to the drug. They are inert, or have only a slight physiological action. Putrescine and Cadaverine (Rielander, Sitzber. Ges. Naturw. Marburg, No 7, 1908), isoamylamine (Barger and Dale, Proc. Physiol. Soc., May 15, 1909), and agmatine (Engeland and Kutscher, Zentralbl. Physiol. 1910, 24, 479) are all amines, derived respectively from ornithine, lysine, leucine and arginine, by decarboxylation. Agmatine has an action on the uterus like that of β-iminazolylethylamine, but very much feebler. It is guanidylbutylamine

$$NH_2\cdot C(NH)\cdot NH\cdot CH_2\cdot CH_2\cdot CH_2\cdot CH_2NH_2$$
and was first discovered in herring roe by Kossel (Zeitsch physiol. Chem. 1910, 66, 257). A few amino-acids have also been found as such : leucine (Buchheim, l.c.), aspartic acid (Barger and Dale, Biochem. J. 1907, 2, 240), leucine, isoleucine, valine (van Slyke, J. Pharmac. exp. Therap. 1909, 1, 265). A mixture of these was described as an active principle, 'clavin' by Vahlen (Acrh. exp. Pharm. Path. 1906, 55, 131). There are further present choline which gives rise to the odour of trimethylamine, when ergot is treated with sodium hydroxide (Brieger, Zeitsch. physiol. Chem. 1887, 11, 184), (for acetylcholine, see above), betaine and uracil (Rielander, l.c.), vernine C₁₆H₂₀O₈N₈,3H₂O, which also occurs in leguminous seedlings (Schulze and Bosshard, Zeitsch. physiol. Chem. 1887, 10, 80), lactic acid, mannitol, trehalose, phytosterols and fats (see below).

Inert constituents which so far have not been found elsewhere are : secale aminosulphonic acid C₁₅H₂₆O₁₆(NH₂)SO₃H (Kraft, l.c.), prisms, m.p. 200°, soluble in water giving an acid solution ; ergothioneine C₉H₁₅O₃N₃S,2H₂O, isolated by Tanret (J. Pharm. Chim. 1909, [vi.] 30, 145) in an amount of 0·1 p.c. and shown by Barger and Ewins (Trans. Chem. Soc. 1911, 99, 2336) to be the trimethylbetaine of thiolhistidine; secalonic acid C₁₄H₁₄O₈, a crystalline yellow colouring matter, m.p. 244°, present to the extent of about 2 p.c. (Kraft, l.c.). This substance is probably the lactone of an hydroxy

acid, and possibly identical with sclerocrystallin (Dragendorff and Podwyssotzki, Arch. exp. Path. Pharm. 1877, 6, 174). Another crystalline yellow colouring matter $C_{15}H_{14}O_7,H_2O$, m.p. 350°, after regeneration of a crystalline acetyl derivative, has been described by Freeborn (Pharm. J. 1912, [iv.] 34, 568). The most important colouring matter of ergot, *sclererythrin*, is not known in a pure condition. It is the cause of the deep purplish red colour of the outer cells of the grain and is valuable for the recognition of ergot in flour, &c. The substance is acidic, and apparently present as a salt, for it is not extracted by ether until the ergot has been moistened with water containing tartaric acid. It is soluble in aqueous alkalis with a red colour. *Clavicepsin* $C_{18}H_{34}O_{16}$, m.p. 198° when anhydrous, $[\alpha]_D^{20} = +142\cdot27°$, was extracted from ergot by Marino-Zuco and Pasquero (Gazz. chim. ital. 1910, 41, 368). It is hydrolysed by acids to two molecules of glucose and one of mannitol. The *oil* is quantitatively the most important constituent (mostly 30–33 p.c.) and has been examined by Rathje (Arch. Pharm. 1908, 246, 692), who found D. = 0·9250, n_D = 1·4685 saponification number 179·3, acid number 11·38, iodine number 74·0, Hehner number 96·25, Reichert-Meissl number 0·63 and true acetyl number 27·44. The percentage composition is oleic acid 68, hydroxyoleic acid 22, palmitic acid 5, unsaponifiable matter 0·35, inorganic matter 0·2, alkaloid 0·6, and glycerol 7·5.

Ergosterol $C_{27}H_{42}O,H_2O$, m.p 165°, and *fungisterol* $C_{25}H_{40}O,H_2O$, m.p. 144°, have been separated by Tanret (Compt. rend. 1908, 147, 75). The second at least seems to exist in other fungi.

The detection of ergot in flour is based on the presence of alkaloids and of sclererythrin, and on the fact that the ergot particles float when the flour is shaken with an alcohol-chloroform mixture of density 1·435. After pouring off, alcohol is added, when the ergot sinks and can be examined microscopically. For further details, *see* Allen's Commercial Organic Analysis, vol. vii., 1913, p. 23, and Marino-Zuco and Duccini (Gazz. chim. ital. 1914, 44, 437).

For a critical discussion of the ergot preparations of the British Pharmacopœia, *see* Carr and Dale (Pharm. J. 1913, [iv.] 37, 130). It should be noted that 'ergotin' is not a pure substance, but a purified soft extract. The varying activity of different extracts should be controlled by physiological test. (G. B.)

ERGOTINE *v.* ERGOT OF RYE.

ERGOTININE *v.* ERGOT OF RYE.

ERICA B *v.* PRIMULINE.

ERICIN. Trade name for salicylic methoxy-

methyl ester $C_6H_4 {<}{\,}^{OH}_{CO\cdot O\cdot CH_2\cdot OCH_3}$

ERICOL. Guaiacol acetate.

ERICOLIN is found in several plants belonging to the order *Ericaceæ*, especially in the herb of the marsh wild rosemary, *Ledum palustœ* (Linn.) (Rochleder and Schwarz, Annalen, 84, 368), less abundantly in the common heath or ling, *Calluna vulgaris* (Salisb.) (Rochleder, *ibid.* €54), in *Rhododendron ferrugineum* (Linn.) (Schwarz, *ibid.* 361), and in the red bearberry, *Arctostaphylos Uva-ursi* (Spreng.) (Kawalier, Sitz. W. 9, 29).

To prepare it from *L. palustre*, the chopped leaves are thrown into boiling water and boiled for several hours. The filtrate obtained after adding basic lead acetate to the liquid is evaporated in a retort to one-third of its bulk. In Thal's modification of this process (Ber. 16, 1502), the liquid is concentrated *in vacuó*, the separated lead salt filtered off, and the liquid freed from lead by hydrogen sulphide. The filtrate is then evaporated to a syrup, and the ericolin dissolved out by anhydrous ether alcohol. The substance left on evaporating this solvent is repeatedly dissolved in a mixture of ether and alcohol till it no longer leaves any residue (Rochleder and Schwarz).

On heating the mother liquor obtained in the preparation of arbutin from the leaves of red bearberry with dilute hydrochloric or sulphuric acid, ericolin is deposited as a resinous precipitate, which may be purified by solution in alcohol and precipitation by water (Kawalier).

Rochleder and Schwarz, after deducting 10·6 p.c. ash, found ericolin to contain 51·71 p.c. carbon and 7·19 hydrogen, whence they deduced its formula to be $C_{34}H_{56}O_{31}$ (51·00 C and 7·00 H).

Thal (*l.c.*), after separating an admixed substance (containing 57·5 p.c. carbon and 7·29 hydrogen), which was insoluble in ether alcohol, from ericolin, assigned to the latter body the formula $C_{28}H_{24}O_3$, but subsequently altered it to $C_6H_{30}O_3$ to explain the decomposition equations of the substance. Ericolin, as prepared by Thal, is a brown-yellow, odourless, hygroscopic, bitter substance decomposing even below 100°. It is decomposed by water. By extracting successively with benzene, chloroform, and a mixture of ether and alcohol, different substances go into solution; it appears that the ericolin is thus broken up into a sugar and ericinol. With dilute sulphuric acid warmed to 100°, a sugar and a resinous brown-yellow viscid mass, hydroericinol, are produced. An analysis of the latter body gave numbers corresponding with the formula $x(C_6H_{12}O_2)$, subsequently modified to $x(C_5H_{10}O_2)$.

The equations representing these decompositions are as follows :—

$$C_{28}H_{30}O_3 + 4H_2O = C_6H_{12}O_6 + C_{22}H_{26}O$$
Ericolin.   Ericinol.

$$C_{22}H_{26}O + 7H_2O = 2(C_{10}H_{20}O_4)$$
Hydroericinol.
Power and Tutin, however, could not isolate ericolin by Thal's process, and they found that ericinol was identical with furfural (Chem. Zentr. 1907, i. 916).

Thal also isolated ericolin from *Calluna vulgaris* (Salisb.), and recognised it by the smell of ericinol in many *Ericaceæ* and *Vacciniea*.

Kanger extracted ericolin from the leaves of the cowberry (*Vaccinium vitis idœa*) by means of ether alcohol. It was then purified by precipitating foreign substances with lead acetate, and removing excess of the latter with sulphuretted hydrogen. The substance so obtained was of a resinous nature, completely soluble in ether alcohol, and corresponded with the composition $C_{16}H_{22}O_{10}$ (Chem. Zeit. 1903, 27, 794). Ericolin is probably not a chemical individual, but consists of a mixture of glucoside-like substances.

Ericolin is poisonous towards many microorganisms, particularly those belonging to the

colon group, but has no action on acid-fast bacilli. Twort (Proc. Roy. Soc. 1909, B. 81, 248) has used it as a medium for the isolation and culture of human tuberculous bacilli from sputum.

ERIGERON CANADENSE is an oil consisting of a terpene boiling at 176°, which, when pure, has sp.gr. 0·850–0·870, and an optical rotation +52°. It is soluble in an equal volume of alcohol, and rapidly resinifies.. The commercial oil has sp.gr. 0·8549–0·8963 ; optical rotation, +28° 48′ to 84·20° ; and b.p. 172°–178° (Kepler and Pancoast, Amer. J. Pharm. 75, 216).

According to Rabak (Pharm. Review, 1905, 23, 81 ; 1906, 326), the oil obtained from the fresh herb (0·66 p.c.) is of a bright-yellow colour with a peculiar odour like that of caraway. On exposure to air, it deposits crystals, and a brownish resinous mass is formed. The oil from the dried herb (0·26 p.c.) was darker in colour, had a powerful odour, and gave no crystals when exposed to air. It also differed from the fresh herb oil in sp gr., optical rotation. and other characteristics. In all probability, the terpeneol found in erigeron oil is a decomposition product. The oil absorbs two molecules of hydrochloric acid to form a solid dihydrochloride $C_{10}H_{16}$,2HCl, melting at 47°–48° (Beilstein and Wiegand, Ber. 15, 2854 ; Wallach, Annalen, 227, 292).

ERINOID. *See* GALALITH.

ERIOCOCCUS CORIACEUS. This is a scale insect consisting of a small pinkish-white sac occurring in clusters, and which encase the stems of young shoots of the Eucalypti, more especially those on old or burnt stumps. These insects contain a colouring matter which dyes wool mordanted with chromium, aluminium, tin, and iron, brown, light amber, pale orange-brown and sage-green shades respectively. The colours thus obtained are not specially brilliant, and are not fast to alkalis (Gurney, Report of the Australasian Association for the Advancement of Science, 1898).   A. G. P.

ERIOGLAUCINE. The trade name of the dyestuff obtained by condensing benzaldehyde-o-sulphonic acid with ethylbenzylanilinesulphonic acid (J. Soc. Chem. Ind. of Basle, Eng. Pat. 25128 ; Gnehm and Schüle, Annalen, 299, 347).

ERODIAMINE $C_{19}H_{17}ON_3$, light yellow plates, m.p. 287°, and *rutaecarpine* $C_{18}H_{13}ON_3$, light yellow needles, m.p. 258°, occur in the fruit of *Erodia rutaecarpa* (Asahina and Kashiwaki, J. Pharm. Soc. Japan, 1915, No. 405, 1293 ; Asahina and Mayeda, *ibid.* 1916, No. 416, 871 ; Amer. Chem. Soc. Abstr. 1916, 607 ; 1917, 332).

I. ·   II.
The annexed constitutional formulæ have been assigned. Perhaps they are not fully established, but they are of considerable interest as showing that the alkaloids are derivatives of

indole ; they also show a relationship to harmaline and harmine. On boiling with alcoholic hydrogen chloride erodiamine (I.) is converted into isoerodiamine $C_{19}H_{17}ON_3$,H_2O, m.p. 155°–156°, and this is decomposed by alcoholic potash into carbon dioxide, N-methylanthranilic acid and a base $C_{10}H_{12}N_2$, m.p. 120°, which has been identified as 2-β-aminoethyl indole. Isoerodiamine is regarded as

$$HN \cdot C_6H_4 \cdot CH : C \cdot CH_2 \cdot CH_2 \cdot N \cdot CO \cdot C_6H_4 \cdot N(Me) \cdot CHOH$$
Rutaecarpine (II.) is similar to erodiamine, but more soluble in alcohol ; hot potassium hydroxide in ammonium hydroxide yields anthranilic acid, and an unidentified product, which on fusion with potassium hydroxide, like the base $C_{10}H_{12}N_2$ from erodiamine, yields 2-indole carboxylic acid   G. B.

ERUBESCITE *v.* BORNITE.

ERUCIC ACID $C_{22}H_{42}O_2$. A homologue of acrylic acid obtained, together with oleic acid, by the saponification of the fixed oil of white mustard. It was found together with behenic acid by Goldschmiedt (Sitz. W. 70, 451) in the oil expressed from black mustard, and by Fitz (Ber. 1871, 442) in the fat oil of grape seeds. It is best obtained by saponifying rape oil (from *Brassica campestris*, Linn.) with alcoholic potash distilling off the alcohol and dissolving the acid liberated on the addition of sulphuric acid in three times its volume of 95 p.c. alcohol ; on cooling to 0°, crystals of erucic acid separate out in an almost pure condition (Reimer and Will, Ber. 1886, 3320). It may be obtained by saponifying colza oil, freeing the erucic acid from arachidic acid by treatment with glacial acetic acid, in which the latter is insoluble (Ponzio, Gazz. chim. ital. 1904, ii. 50). It is also present in cod liver oil (Bull. Ber. 1906, 3570).

Erucic acid crystallises in colourless needles, m.p. 34° ; b.p. 281° at 30 mm. Heated with phosphorus oxychloride, it forms an anhydride $C_{44}H_{82}O_3$, an oil which may be crystallised in a freezing mixture. By treatment with nitrous acid, or better, by warming erucic acid with dilute nitric acid to the melting-point and then adding sodium nitrite, brassidic acid (brassic acid) is produced. This acid stands to erucic acid in the same relation as elaidic to oleic acid. *Cf.* Mascarelli, Atti R. Accad. Lincei, 1917, [v.] 26, i. 71. Fused with potash, erucic acid yields aradic (arachidic) and acetic acids. Concentrated nitric acid converts erucic acid into brassilic acid ($C_{13}H_{24}O_4$), pelargonic acid, arachidic acid, and a small .quantity of dinitrononane (Fileti and Ponzio, J. pr. Chem. [2] 48, 323), and concentrated sulphuric acid into behenolactone (Shukow and Schestakow, Chem. Zentr. 1908, ii. 1415). With hydriodic acid and amorphous phosphorus, it is converted into behenic acid (Goldschmiedt, J. 1876, 579). On treatment with phosphorus triiodide, iodobehenic acid is obtained, which on treatment with alcoholic potash, yields *iso*-erucic acid, m.p. 54° (Ponzio, *l.c.*). Erucic acid is converted into behenic acid by heating with iodine in a sealed tube for 4 hours at 270° (Reychler, Bull. Soc. chim. [3] 1, 296). When bromine is added to erucic acid under water, a dibromide $C_{22}H_{42}Br_2O_2$ is produced. It crystallises from alcohol in small white nodular crystals, m.p. 42°–43°, and is

reduced to erucic acid by sodium amalgam in alcoholic solution. Its barium and lead salts $(C_{22}H_{41}Br_2O_2)_2Ba$ and $(C_{22}H_{41}Br_2O_2)_2Pb$ are white, viscid, easily decomposable precipitates (Otto, Annalen, 127, 182; 135, 226). Erucic acid dibromide heated in sealed tubes to about 145° for 7–8 hours, with 4 or 5 mols. potassium hydroxide in alcoholic solution, yields the potassium salts of behenolic acid

$$C_{22}H_{40}O_2(=C_{22}H_{42}Br_2O_2-2HBr)$$

(Holt, Ber. 1892, 961). Behenolic acid, on treatment with zinc-dust and acetic acid, yields brassidic acid and not erucic acid. At ordinary temperatures, only 1 mol. of hydrobromic acid is abstracted by potash in alcoholic solution; monobromerucic acid $C_{22}H_{41}BrO_2$ is formed, with rise of temperature and separation of potassium bromide. On diluting the solution with water and adding hydrochloric acid, the acid separates as an oil which soon solidifies. It melts at 33°–34° and remains liquid for a long time. It is heavier than water, and insoluble therein, but dissolves readily in alcohol and ether. It unites with bromine, forming a dibromide $C_{22}H_{41}BrO_2\cdot Br_2$, which melts at 31°–32°, and forms amorphous viscid salts.

When erucic acid dibromide is triturated with water and an excess of silver oxide, and heated until it turns brown and evolves hydrogen bromide, the mass, on boiling with water, yields a yellow oil which is a mixture of liquid hydroxyerucic acid $C_{22}H_{42}O_3$ and dihydroxybehenic acid $C_{22}H_{44}O_4$. The latter partially crystallises out on long standing. For complete separation, the washed oil is saponified with baryta water; the precipitate is exhausted with ether and the dissolved barium hydroxyerucate is decomposed by hydrochloric acid. The hydroxyerucic acid, which separates as a colourless oil, is purified from alcohol. It is viscid, lighter than water, insoluble therein, but miscible in all proportions with alcohol and ether. Its salts $C_{22}H_{41}O_3M$ are amorphous. All excepting those of the alkali metals and barium are insoluble in water. Hydroxyerucic acid may also be formed from monobromerucic acid by the action of silver oxide. Boiled with potash lye, it is converted into dihydroxybehenic acid (Hausscknecht, Annalen, 163, 40). Dihydroxybehenic acid, m.p. 132°–133°, is also obtained by the oxidation of erucic acid with potassium permanganate (Hazura and Grüssner, Monatsh. 9, 947). Sodium erucate $C_{22}H_{41}NaO_2$ is soluble in alcohol, and gives precipitates of lead and barium erucates on the addition of an alcoholic solution of the acetates of these metals. The silver salt is a curdy precipitate, which becomes coloured on exposure to light.

Ethyl erucate $C_{22}H_{41}(C_2H_5)O_2$ is a colourless oil boiling above 360° without decomposition. The amide $C_{22}H_{41}O(NH_2)$, m.p. 84° (Reimer and Will, l.c.), m.p. 78°–79° (Krafft and Tritschier, Ber. 1900, 3580), and the anilide, m.p 55°, are crystalline bodies readily soluble in ether or benzene, sparingly soluble in alcohol.

ERUCIN. A crystalline body said to exist in white mustard seed. It is insoluble in water, sparingly soluble in alcohol, easily in ether or in oils (Simon, Pogg. Ann. 64, 293).

Dierucin $C_2H_4OH(C_2H_{41}O_2)_2$. When rape oil is allowed to stand for a long time, a yellowish tallow-like deposit is found frequently in the casks. This, by repeated solution in ether and subsequent addition of alcohol, may be obtained in silky needles. Dierucin melts at 47° and is readily soluble in ether and light petroleum, insoluble in cold but soluble in hot alcohol. A trierucin could not be separated from rape oil, but was obtained by heating dierucin and erucic acid at 300°, m.p. 31° (Reimer and Will, l.c.) (v. OILS AND FATS).

ERVASIN. Trade name for acetyl p-cresotinate.

ERYTHRENE. See BUTINENE.

ERYTHRIN, _Erythric acid, Erythrinic acid, Erythrolccanoric acid_ $C_{20}H_{22}O_{10},H_2O$, is a constituent of most lichens from which archil is prepared. It was discovered by Heeren (Schweigger's Jour. f. Chem. 59, 513) in _Rocella tinctoria_ (D. C.), from which lichen and several others of the same genus it may be extracted by boiling water, or better with milk of lime (cf. also Kane, Stenhouse, and Hesse (l.c.); Schunck, Annalen, 61, 69; De Luynes, Annales de Chim. [4] 2, 385; Menschutkin, Bull. Soc. chim. [2] 2, 424).

The method adopted by Stenhouse to prepare this substance from the _Rocella fuciformis_ is as follows (Annalen, 68, 72, and 149, 290). Three pounds of the lichen are macerated for 20 minutes in a milk of lime made by shaking ½ lb. of lime in 3 gallons of water, and the product filtered by means of a bag filter. The clear liquid, as it passes through, is immediately precipitated with hydrochloric acid, as prolonged contact with the lime decomposes part of the erythrin. The crude erythrin collected on bag filters is freed from acid and calcium chloride by stirring it up once or twice with a considerable quantity of water and again collecting.

Erythrin forms small colourless needles, melting at 148° (Hesse, Ber. 1904, 37, 4693), and not at 164°, as stated by Ronceray (Chem. Zentr. 1904, ii. 1504), and is sparingly soluble in water, easily soluble in alcohol, ether, and alkalis. Alcoholic ferric chloride gives a purple-violet colouration, which passes to brownish-red on addition of excess of the reagent.

When boiled with water, erythrin gives (a) orsellinic acid and (b) picro-erythrin (Schunck, Annalen, 61, 65)

$$C_{20}H_{22}O_{10}+H_2O=(a)\ C_8H_8O_4+(b)\ C_{12}H_{16}O_7$$
whereas by boiling with alcohol, picroerythrin and orsellinic acid ethyl ester (c) are produced (Heeren, l.c.; Kane, Annalen, 39, 25)

$$C_{20}H_{22}O_{10}+C_2H_5OH=(c)\ C_8H_7(C_2H_5)O_4+C_{12}H_{16}O_7$$
With amyl alcohol, a similar reaction occurs with formation of (d) amylorsellinate and picro-erythrin (Hesse, Annalen, 139, 22)

$$C_{20}H_{22}O_{10}+C_5H_{12}O=(d)\ C_8H_7O_4'C_5H_{11}+C_{12}H_{16}O_7$$
On the other hand, excess of lime water (Lamparter, Annalen, 134, 255) gives orcin, CO_2, and erythrite

$$C_{20}H_{22}O_{10}+2H_2O=2C_7H_8O_3+CO_2+C_4H_{10}O_4$$
Tribromerythrin $2C_{20}H_{19}Br_3O_{10},3H_2O$ (Hesse, Annalen, 117, 310; and ibid. 139, 32) consists of white crystalline spherules which cake together a little above 100° and melt at 139°. Boiled with alcohol, it is resolved into _ethyldibromorsellinate_ and _brompicroerythrin_.

Picroerythrin or *erythro-orsellinic acid*

$$C_{12}H_{16}O_7,3H_2O$$
forms colourless prisms, melts at 158°, is readily soluble in hot water, and gives with ferric chloride a purple-violet colouration. It appears to be most readily obtained pure by Hesse's method of boiling erythrin with amyl alcohol (*l.c.*).

Digestion with hot baryta water converts picroerythrin into CO_2, orcin, and erythrite

$$C_{12}H_{16}O_7 + H_2O = CO_2 + C_7H_8O_2 + C_4H_{10}O_4$$
The experiments of de Luynes, Menschutkin, and Hesse have confirmed the view first put forward by Berthelot, that erythrin is the *mono-lecanoric ester* (1), and picroerythrin the *mono-orsellinic ester* of *erythrite* (2).

According to Hesse (Ber. 1904, 37, 4693), erythrin contains a free carboxyl group, and must therefore be represented as follows :—

$$C_4H_6(OH)_3 \cdot O \cdot C_6H_2(OH)CO \quad O \cdot C_6H_2(OH)COOH$$
$$\qquad \qquad \qquad | \qquad \qquad \qquad |$$
$$\qquad \qquad \qquad CH_3 \qquad \qquad \quad CH_3$$
whereas picroerythrin has the formula .

$$O \cdot CH_2(CH \ OH)_2 \cdot CH_2OH$$
$$\qquad \quad |$$
$$\qquad \quad C_6H_2(OH)COOH$$
$$\qquad \quad |$$
$$\qquad \quad CH_3$$
On the other hand, Zerner (Monatsch., 1914, 35, 1021) considers that the structure of erythrin is best represented thus :

Me   Me

HO $\langle$ $\rangle$—CO—O—$C_4H_6(OH)_2$—O—$\langle$ $\rangle$—COOH
      | |
      OH   OH
β-Erythrin $C_{21}H_{24}O_{10}$ is prepared by the action of lime water on some varieties of the *R. fuciformis* (Menschutkin, *l.c.*). It is a white crystalline powder ; m.p. 115°–116° (Lamparter, *l.c.*) ; nearly insoluble in water, soluble in alcohol and ether with violent evolution of CO_2. Boiled with water, orsellinic acid, and β-picroerythrin are produced ; with alcohol, the latter body together with ethylorsellinate.

β-Picroerythrin $C_{13}H_{16}O_{10}$ crystallises in needles, very soluble in water and alcohol. Boiled with baryta water, it is resolved into CO_2, erythrite, and β-orcinol (Menschutkin).

According to Hesse (*l.c.*), it is probable that β-erythrin is not a chemical individual, but consists mainly of erythrin, the properties of which are modified by the accompanying impurities. A. G. P.

ERYTHRITE or **Cobalt-bloom.** A mineral consisting of hydrated cobalt arsenate, $Co_3(AsO_4)_2$, $8H_2O$, crystallising in the monoclinic system and isomorphous with the iron salt vivianite. Sometimes, as at Schneeberg in Saxony, it occurs as beautiful radially-arranged groups of blade-shaped crystals with a bright crimson colour and brilliant lustre. More usually, however, it forms an earthy, peach-blossom red encrustation on other cobalt minerals, of which it is an alteration product. It has been found in the Dolcoath mine in Cornwall, Thuringia, Allemont in France, Cobalt in Ontario, Chile, &c The name was given by F. S. Beudant,

in 1832, from ἐρυθρός, red. The same name was also used by T. Thomson in 1843 for a flesh-red variety of orthoclase-felspar.

L. J. S.

ERYTHRITOL. *Erythrol, Erythromannite, Erythrite* (*v.* CARBOHYDRATES).

ERYTHRODEXTRIN *v.* DEXTRIN.

ERYTHROL NITRATE *v.* SYNTHETIC DRUGS.

ERYTHROPHLEINE $C_{29}H_{43}O_7N$ (?) is an amorphous alkaloid from Sassy bark of *Erythrophlœum guineense*, G. Don., a large leguminous tree from the West Coast of Africa. The bark is used as an arrow poison and in ordeals, and is also known as Casca, Red water, or Mancona bark. The alkaloid yields only amorphous salts, and is the only known one having a digitalis-like action on the heart. Heated with concentrated hydrochloric acid it is hydrolysed to methylamine and an amorphous acid. Erythrophlœine hydrochloride is used to a limited extent in medicine (Gallois and Hardy, Bull. Soc. chim. 1876, 26, 39; Harnack, Chem. Zentr. 1897, i. 301; Power and Salway, Amer. J. Pharm. 1912, 84, 337).

G. B.

ERYTHROSIN (*Tetraiodofluorescein*)

$$C_{20}H_8O_5I_4$$

is prepared by electrolysing a mixture of fluorescein (1 part) and finely powdered iodine (1·5 parts) in soda solution. The vessel is provided with a diaphragm, and the fluorescein mixture occupies the anode space, whilst a dilute solution of soda or sodium hydroxide forms the kathode liquid (D. R. P. 108838, 1899 ; Chem. Zentr. 1900, i. 1176 ; *cf. also* Frdl. 1877-87, 315).

The commercial product is a red-brick powder dissolving in dilute alkalis without any marked fluorescence. It can be purified by dissolving in aqueous ether, filtering and shaking with dilute sodium hydroxide. The sodium salt is precipitated by the addition of strong alkali, and, after filtering, washing, and recrystallisation from alcohol, it is dissolved in water, and the free erythrosin is liberated by treatment with hydrochloric acid (Mylius and Foerster, Ber. 1891, 24, 1482). When pure, it is of a lighter colour than the impure product, almost insoluble in absolute ether, benzene, or chloroform, but more readily so in acetone, alcohol, and aqueous ether. The colour of erythrosin fades under the influence of light and of hydrogen peroxide, particularly in the presence of potassium hydroxide (Zeitsch. Farbenindustr. 1908, 7, 299). Light also causes it to act hæmolytically in photodynamic reactions (Sacharow and Sachs, Chem. Zentr. 1905, i. 1420).

Erythrosin considerably enhances the action of light in its influence on bacteria (Mettler, Chem. Zentr. 1905, ii. 1037 ; Huber, *ibid.* 1906, i. 148 ; Sacharow and Sachs, *l.c.*). Erythrosin is employed in the cotton and paper industries ; and Thouert (Compt. rend. 1909, 148, 36) has attempted to apply it to colour photography, but with little success so far (*cf. also* Stark, Physikal. Zeitsch. 1907, 8, 248) ; it has also been used as a sensitiser in photo-electric experiments (Schlenderberg, J. Phys. Chem. 1908, 12, 574) and as an indicator in analysis (Mylius and Foerster, *l.c.* ; J. Amer. Chem. Soc. 1899, 21, 359).

Erythrosin is often mixed with rose Bengal (tetraiodochlorofluorescein) to suppress its fluorescence, and with common salt to increase its solubility. The former mixture is often used in France to colour foodstuffs, but the presence of rose Bengal in erythrosin is forbidden in America. Jean (J. Soc. Chem. Ind. 1908, 70) gives a method for testing and estimating rose Bengal in erythrosin.

Silver erythrosin, which is of an intense blue colour, is prepared by dissolving 1 gram of erythrosin in 400 c.c. water, adding 7·1 c.c. of a 10 p.c. solution of potassium bromide, and then 12 c.c. of a 10 p.c. silver nitrate solution. It forms a colloidal solution which becomes 'ripened' on warming or standing for a few days, depositing a very fine sediment which has a pure blue colour in transmitted light (Lüppo-Cramer, Zeitsch. Chem. Ind. Kolloide, 1907, i. 227 ; 1908, 2, 325).

The sodium or potassium salt is sometimes known as Erythrosin B, Pyrosin B, Iodeosin Dianthine B, Éosin J., &c.

ERYTHROXYANTHRAQUINONE $C_{14}H_8O_3$ is produced, along with an isomeric hydroxyanthraquinone, by the action of phthalic anhydride on phenol, in presence of sulphuric acid, $C_8H_4O_3 + C_6H_6O = H_2O + C_{14}H_8O_3$. Salicylic acid, anisole, and even anisic acid behave in the same way as phenol. The two hydroxyanthraquinones are separated by boiling with water and barium carbonate ; erythroxanthraquinone is unaltered by this treatment, whereas in the case of the isomeride a soluble barium compound is formed.

Erythroxanthraquinone may also be prepared from aminoanthraquinone, dissolved in acetic acid to which a little sulphuric acid has been added, by adding potassium nitrite till the solution becomes yellow. After a short time, on adding water and boiling, yellow flakes of erythroxanthraquinone separate, and increase as the acetic acid evaporates (D. R. P. 97688 ; Rower, Ber. 1882, 15, 1793 ; Perger, J. pr. Chem. [2] 18, 147).

It is also formed by oxidising the amino-salt with fuming sulphuric acid (D. R. P. 67063 ; Frdl. iii. 203) ; or by heating erythroxanthraquinone acid ($C_{15}H_8O_5$ at 270° (Birnkow, Ber. 1887, 20, 2438), and by heating anthraquinone-a-monosulphonic acid with a mixture of alkali hydroxide and a salt of an alkaline earth metal under pressure (Fr. Pat. 336867 ; J. Soc. Chem. Ind. 1904, 438 ; *ibid.* 1905, 841).

Erythroxanthraquinone crystallises from alcohol in groups of pomegranate-yellow needles, more soluble in hot than in cold alcohol. It melts at 173°-180° (Baeyer and Caro), at 190° (Liebermann), at 191° (Römer). It begins to sublime at 150°, and condenses to form fine needles, reddish-yellow in colour, like alizarin. It is almost insoluble in dilute ammonia, and only slightly soluble in strong ammonia. With lime or baryta water it gives a dark-red, almost insoluble lake, decomposable by carbon dioxide. The absorption spectrum of a sulphuric acid solution of erythroxanthraquinone differs from that of its isomeride, hydroxyanthraquinone; the latter body is also more easily converted into alizarin by fusion with caustic potash than the former (Baeyer and Caro, Ber. 7, 986).

Nitric acid oxidises ethythroxyanthraquinone to phthalic acid.

When sodium erythroxyanthraquinone sulphonate is heated with bromine and water at 120°-123°, 2 : 4-*dibromo*-1-*hydroxyanthraquinone* is formed, crystallising in reddish-yellow needles, m.p. 233°. When heated with p-toluidine at 80°-100°, this bromine derivative loses the bromine atom in the -4- position, and is converted into bromoquinizarin blue

$$C_6H_4 \underset{CO}{\overset{CO}{\diagdown}} C_6 \cdot HBr(OH)(NHC_7H_7)$$
which crystallises in blue needles, giving a green colouration with sulphuric acid (D. R. P. 127532, 1902).

Erythroxyanthraquinone forms an acetate $C_{16}H_{10}O_4$, yellow needles, m.p. 176°-179° (Liebermann and Hagen, Ber. 1882, 5, 1804).

The constitution of erythroxyanthraquinone has been established by Liebermann (Ber. 10, 611 ; 11, 1611), who synthesised it from a reduction product of quinizarin, hydroxyhydroanthranol $C_6H_4 \underset{CH(OH)}{\overset{CH_2}{\diagdown}} C_8H_3(OH)$, in which the hydroxyl-group in the benzene nucleus occupies the ortho- position Frande (Ber. 12, 237) was also able to show that in methylhydroxyanthraquinone, a derivative of ordinary hydroxyanthraquinone, the hydroxyl-group was in the para- position, and hence, in the isomeric erythroxyanthraquinone, the hydroxyl- group must be in the ortho- position with regard to the ketone group. Erythroxyanthraquinone is therefore *o*-hydroxyanthraquinone (*v.* ALIZARIN AND ALLIED COLOURING MATTERS).

ESCALIN. Trade name for a paste of aluminium powder and glycerol.

ESERAMINE, ESERIDINE, ESEROLINE *v* ORDEAL BEAN.

ESERINE or **PHYSOSTIGMINE**

$$NHMe \cdot CO \cdot NHC_{13}H_{16}N \cdot OH$$

(Herzig and Meyer, Monatsh. 1897, 18, 389 ; Heubner, Chem. Zentr. 1905, ii. 1111 ; Straus, Ann. 1913, 401, 350 ; 1914, 406, 332 ; the most recent work is by Polonovski and callaborators, *e g.* van Bull Soc. chim. 1918, 23, 356) is the most important of the alkaloids occurring in Calabar bean, in the seed of which it was first found by Jobst and Hesse, in 1864 (Annalen, 1864, 129, 115 ; Hesse, *ibid.* 1867, 141, 82).

It is present in variable amount (0·04-0·27 p.c. Carr and Reynolds, Pharm. J. 1908, 542), and may be extracted by shaking the powdered seed with warm alcohol containing about 1 gram of tartaric acid per litre. The alcohol of the extract is distilled off and the residue is taken up with water, filtered to remove resinous matter and repeatedly shaken with ether until the latter ceases to be coloured. The aqueous extract is then made alkaline with sodium bicarbonate and finally repeatedly shaken out with ether. On evaporation, the alkaloid separates in scaly crystals which may be purified by recrystallisation from ether.

Eserine forms thin rhomboidal, colourless lamellæ, m.p. 105°-106°, which gradually assume a rose tint and even a yellow colour when exposed to air. It is sparingly soluble in water,

but readily so in alcohol, ether, chloroform, benzene, and carbon disulphide. Eserine is lævo-rotatory, its specific rotation varying between $-82°$ and $-120°$, depending on the solvent employed (Petit and Polonovski, Bull. Soc. chim. 1893, 9, 1008; cf. Orloff, Chem. Zentr. 1897, i. 1214). Polonovski and Nitzberg, Bull. Soc. chim. 1915, 17, 235 et seq.; idem. 1916, 19, 27, 46.

When eserine is isolated in the form of its salicylate, the base liberated with sodium carbonate, extracted with ether, and finally allowed to crystallise from a mixture of benzene and petroleum, it separates in stout prisms, m.p. $86°-87°$, $[a]_D$ $-75·8°$. By recrystallising in the presence of a crystal of Petit and Polonovski's modification, m.p. $105°-106°$, it is completely converted into the latter, and has $[a]_D-75·8°$; the alkaloid is therefore dimorphous (Salway, Chem. Soc. Trans. 1911, 2151).

When eserine or its salts are distilled with caustic potash in a current of hydrogen, methylamine and carbon dioxide are amongst the products of decomposition, whilst the residual liquid contains eseroline, a colourless crystalline body, which turns red by the action of moisture. Eseroline is also formed, together with methyl carbamide, when eserine is heated in a sealed tube with alcoholic ammonia at 150°. When heated with aqueous potash in presence of air, eserine yields rubreserine $C_{13}H_{16}N_2O_2$, red needles; these, in alkaline solution, are gradually converted into eserine blue, which, according to Ehrenberg (Chem. Zentr. 1894, ii. 439), is a true dye, colouring wool and silk without mordants. The constitution of eserine blue is not known, c.f. Salway, Chem. Soc. Trans. 1912, 986. It is not poisonous, but it has a paralysing effect on the heart and central nervous system of the frog (Heubner, l.c.).

Salts of eserine. Eserine salicylate

$$C_6H_4(OH)CO_2H,C_{15}H_{21}O_2N_3$$
forms slightly bitter, colourless, stout prisms, m.p. $180°-181°$ (Salway), soluble in 150 parts of cold and 30 parts of boiling water, in which it forms an acid solution; it is more readily soluble in alcohol and in chloroform.

Eserine metacresotate (metahydroxytoluate)

$$C_{15}H_{21}O_2N_3·C_6H_3(OH)MeCO_2H$$
m.p. $156°-167°$, is prepared by mixing ethereal solutions of metacresotic acid and of eserine. Eserine benzoate, m.p. $115°-116°$, soluble in four parts of cold water, and eserine hydrogen citrate, are prepared similarly. The two former are not deliquescent, and yield neutral aqueous solutions; whereas the latter, and also normal eserine tartrate, prepared by dissolving eserine in tartaric acid and crystallising over sulphuric acid, are very deliquescent (Petit and Polonowsky, l.c.). The methiodide forms deliquescent yellow prisms, m.p. 100° (decomp.), and the sparingly soluble picrate crystallises in feathery yellow needles, m.p. 114°. Eserine yields no definite aurichloride or platinichloride.

Eserine sulphate $(C_{15}H_{21}O_2N_3)_2H_2SO_4$ is prepared by adding a 10 p.c. sulphuric acid, drop by drop, to an ethereal solution of eserine until the newly formed salt no longer separates. After filtration, it is carefully dried at about 40°. It

is a white or yellowish-white micro-crystalline powder, odourless, and having a bitter taste. It is readily soluble in water, alcohol, and in chloroform. Gold chloride solution, when added to the aqueous solution of the salt, gives a beautiful purple colour; whilst platinic chloride precipitates a yellowish-white salt. When evaporated with ammonia, the sulphate, like the salicylate, yields a bluish residue. If a little eserine sulphate is placed on a glass slip and moistened with water, and then a drop of sulphuric acid added, characteristic crystals of a sparingly soluble sulphate separate. This characteristic appearance is maintained for some time, but eventually the crystals become oily and then resinous (Reichard, Pharm. Zeit. 1909, 50, 375). Eserine and its salts turn red on treatment with alkali or on standing in solution, but the sulphite $C_{15}H_{21}O_2N_3,H_2SO_3$, the aqueous solution of which does not turn red, but remains colourless, has been prepared by Merck by treating a solution of eserine with sulphurous acid, and evaporating the mixture (D. R. P. 166310; J. Soc. Chem. Ind. 1906, 443). It is a white powder, readily soluble in water.

A derivative, the intensity of the fluorescence of which exceeds that of all known substances, is obtained by allowing an aqueous solution of physostigmine to stand for a few months until it has become deep blue, then adding phthalic acid. The substance forms dark-blue crystals with a blood-red fluorescence, and colours cotton, silk, alcohol, ether, &c., dark blue with no fluorescence. The aqueous solution, on the other hand, is colourless by transmitted light, but shows a beautiful red fluorescence by reflected light (Goubert, Compt. rend. 1909, 149, 852).

Eserine and its salts should be kept in amber-coloured, well-stoppered phials.

Test for eserine or its salts.—A small fragment (the size of a grain of sand) is placed in a porcelain capsule and dissolved in a drop or two of fuming nitric acid. The dark-yellow solution formed on warming is evaporated with stirring; the residue, which is of a pure green colour, dissolves in water, strong alcohol, and in sulphuric acid to a clear green solution. 0·005 gram of the alkaloid can thus be detected. The green colouring matter has been termed chloreserine (Ferreira da Silva, Compt. rend. 1893, 117, 330; Formanek, Chem. Zentr. 1895, i.1148; Reichard, l.c.). When exposed to nitric acid fumes, the blue residue becomes violet-blue; and when dissolved in a drop of nitric acid it forms a beautiful reddish-violet solution, which soon changes to blood-red, and on standing or on dilution becomes greenish-yellow. Eserine reduces molybdic acid very slowly in the cold, but rapidly gives a blue colouration on warming (Reichard, l.c.). With ammonium selenite in concentrated sulphuric acid, eserine gives a lemon-yellow colouration, which becomes orange, and then paler after standing for 3 hours (da Silva, Compt. rend. 1891, 112, 1266). Eserine can also be detected by means of the polarisation microscope (Kley, Rec. trav. chim. 1903, 22, 367). (For the estimation of eserine or physostigmine, see Heikel, Chem. Zentr. 1909, i. 949.)

Eserine and its salts are of considerable therapeutic value, being employed chiefly as a myotic to contract the pupil of the eye and to decrease intraocular pressure in glaucoma.

• According to Pal (Chem. Zentr. 1900, ii. 1031), eserine forms an antidote to the poisonous effect of curare.

Bilateral antagonism exists between eserine and curare in their effect on muscle. Those muscles which, like the diaphragm, are last paralysed by curare are first set free again by the injectio i of eserine. The latter also stimulates the respiratory centre (Rothberger, Pflüger's Archiv. 1901, 87, 117).

(For other investigations on the physiological effect and use of eserine or physostigmine, *see* Matthews and Brown, Amer. J. Physiol. 1904, 12, 173; Edmund and Roth, *ibid.* 1908, 23, 28, 46; Joseph, *ibid.* 1909, 23, 215; Anderson, J. Physiol. 1905, 33, 414; Magnus, Pfluger's Archiv. 1908, 123, 99; Kress, *ibid.* 1905, 109, 608; Modrakowski, *ibid.* 1907, 118, 52; Unger, *ibid.* 1907, 119, 373; Harnack, Chem. Pharm., 1917, 82, 205) (*V.* ORDEAL BEAN.) G. B.

ESPARTO, *Stipa marcrochloa* (*tenacissima*) (Linn.). This grass is a native of Spain, Portugal, Greece, and North Africa. It is largely used as a raw material for paper making, having been introduced into this country by Routledge. For this purpose it possesses many advantages, as it grows abundantly without cultivation, is easily harvested, yields a large percentage of cellulose of high quality with comparatively simple treatment.

Of the various kinds known to commerce, such as Spanish, Tripoli, Arzen, Oran, Sfaz, Gabes, &c., the first-named is preferred by paper makers, as it yields more and better fibre. It therefore commands a higher price.

To give some idea of the importance of esparto as a paper-making material, it may be mentioned that the annual imports into the United Kingdom are between 200,000 and 300,000 tons.

It is also used for the purpose of making coarse mats and ropes (*v.* Spon's Enc. of the Industrial Arts).

Esparto arrives in this country firmly pressed into bales. The first operation which it undergoes in the paper mill is that of ' dry-picking,' in contradistinction to a subsequent process known as ' wet-picking.' The grass is spread out on tables covered with coarse wire cloth, and any root ends, weeds, &c., which may have found their way into the bales through imperfect gathering are picked out. Any sand or dirt escapes through the wire cloth. The removal of dirt can be more completely effected by machinery. For this purpose the grass is fed into a mechanical duster or willow, where it receives a violent shaking, the dirt being loosened and removed. The cleaned esparto is then fed into ' vomiting ' boilers, where it is treated with caustic soda solution at pressures varying from 10 to 40 lbs. per sq. inch for from 3 to 5 hours. The amount of soda required is about 17 lbs. of 60 p.c. caustic soda per cwt., but it varies with the quality of the grass, the form of boiler, the pressure at which it is boiled, and the time allowed. When the boiling is completed, the liquor is run away, evaporated to dryness, and ignited, and the alkali recovered in the form of

carbonate. This is dissolved in water, converted into caustic by means of lime, and is again available for use.

The boiled grass is washed once or twice in the boiler, and then subjected to the ' wet-picking ' process, whereby any unboiled portions are removed. The process is being gradually abandoned in favour of what is known as the ' presse-pâte ' system, which consists in purifying the pulp by passing it when bleached through a series of strainers and knotters. It is then made into a coarse web of pulp on the ' presse-pâte,' which may be described as a paper machine without the drying cylinders.

The subsequent treatment of esparto does not differ essentially from that of other fibres, and need not be particularly described.

The haulms (really leaves) of esparto vary in length from 0·3 to 0·5 m., the mean thickness being about 1·5 mm.; the individual fibres are 100–400 mm. long, and 0·009–0·5 mm. thick.

The fibres possess, owing to their fineness and their tendency to curl, considerable ' felting ' properties. Paper made from esparto is soft to the touch, ' bulks ' well, and at the same time is strong.

Esparto fibre can be recognised in a paper by the fact that when boiled with a solution of aniline sulphate a rose-pink colour is developed. A similar colour is produced with straw cellulose, but of a paler shade. With iodine and sulphuric acid the wall of the actual bast-fibre assumes a rusty colour, showing that it is not composed of cellulose ; with aniline sulphate (cold) it is stained yellow ; and with phloroglucinol and hydrochloric acid a crimson colour is assumed, thus demonstrating the presence of bodies characteristic of lignified walls. They can be distinguished by the size and shape of the peculiar serrated epidermal cells, which are to be seen when the commercial fibre is examined under the microscope.

Moreover, esparto pulp always has a number of the short conical, often hooked, hairs which line the inner (upper) surface of the ' rolled ' leaf, and which serve to distinguish it from straw ; the outer (lower) surface of the leaf is glabrous.

The chemical characteristics of esparto are those of the ligno-celluloses and the pecto-celluloses, the latter predominating.

Its composition is shown by the following analyses (Hugo Muller) :—

		Spanish.	African.
Cellulose	. .	48·25	45·80
Fat and wax .	.	2·07	2·62
Aqueous extract	.	10·19	9·81
Lignin and pectous			
substances	.	26·39	29·30
Ash . .	.	3·72	3·67
Water . .	.	9·38	8·80
		100·00	100·00

The names ' esparto,' ' sparto,' and ' alfa ' (' halfa '), are also given to the leaves of another grass, *Lygeum spartum* (Loefl.), which likewise grows in Spain and North Africa. These leaves are used as an inefficient substitute for those of *Stipa.* Microscopically they differ, in that the hairs have a considerable lumen, and are

usually blunt-ended; the epidermis has peculiar little rounded silica cells; and the ribs of bast fibres are isolated (not linked together to form a continuous band, as in *Stipa*).

ESTERIFICATION. The reaction between an acid and a monohydric alcohol appears, at first sight, to be exactly analogous to the neutralisation of an acid by a monoacid base: the equations are:

$$CH_3 \cdot CO \cdot OH + C_2H_5 \cdot OH = CH_3 \cdot CO \cdot OC_2H_5 + H_2O$$

and

$$CH_3 \cdot CO \cdot OH + NaOH = CH_3 \cdot COONa + H_2O$$
The product formed in the second reaction is a metallic salt, and that in the first reaction is termed an alkyl salt or more commonly an *ester*. The esters can be regarded as metallic salts in which the metallic radicals have become replaced by alkyl-groups. Corresponding with mono-, di-, and trivalent-metallic radicals are the mono-, di-, and trivalent hydrocarbon radicals, methyl CH_3-, ethyl C_2H_5-, propyl C_3H_7-, &c., methylene $CH_2=$, ethylidene $C_2H_4=$, &c., glyceryl $C_3H_5\equiv$, &c. The process of the conversion of an acid into its alkyl-salts is usually termed *esterification*, and is the common method by means of which esters are prepared. Although this reaction appears to be similar to the process of neutralising an acid by means of an alkali, there are two important points of difference.

1. The reaction between an acid and an alkali in aqueous solution is instantaneous, whereas the reaction between an acid and an alcohol is usually slow, and lends itself readily to study as a time reaction.

2. In the process of neutralisation between strong acids and strong alkalis, the reaction proceeds to completion when equivalent quantities of acid and alkali are used; but when equivalent amounts of acid and alcohol are brought together, complete conversion into ester and water never takes place. The reaction begins slowly and proceeds until a state of equilibrium is established. The rate at which the reaction proceeds, and the final equilibrium depend upon the specific acid and alcohol employed and upon the temperature. The process of esterification is a typical balanced or reversible reaction:

$$R \cdot CO_2H + R' \cdot OH \rightleftharpoons R \cdot CO_2R' + H_2O$$
as the water formed in the process of esterification can hydrolyse the ester to a certain extent. This reaction is one of the best to study in order to illustrate the effects of mass action.

The reaction between acetic acid and ethyl alcohol was studied by Berthelot and Péan de St. Gilles, in 1862; they showed that working with equivalent quantities of alcohol and acid, equilibrium is reached when 66 p.c. of the reacting compounds have been transformed into ester and water. They were able to show that, by working with an excess of alcohol, a higher percentage of the acid can be transformed, as illustrated by the following numbers.

Equivalents of alcohol for 1 equivalent of acid	0·2	0·5	1·0	1·5	2·0	4·0	12	50
p.c. of acid transformed into ester	19	42	66·5	78	83	88	93	100

According to Guldberg and Waage's law of mass action formulated in 1867, the rate of chemical reaction is proportional to the concentrations (molecular) of the reacting substances, and to a constant which is characteristic of the reaction and retains the same value provided the temperature is constant. In the balanced reaction:

$$CH_3 \cdot CO_2H + EtOH \rightleftharpoons CH_3 \cdot CO_2Et + H_2O$$
the direct reaction proceeds at a rate which can be denoted by $K.a.b$, where K is the specific constant for this reaction, and a and b are the concentrations of the acid and alcohol at the time of measuring the rate. Similarly, the reverse reaction proceeds at a rate $K'.c.d$, where c and d are the concentrations of the ester and water at the particular time. When the state of equilibrium is reached, we have:

$$K.a.b = K'.c.d$$

Using one equivalent of acid and one equivalent of alcohol, Berthelot and St. Gilles showed that equilibrium is reached when 0·66 mol. of acid and of alcohol have been transformed, leaving 0·33 mol. in the free state; we thus have:

$$K \times 0.33 \times 0.33 = K' \times 0.66 \times 0.66$$

$$\text{or } \frac{K}{K'} = \left[\frac{0.66}{0.33} \right]^2 = 4$$

The ratio K/K' is denoted by K, and is usually termed the equilibrium constant. It is the ratio of the constants for the direct and reverse reactions, and is independent of concentration, but may vary with temperature.

This equilibrium constant enables us to calculate the amount of acid transformed when any known quantities of the given acid and alcohol are mixed at the given temperature and kept until equilibrium is attained.

With a mixture of a, b, c, d equivalents of acid, alcohol, ester, and water at the given temperature, $a-x$ and $b-x$ equivalents of acid and alcohol will be present when equilibrium is attained, and $c+x$ and $d+x$ equivalents of ester and water will also be present, as each equivalent of acid reacts with an equivalent of alcohol and produces one equivalent of both ester and water.

$$\frac{K}{K'} = \frac{(c+x)(d+x)}{(a-x)(b-x)}; \text{ but } \frac{K}{K'} = 4$$

$$\therefore \frac{(c+x)(d+x)}{(a-x)(b-x)} = 4$$

and x can be calculated when a, b, c, d are known.

It is necessary to distinguish between esterification by means of the acid and alcohol alone, and esterification of an acid by an alcohol in the presence of a catalytic agent. The former process is generally termed 'direct esterification,' or sometimes 'autocatalytic esterification,' as it has been suggested that the organic acid itself can act as a catalyst to a certain extent. The second process is termed the catalytic method of esterification, and is the method most commonly used in the laboratory for the preparation of esters.

Catalytic esterification. The modern laboratory method is due to E. Fischer and Speier (Ber. 1895, 28, 3252). It consists in heating the acid with excess of alcohol, usually about five times the theoretical amount, in the presence of a catalyst. The most efficient catalysts are strong acids, and hydrogen chloride (about 3 p.c. of the alcohol) or concentrated sulphuric acid (about 10 p.c. of the alcohol) is generally used. When hydrogen chloride is used it is advisable to prepare a 3 p.c. solution of this in the alcohol before adding the organic acid. The 3 p.c. solution is best prepared by weighing the alcohol and passing in the dry gas by means of a delivery tube which just touches the surface of the liquid, and weighing from time to time until the requisite increase in weight is attained. The organic acid is then added, and the whole boiled in a reflux apparatus for 3 hours. The greater part of the alcohol is distilled off, the residue poured into about 5 times its volume of cold water, and the solution neutralised with sodium carbonate. It is then extracted with ether, the ethereal solution dried and distilled, when a 90 p.c. yield of the ester can usually be obtained. Esters which are readily hydrolysed by water, or esters which are extremely soluble in water, can sometimes be isolated by subjecting the reaction mixture to distillation under reduced pressure. J. and M. Phelps (Amer. J. Sci. 1907, [iv.] 24, 194) advise heating the acid, e.g. succinic or benzoic, with about its own weight of 1 p.c. alcoholic hydrogen chloride, and a small amount of solid zinc chloride at 100°–110°, and afterwards passing in a current of alcohol (compare *ibid.* 1908, 26, 281). For constants and properties of common esters, *see* Mathews and Faville (J. Physical Chem 1918, 22, 1.)

The function of the catalyst is to accelerate the rate of esterification; many acids which react very slowly with alcohol alone, e.g. acetic acid at the ordinary temperature, can be transformed rapidly into esters in the presence of a small amount of catalyst. Hydrogen chloride is a more efficient agent than sulphuric acid, the ratio being three to one (Kailan, Monatsh. 1909, 30, 21); but sulphuric acid is frequently used, as it is more convenient to work with. Phelps (Amer. J. Sci. 1908, [iv.] 260, 290, 296) has examined the action of various acid sulphates, e.g. NaHSO₄, KHSO₄, piperidine and aniline hydrogen sulphates, but finds that they are not so efficient as sulphuric acid, and similarly he has studied the action of metallic chlorides on the catalytic action of hydrogen chloride. Charcoal (Freundlich, Zeitsch. physikal. Chem. 1906, 57, 412) and finely divided platinum (Sudborough and Turner) also act as feeble catalysts. It is usually stated that the presence of the catalyst does not affect the equilibrium, and that provided the ratio of alcohol is kept the same, the percentage of ester formed when equilibrium has been obtained, is the same in both catalytic and direct processes; but Phelps does not agree with this statement. Ultra violet light brings about esterification of solutions of benzoic and other cyclic acids, especially in the presence of a trace of hydrochloric acid (Stoermer and Ladewig, Ber. 1914, 47, 1803).

The amount of ester formed by the catalytic process depends upon the specific acid and alcohol used, and tends to become less when the ester is readily hydrolysable. In the case of esters extremely soluble in water, or very readily hydrolysed, it is not advisable to pour into water, but to distil immediately under reduced pressure. Phelps and Eddy (Am. J. Sci. 1908, 26, 253) recommend adding solid potassium carbonate to the reaction mixture and distilling under reduced pressure. Certain finely divided metallic oxides have a catalytic action on the formation of esters.

A method of catalytic esterification consists in passing a mixture of the vapours of the acid and alcohol through a tube containing finely divided titanium dioxide at 290°–300° (Sabatier and Maihle, Compt. rend. 1911, 152, 494 ; A. Mailhe, Chem. Zeit. 1913, 37, 777 and 806).

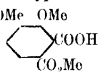
According to Hauser and Klotz (Chem. Zeit. 1913, 37, 146), glucinum oxide is more efficient than titanium oxide, and even tertiary alcohols yield esters when this oxide is used.

Senderens and Aboulenc (Compt. rend. 1911, 152, 1671, 1855 ; 1912, 155, 168, 1012) state that by the addition of 5 p.c. of aluminium sulphate or of potassium hydrogen sulphate to a mixture of equivalent amounts of acetic acid and ethyl alcohol an 82 p.c. yield of ester is obtained, and that 1 p.c of sulphuric acid by volume gives an 86·5 p.c yield. The actual catalyst is stated to be ethyl hydrogen sulphate.

Various esters derived from cyclic alcohols, e.g. cyclohexanol, have been prepared by the method. The temperature, however, must not be too high and the method does not work with aromatic acids containing a carboxylic group directly attached to the benzene nucleus.

For use of (a) anhydrous calcium chloride, *see* Chem. Soc. Abstr 1911, i. 601, (b) nickel sulphate Kurtenacker and Habermann, J. Pr. Chem. 1911, (ii.) 83, 541, and (c) dilute sulphuric acid Bodroux, Compt. rend. 1913, 156, 1079 ; 157, 938, 1428. A convenient method for certain esters appears to be a saturated aqueous solution of sodium chloride as solvent and a little sulphuric acid as catalyst.
Relationship between constitution and esterification using the catalytic method. V. Meyer and Sudborough (Ber. 1894, 27, 510, 1580, 3146) were the first to point out any clear relationship between the constitution of an acid and its conversion into an ester by the catalytic method. Their original method was to saturate the alcoholic solution of the acid with hydrogen chloride, to leave at the ordinary temperature for several hours, and then to isolate and weigh the ester formed. Subsequently the Fischer-Speier method was used. They were able to show that practically any substituted benzoic acid, in which the two ortho- positions with respect to the carboxylic group are substituted, does not yield appreciable amounts of ester when its alcoholic solution is saturated with hydrogen chloride and kept for several hours at the ordinary temperature, or when the acid is boiled with a 4 p.c. solution of hydrogen chloride in alcohol. All substituents react in much the same manner, e.g. CH₃, Cl, Br, F, I, CO₂H, NO₂, &c., but the substituents F, OH, CH₂ have not so marked an effect as nitro-, carboxylic, and halide radicals ; e.g. acids of the type

$$C_6H_2Me_3 \cdot CO_2H(CO_2H : Me_2 = 1 : 2 : 4 : 6)$$

are esterified to an appreciable extent when hydrogen chloride is passed through their


boiling alcoholic solutions for several hours (Meyer and Sudborough, Ber. 1894, 27, 1580; Meyer, *ibid.* 1895, 28, 182, 1254; compare also Kahn, *ibid.* 1902, 35, 3857).

The presence of a second benzene nucleus, as in naphthalene- and anthracene-carboxylic acids, has much the same effect as nitro- or halogen substituents; thus 2-chloro-1-naphthoic acid, anthracene-7-carboxylic acid and 1-chloroanthracene-9-carboxylic acid do not yield esters by the catalytic method, whereas the isomeric 3-chloro-2-naphthoic acid, anthracene-1-carboxylic acid, and 3-chloroanthracene-2-carboxylic acid yield 90 p.c. of ester under the same conditions.

It has been shown by V. Meyer (Ber. 1895, 28, 3197; and Rupp, *ibid.* 1896, 29, 1625) that the dibasic acids :—tetrachloro-, tetrabromo-, and tetraiodo-terephthalic acids, tetrachloro-, tetrabromo-, and tetraiodo-*iso*phthalic acids, *i.e.* acids in which both carboxylic groups are diortho- substituted, do not yield esters when heated with a 3 p.c. solution of hydrogen chloride in alcohol. An acid in which one of the carboxylic groups is diortho- substituted and the other is not, yields an acid ester under similar conditions, *e.g.* 2 : 6-dimethylterephthalic

acid, $C_6H_2Me_2(CO_2H)_2$ gives CO_2Me

(Jannash and Weiler, Ber. 1895, 28, 531). Similarly, hemipinic acid, 3:4-dimethoxyphthalic

acid, gives the acid ester

(Wegscheider, Monatsh. 1895, 16, 135). (For further examples, *see* Wegscheider, *ibid.* 1900, 21, 621, 638; 1902, 23, 405; McKenzie, Chem. Soc. Trans. 1901, 79, 1135.) An apparent exception is met with in the case of 3:6-dichlorophthalic acid, which, according to Graebe (Ber. 1900, 33, 2026), yields the acid ester

when its alcoholic solution is saturated with hydrogen chloride and kept at the ordinary temperature. Tetrachloro-, tetrabromo-, and tetraiodo-phthalic acids also yield acid esters (Rupp, *ibid.* 1896, 29, 1625); o-nitrophthalic acid and papaverinic acid (Miller, Annalen, 1881, 208, 243; Wegscheider and Lipschitz, Monatsh. 1906, 21, 790; Wegscheider, *ibid.* 1902, 23, 369) behave in a similar manner, yielding neutral esters, and it is probable that the esters are formed by the conversion of the acids into their anhydrides under the influence of the hydrogen chloride or sulphuric acid, and the subsequent addition of alcohol to the anhydrides. 3:6-Dichlorobenzoylbenzoic acid and tetrachlorobenzoylbenzoic acid are also readily esterified, and it is possible that these react with alcohol as the tautomeric hydroxyphthalides; *e.g.* :
(Graebe). The results obtained with tri-, or even hexa-carboxylic acids show the same inhibiting effect of ortho-substituents. Thus trimesic acid, benzene 1:3:5-tricarboxylic acid, yields a neutral ester; hemimellitic acid, the 1:2:3-tricarboxylic acid, yields a dimethyl ester; pyromellitic acid, benzene-1:2:4:5-tetracarboxylic acid, yields a normal ester; prehnitic acid, 1:2:3:4-tetracarboxylic acid, gives a dimethyl ester in the cold, and the neutral ester on heating; the formation of the latter is probably due to the fact that an anhydride is first formed, and this, with methyl alcohol, gives the dimethyl ester
which is further esterified to the normal ester. Dinitro-pyromellitic acid, mellitic acid, and hexahydromellitic acid do not yield esters (Meyer, Ber. 1894, 27, 1590; 28, 182; 1896, 29, 840). *Iso*hydromellitic acid, on the other hand, yields a monomethyl ester (Van Loon, *ibid.* 1895, 28, 1272).

Substituted benzoic acids in which the substituents are not in ortho- positions, give good yields of esters by the Fischer-Speier method, and this difference in behaviour has been used for the following purposes : 1. Separation of an ortho-disubstituted benzoic acid from isomerides (compare Martz, Ber. 27, 3147, for separation of dinitro-benzoic acids; Jannasch and Weiler, *ibid.* 3445, for separation of isomeric trimethyl-benzoic acids). Rosanoff and Prager (J. Amer. Chem. Soc. 1908, 30, 1912) show that a mixture of benzoic acid with an ortho- substituted benzoic acid can be separated by partial esterification in the cold with a 3 p.c. solution of hydrogen chloride in ethyl alcohol. 2. Determination of the constitution of particular substituted benzoic acids. (Compare V. Meyer, Ber. 1895, 28, 187, for 2-methyl-5-bromobenzoic acid; Zincke and Francke, Annalen, 1896, 293, 123, for 4-acetyl-5-bromo-*iso*-phthalic acid; and Matthews, Chem. Soc. Proc. 1900, 16, 187, for 2:3:5-trichlorobenzoic acid. *See* also Blaise, Compt. rend. 1898, 126, 733, for substituted succinic acids.)

When the carboxylic group is not directly attached to the benzene nucleus, but is united to a side chain, the presence of ortho- substituents does not prevent the formation of esters, *e.g.* 2:4:6-tribromo-3-aminophenylpropionic acid and 2:4:6-tribromophenylpropionic acid, mesitylacetic and mesitylglyoxylic acid all gave good yields of esters when the alcoholic solutions are saturated with hydrogen chloride. Kellas (Zeitsch. physikal. Chem. 1897, 24, 221) and Goldschmidt (Zeitsch. lect. Chem. 1909, 15, 4) have shown that the introduction of one ortho- substituent into the benzoic acid molecule retards esterification to an appreciable extent, the nitro- group having a greater inhibiting effect than Me, Cl, Br, or I. Kailan also shows that o-aminobenzoic acid hydrochloride is esterified more slowly than its isomerides (Monatsh. 1906, 27, 1038); but he finds that o-nitrocinnamic acid is esterified more readily than the p- and m-nitro acids (*ibid.* 1907, 28, 1163). Goldschmidt was able to show that using a dilute alcoholic solution of the acid with hydrogen chloride as catalyst, the velocity of the reaction can be determined by means of the equation for a unimolecular reaction, $K=$

$1/t(\log a/a-x)$; since under these conditions the mass of the alcohol can be regarded as constant, and the reaction is practically non-reversible in the presence of the large excess of alcohol. The concentration of the acid at any given moment can be determined by direct titration with standard barium hydroxide solution, using phenolphthalein as indicator. When, however, the ester formed is readily hydrolysed, as in the case of ethyl formate, ethyl trichloracetate, and ethyl pyruvate, it is necessary to titrate with ammonium hydroxide solution, using litmus as indicator, as the end point is not definite when baryta is used, owing to the instantaneous hydrolysis of the ester by the baryta. The constant K is directly proportional to the concentration of the hydrogen chloride in the absence of water, and falls somewhat as t (time) increases, owing to the fact that the water produced during the esterification has a retarding effect. The influence of small amounts of water has been studied by Kailan (Monatsh. 1906, 27, 543, 997 ; 1907, 28, 115, 571, 673, 705, 965, 1069, 1137, 1187 ; 1908, 29, 799 ; 1909, 30, 1), who has shown that the relationship between the rate of esterification and the amount of water can be represented by means of an equation of the type, e.g. in the case of cinnamic acid

$$\frac{1}{K}=0.665+\frac{4876}{c}-\frac{1.678}{c_2}+\left(2.911-\frac{3.212}{c}+\frac{4.358}{c_2}\right)w$$
$$+\left(-27.54+\frac{31.78}{c}-\frac{2.284}{c_2}\right)w^2$$

for concentrations of water $w=0.3$ to 1.3, and for concentrations of hydrogen chloride $c=0.15$ to 0.66. (Compare also Fitzgerald and Lapworth, Chem. Soc. Trans. 1908, 93, 2168.)

The inhibiting action of water on a mixture of acid and alcohol is readily shown by comparing the rates of esterification of the same mixture of acid and alcohol : (a) in presence of water ; (b) in presence of a corresponding quantity of benzene (Kailan, Zeitsch. physikal. Chem. 1915, 89, 676). When 25 or 50 volume p.c. of alcohol is used the relative effects of benzene and water are as 1 : 100 or 150. The effect of water on the esterification of dibasic acids has also been examined (Kailan, ibid. 1913, 85, 706 ; 1914, 87, 619).

Sirks (Rec. trav. chim. 1908, 27, 237) has obtained the following values for the esterification constants of the isomeric dinitrobenzoic acids at 25°, using ethyl alcohol containing a little water with hydrogen chloride as catalyst : 3 : 4-dinitro-acid, 0.0086 ; 3 : 5-acid, 0.0050 ; 2 : 3-acid, 0.0005 ; 2 : 5-acid, 0.0003 ; 2 : 4-acid, 0.0002 ; and 2 : 6-acid, nil. The values for $E_{EtOH}^{25°}$ obtained for benzoic, m-, and o-nitrobenzoic acids were 0.0132, 0.0071, 0.001.[1]

These numbers indicate the retarding effect of one or two nitro- groups in the ortho- position ; even one m- group retards, but the introduction of a second nitro- group into the meta- position of the m-nitro- acid molecule, increases the rate.

[1] The letter E is used to denote the esterification constant of an acid, using normal hydrogen chloride as catalyst, and the temperature and specific alcohol are also given, as the constant varies with these.

From a comparison of the rates of esterification of these acids with their dissociation constants, Sirks comes to the conclusion that acids with small dissociation constants are esterified more readily by the catalytic method than acids with high dissociation constants ; but an examination of certain alkyl- derivatives of aliphatic acids shows that the statement does not hold good generally.

Sudborough and Lloyd, by using Goldschmidt's method of determining esterification constants, have shown that the introduction of one substituent into the acetic acid molecule has a retarding effect, whatever the nature of the substituent. The introduction of two substituents usually has a more marked effect than one, and three a greater influence than two, when the two or three substituents are alike. A comparison of the esterification constants for the normal fatty acids gave the following values for $E_{MeOH}^{15°}$: formic 1124, acetic 104, propionic 92, and from butyric to stearic values between 50 and 54. The introduction of a carbonyl- group in place of the α-methylene group of a normal fatty acid produces a retardation (Kailan, Monatsh. 1907, 28, 1187 ; Sudborough, Chem. Soc. Trans. 1912, 101, 1227). The introduction of methyl- groups into the molecule of methyl hydrogen succinate also produces a lowering of the esterification constant (Bone, Sudborough, and Sprankling, Chem. Soc. Trans. 1904, 85, 534).

In the case of unsaturated acids, the following generalisations have been drawn (compare Sudborough and Lloyd, Chem. Soc. Trans. 1898, 73, 81 ; Sudborough and Roberts, ibid. 1905, 87,1840 ; Sudborough and Thomas, ibid. 1907, 91, 1033 ; Sudborough and Gittins, ibid. 1909, 95, 315 ; Sudborough and Davies, ibid. 975). 1. An αβ-unsaturated acid is esterified much less readily than its saturated analogue ; in many cases the ratio is 1 : 40. 2. An αβ- unsaturated acid is esterified far less readily than the isomeric acids, in which the double linking is further removed from the carboxyl- group. As a rule, βγ- unsaturated acids are esterified more readily than their saturated analogues ; e.g. βγ-phenylcrotonic acid has $E_{MeOH}^{15°}$ 86.6, and the saturated γ-phenyl-n-butyric acid $E_{MeOH}^{15°}$ 56.25. γδ-Acids and other unsaturated acids, in which the double linking is further removed from the carboxyl- group, are esterified at much the same rate as the corresponding saturated acids ; e.g. E for oleic acid is 54.3, and for palmitic acid 49.7. 3. In most cases the introduction of a substituent into the α- position in the acrylic acid molecule has a greater inhibiting effect than when introduced into the β- position. 4. The effect of a substituent in the cis- position is more marked than in the trans-; thus an acid of the type

$$\begin{array}{c} X\!-\!C\!-\!H \\ \| \\ Y\!-\!C\!-\!CO_2H \end{array}$$

is more readily esterified than the isomeride

$$\begin{array}{c} H\!-\!C\!-\!X \\ \| \\ Y\!-\!C\!-\!CO_2H \end{array}$$
The difference in the rates of esterification of an αβ- unsaturated acid and the saturated analogue, a difference which has been confirmed by Kailan (Monatsh. 1907, 28, 1137) in the case

of cinnamic and hydrocinnamic acids, affords a very convenient method for separating mixtures of the two. This is well shown in the preparation of hydrocinnamic acid. The acid is obtained by the reduction of cinnamic acid, and is liable to contain small amounts of the latter, which are difficult to remove by crystallisation, but a complete separation can be effected by the action of a dilute solution of hydrogen chloride in ethyl alcohol. . The saturated acid is completely transformed into ester, and, under suitable conditions, the unsaturated acid remains unesterified. A similar method can also be used with advantage for the separation of a mixture of an $\alpha\beta$- unsaturated acid and the isomeric $\beta\gamma$-acid ; this method is preferable to the older method used by Fittig, in which the $\beta\gamma$-acid was transformed into the γ-lactone (Sudborough and Thomas, Chem. Soc. Trans. 1911, 99, 2307).

Gyr (Ber. 1908, 41, 4308) has determined the esterification constants of a number of mono-, di-, and tri- substituted acetic acids, and confirms the results obtained by Sudborough and Lloyd. The values, for example, for acetic, phenyl acetic, diphenyl acetic, and triphenyl acetic, at 25° are respectively 7·76, 3·57, 0·20, and 0·001. Gyr worked with absolute methyl alcohol, and recommends boiling some three or four times with small amounts of metallic calcium in order to remove the last traces of water.

Kistiakowsky (Zeitsch. physikal. Chem. 1898, 27, 250) has determined the velocity of reaction of an acid and alcohol in mixtures of the alcohol and water containing hydrogen chloride. In this case the esterification and hydrolysis proceed side by side, and the velocity constants for the two are denoted by K and K'. Then :

$$K = \frac{1}{t} \cdot \frac{\xi}{a} \log_e \frac{\xi}{\xi - x} \text{ and } K' = \frac{1}{t} \cdot \frac{a - \xi}{a} \log_e \frac{\xi}{\xi - x}$$

$$K + K' = \frac{1}{t} \log_e \frac{\xi}{\xi - x}$$

when the amounts of water and alcohol are large compared with the amount of acid present. ξ denotes the gram-molecules of acid transformed into ester at equilibrium, and x the number of gram-molecules transformed at end of time t. K can also be calculated from $K + K'$ by means of equation :

$$K = (K + K') \frac{\xi}{a}$$

The values of K and K' and also the value $\frac{\xi}{a}$ are independent of the original concentration of the organic acid.

The same values for K and K' are obtained when a mixture of acid, alcohol, water, and catalyst, or ester, alcohol, water, and catalyst are used, provided the proportion of water and alcohol and the concentration of the catalyst are kept the same.

The temperature coefficient between $t = 25°$ and $t = 30°$ is about 10 p.c. per degree, using mixtures of alcohol and water containing 13–70 p.c. alcohol.

The values of both K and K' fall on passing from formic to acetic, and again from acetic to monochloracetic.

The effect of the proportion of alcohol and water present is marked. The value of K in the

case of formic acid rises from 0 to 300 as the percentage of alcohol increases from 0 to 91·4, whereas the value for K' falls from 198 to 60, as the percentage of alcohol is increased from 0 to 91·4. In the absence of a catalyst, the velocity of esterification falls as the organic acid is used up, whereas the velocity of hydrolysis is first small, and gradually increases as fresh acid is formed, and both K and K' diminish with an increase in the amount of alcohol present.

Direct method of esterification. The reaction between alcohol and a mineral acid is frequently used as a method for the preparation of ethyl esters of inorganic acids, e.g. ethyl chloride' bromide, nitrite, sulphate (for ethyl bromide, cf. Weston, Chem. Soc. Trans. 1915, 107, 1489 ; Holt, ibid. 1916, 109, 1).

Norris, Watt, and Thomas (J. Amer. Chem. Soc. 1916, 38, 1071) have studied the reaction between different alcohols and dilute solutions of hydrochloric and hydrobromic acids. They find that the rate of formation of esters in the case of primary alcohols tends to decrease as the molecular weight of the alcohol increases. Of the three groups of alcohols, the tertiary are the most, and the primary least, reactive.

Menschutkin, working with the fatty acids (J. pr. Chem. 1881, [ii.] 24, 49 ; ibid. 1882, [ii.] 25, 193 ; Ber. 1897, 30, 2783), was one of the first to draw attention to the relationship between the rate of esterification and the constitution of the acid and of the alcohol, and found that the amount of acid converted into ester in a given time diminished with the complexity of the acid molecule, and also with the complexity of the alcohol molecule. By heating a given amount of acetic acid with equivalent amounts of different alcohols for one hour at 135°, Menschutkin was able to show that, on the whole, a primary alcohol is esterified more rapidly than a secondary, and a secondary than a tertiary. Some of the results obtained by Menschutkin for primary alcohols are not true measures of velocity, as equilibrium had already been obtained within the hour. It is also pointed out that the introduction of side chains or of negative substituents into a primary alcohol also tends to lower the rate of esterification, and the greater the number of such groups introduced the more pronounced is the effect. The introduction of an olefine linking into the molecule of the alcohol in the $\alpha\beta$- position also diminishes the rate of esterification. Subsequent experiments made by heating the alcohol with given weights of acetic anhydride gave similar . results. Still later work with hydroxy-polymethylenes (Chem. Soc. Trans. 1906, 89, 1533), using the acetic anhydride method, indicates that these compounds are esterified more readily than analogous open-chain compounds, e.g. the value for methyl-propyl-carbinol and cyclopentanol are respectively 98 and 189, and that cyclic tertiary alcohols are esterified least readily and primary most readily. The results also indicate that methyl- groups in the o- position with respect to the hydroxyl- group also produce retardation, but not to the same extent as when attached to the carbon atom to which the OH is attached. Michael and Wohlgast (Ber. 1909, 42, 3157) have determined the rates

of esterification of trichloracetic acid with various alcohols at 25° and 50°, and give the following numbers, using the equation for a bimolecular reaction :—

Primary alcohols	$K \times 10^4$ 25°	50°	Secondary	$K \times 10^5$ 25°	Tertiary	$K \times 10^6$ 25°
Methyl . .	3690	24,000	Dimethyl-carbinol .	98	Ter-butyl .	118
Ethyl . .	650	4,210	Methyl-ethyl „	90	Ter-amyl .	248
Propyl . .	725		Methyl-propyl „	76		
Butyl . .	1200		Methyl-hexyl „	109		
*Iso*butyl .	740					
Heptyl . .	1160					
Octyl . .	1860					
Cetyl . .	2500	16,300				

According to Michael, factors which are of importance are : 1. Degree of association of the alcohol ; as this is greater in the case of the simpler alcohols, the rate of esterification would be reduced to a greater extent. 2. Readiness with which the alcohol decomposes into H and R·O· in order to react with the carbonyl- group. 3. The influence of alkyl-groups on the affinity of the R·O· and H for the unsaturated atoms of the carbonyl- group. Michael claims that his results do not afford the slightest evidence for the view that atoms or groups can produce effects by mere filling of space.

As regards the influence of the constitution of the acid on the velocity of esterification, Menschutkin drew the following conclusions as the result of experiments made by heating the respective acids for one hour with *iso*butyl alcohol. The introduction of an alkyl- group into the formic acid molecule invariably produces a retardation in the esterification. The introduction of alkyl- groups into the acetic acid molecule also produces a retardation, and this is greatest when three alkyl- groups replace the three hydrogen, *e.g.* trimethylacetic acid, and is least when only one alkyl- group is introduced. Unsaturated acids of the type of crotonic and cinnamic are esterified less readily than their saturated analogues.

Lichty (Amer. Chem. J. 1895, 17, 27 ; 1896, 18, 590) found, however, that in the case of the chlorinated acetic acids the introduction of a chlorine atom into the acetic acid molecule tends to facilitate the formation of ester when the direct method is used. The presence of an *αβ*- ethylene linking has not the same marked effect in direct esterification as in catalytic esterification (Thomas and Sudborough, Chem. Soc. Trans. 1912, 101, 317). It is obvious that the results obtained by the direct and catalytic methods of esterification are not comparable, and Sudborough and Feilmann (Chem. Soc. Proc. 1897, 13, 241) have suggested that at least two factors are concerned in the process of esterification when using the same alcohol, viz. (1) strength of the acid esterified ; (2) the presence of substituting groups in close proximity to the carboxyl- group. When the direct method of esterification is used, the former appears to be the determining factor, whereas with the catalytic method the latter is of primary importance ; but in either case both factors are involved. Compare also Flürscheim, Chem. Soc. Trans. 1909, 95, 718.

Rosanoff and Prager (J. Amer. Chem. Soc. 1908, 30, 1895) have also shown that *di*ortho-substituted benzoic acids can be esterified by the direct method, provided they are heated with

excess of the alcohol at a comparatively high temperature (183°) for about 100 hours. The reaction proceeds even at the boiling-point of alcohol, but requires prolonged heating. Rosanoff and Prager determined both the velocity constant K and the reciprocal of the equilibrium constant, viz. $K' = K'/K$. They used different weights of alcohol and acid in each experiment, and by taking the volume of the solution into account, they calculated K by means of the equation :

$$K = \frac{2.3026v}{t\sqrt{(a-b)^2+4ab\mathbf{K}'}} \times$$
$$\log_{10} \frac{2ab - x(a+b-\sqrt{(a-b)^2+4ab\mathbf{K}'})}{2ab \quad x(a+b+\sqrt{(a-b)^2+4ab\mathbf{K}'})}$$

where a and b are the molar concentrations of the acid and alcohol, v is the volume of the mixture in litres, x the number of gram-molecules of the ester formed after time t (in days). The values of K obtained for a few acids are :

Benzoic . . .	.	0.630
2 : 3 : 5-Tribromobenzoic	.	0.370
3 : 4 : 5- „	.	0.900
2 : 4 : 6- „	.	0.088
2 : 4 : 6-Trichlorobenzoic	.	0.031
Acetic . . .	.	1.450
Propionic . .	.	0.950
*Iso*butyric . .	.	1.070
Trimethylacetic .	.	0.180
Chloracetic . .	.	2.460
Dichloracetic . .	.	6.380 ⎱ at 80°
Trichloracetic . .	.	12.000 ⎰

and it is pointed out that in many of these cases an increase in velocity of esterification runs parallel with an increase in the electrolytic dissociation constants of the acids, although the two sets of constants are not proportional.

Michael and Oechslin (Ber. 1909, 42, 317) have determined the amounts of ester formed when various mono- substituted benzoic acids are heated with methyl alcohol in sealed tubes at 135° without a catalyst, but they did not determine the actual constants. They found that many *m*- and *p*- substituted benzoic acids containing negative substituents are esterified somewhat more readily than benzoic acid, but that an *ortho*- substituent, with the exception of Cl, tends to retard esterification, and that the effect is the greatest in the case of the methyl-group.

The following are some of the values obtained after 7 hours : benzoic 11.1, *o*-chlorobenzoic 11.9, *o*-bromobenzoic 10.4, *o*-iodobenzoic 9.7, *o*-nitrobenzoic 10.0, salicylic 7.7, and *o*-toluic 6.2.

The results obtained by Rosanoff and Prager and by Michael and Oechslin are compatible

with the view that at least two factors are concerned in esterification either by the catalytic or the direct method ; that in the former case the chief factor is the presence of substituents in close proximity to the carboxyl- group (steric hindrance) whereas the strength of the acid, as measured by its dissociation constant, is of but secondary importance ; in the direct method the relative values of the two factors are frequently the exact opposite. (Note : The dissociation constant for s-trichlorobenzoic acid is not known.) The results do not justify the conclusion drawn by both Rosanoff and Michael, that substituents do not retard esterification by mere space filling.

For direct esterification of dibasic acids, *see* Kailan (Zeitsch. physikal. Chem. 1915, 89, 676).

The reaction between a mercaptan and an acid is analogous to that between an alcohol and an acid, and the product is the ester of a thio-acid. The reaction has been studied in detail by L. S. Pratt and E. E. Reed (J. Amer. Chem. Soc. 1915, 37, 1934) at a temperature of 243°, and using different mercaptans. The limiting values are much less than when the corresponding alcohols are used, and tend to diminish as the molecular weight of the alcohols increases.

Other methods for preparing esters. Esters which cannot be obtained by direct esterification, *e.g.* the esters of diortho- substituted benzoic acids, can be prepared by the following methods : 1. Action of the alcohol on the acid chloride or acid anhydride. The latter action is accelerated by the presence of small amounts of a strong acid (Reychler, Bull. Soc. chim. Belg. 1907, 21, 428).. 2. Action of the alkyl iodide on the dry silver salt, or, in the case of aromatic acids, by the action of alkyl chlorides on dry potassium salts in the presence of a trace of a base such as triethylamine. Benzyl benzoate is readily prepared by heating together at 95°–100° potassium benzoate (100), benzyl chloride (120), and triethylamine (1). 3. Action of methyl sulphate on an aqueous solution of the sodium salt of the acid (Werner and Seybold, Ber. 1904, 37, 3658). 4. Action of an ethereal solution of diazomethane on the acid.

Sulphonic acids. Sulphonic acids do not give good yields of esters when warmed with alcohol alone or with alcohol and a mineral acid. This is probably due to the fact that the ester formed immediately reacts with the alcohol, giving the free acid and an ether :

$$C_6H_5 \cdot SO_2 \cdot OMe + MeOH = C_6H_5 \cdot SO_2 \cdot OH + Me_2O$$
(comp. Krafft and Roos, Ber. 1893, 26, 2823 ; Wegscheider and Furcht, Monatsh. 1902, 23, 1094). The esters are not formed when the sodium salt of the acid is warmed with alkyl iodide and alcohol (Wegscheider and Furcht) ; but can be obtained by the action of methyl sulphate on the acid or by the action of the alcohol on the acid chloride at low temperatures (Krafft, Ber. 1892, 25, 2256).

Esters of dibasic acids. A dibasic acid can give rise to both an acid and a normal ester, *e.g.* $CO_2H \cdot CH_2 \cdot CO_2H \rightarrow CO_2H \cdot CH_2 \cdot CO_2Me$ and $CO_2Me \cdot CH_2 \cdot CO_2Me$. With the exception of diortho- substituted aromatic dibasic acids, the normal esters can be obtained by the Fischer-Speier method of esterification. For the preparation of the acid esters, the following methods

are resorted to : 1. Addition of alcohol or of sodium alkyl oxide to the acid anhydride. 2. Partial hydrolysis of the normal ester. 3. Partial esterification of the acid. 4. The action of alkyl iodides on the acid silver salts, if these can be prepared, or on the acid potassium salts. In the case of a symmetrical dibasic acid, the same acid ester is formed by all these methods, although, in most cases, except those coming under the first heading, the yields are not very good, as free acid and normal esters are also formed, and the separation is not always easy.

With an unsymmetrical dibasic acid, two isomeric acid esters (the a and the b) [1] can exist, and which of these is formed depends largely on which method of preparation is used. Wegscheider has carried out numerous experiments (comp. Monatsh. 1895, 16, 75 ; 1897, 18, 418, 629 ; 1899, 20, 685 ; 1900, 21, 621, 638, 787 ; 1902, 23, 317, 357, 369, 393, 405 ; 1903, 24, 413, 915 ; 1905, 26, 1039 ; 1906, 27, 487, 777 ; 1907, 28, 819 ; 1908, 29, 525, 531, 535, 541, 557 ; sulphonated benzoic acids, *ibid.* 1902, 23, 1093 ; tribasic acids, *ibid.* 1910, 31, 1253) on the following acids : hemipinic (3 : 4-dimethoxyphthalic), nitrohemipinic, camphoric, nitro-, bromo-, amino-, and hydroxy-terephthalic, 3- and 4-nitrophthalic, 4-hydroxyphthalic, phthalonic, homophthalic, aspartic, phenyl-succinic, and papaverinic, and has drawn the following conclusions under the assumption that the two carboxylic groups differ appreciably as regards their relative strength : 1. By the addition of alcohol to the anhydride and by the action of alkyl iodides on the acid potassium or acid silver salts, the stronger carboxyl- group is esterified, so that under these conditions a-acid esters are formed. If there is but little difference in the relative strengths of the two carboxyl-groups, then a mixture of the two acid esters is obtained, but the a- compound preponderates ; *e.g.* $C_6H_2(CO_2H)_2(OMe)_2(1:2:3:4)$ gives, by these methods, the acid ester :

$$C_6H_2(CO_2H)(CO_2Et)(OMe)_2$$
$$123.4$$

$$CO_3H \cdot C_6H_3 \begin{cases} CO & (2) \\ CO & (3) \end{cases} O \text{ gives } C_6H_3 \begin{cases} CO_3H & (1) \\ CO_3Me & (2) \\ CO_3H & (3) \end{cases}$$
Exception : phenyl succinic anhydride. Diazo-methane and the acid give mainly neutral ester, but also small amounts of acid ester derived from the stronger carboxyl- group. 2. By the process of catalytic esterification the carboxylic acid group, which is freer from adjacent sub-stituents, is esterified first ; thus opianic acid gives the b- ester $C_6H_2(CO_2Et)(CO_2H)(OMe)_2$, $123:4$ but neutral ester and small amounts of the a-isomeride may also be formed, especially if the conditions are such that anhydride formation can occur. The same rule holds good for direct esterification if the possibility of anhydride formation is excluded. 3. The addition of sodium alkylate in the absence of alcohol and water to the anhydride yields the b- acid ester, with appreciable amounts of the isomeride. 4. The partial hydrolysis of the neutral ester gives the acid ester, which is difficult to prepare

[1] The term b- ester is given to the acid ester with the higher dissociation constant, and the isomeride is termed the a- (Ber. 1902, 35, 4829 ; 1903, 36, 304).

by the method of catalytic esterification; *e.g* dimethylhemipinate gives the *a*-acid ester. Exceptions : the hydrolysis of methyl hydroxy-terephthalate, 4-hydroxyphthalate, 4-nitroph-thalate, aminoterephthalate, phthalonate.

For formation of esters of phthalic acid in presence of hydrochloric acid and hydrolysis of the esters, *see* Wegscheider and Amann (Monatsh. 1915, 36, 549 and 633).

In the case of the majority of symmetrical dibasic acids the two carboxylic groups are esterified at the same rate; in other words, the replacement of OH by OEt does not affect the rate of esterification. In the case of both maleic and oxalic acids, however, there is a retardation produced by the conversion of one of the CO_2H groups into a CO_2Et. This is attributed by Kailan (Zeitsch. physikal. Chem. 1914, 87, 619) to the proximity of the two carboxylic groups to one another, and as the retardation is greater in the case of maleic acid, it is argued that in this acid the two carboxylic groups are closer than in oxalic acid.

Theories of esterification.—*Direct method :* The reaction between the acid and alcohol is not a simple ionic reaction, since the acid with the highest dissociation constant is not neces-sarily esterified most readily, and in the case of a dibasic acid it is not always the stronger CO_2H group which is esterified first. The view usually accepted at the present time is that an additive compound of alcohol and acid of the type

$$R \cdot C \!\!\!\begin{array}{c} \diagup OEt \\ \diagdown OH \end{array}$$
i.c. a dialkyl- derivative of an ortho-carboxylic acid, is first formed by the addition of a molecule of alcohol to the carbonyl- group of the acid (Wegscheider, Monatsh. 1895, 16, 137 ; Henry, Ber 1877, 10, 2041). Michael suggests that before this additive compound is formed an unstable ' Kekulé double molecule ' is formed, perhaps by the coming into play of the two latent valencies of the oxygen atoms :

$$R \!\!\!\begin{array}{c} \diagup C = 0 \diagup OH \\ \diagdown OH \quad\ \diagdown Et \end{array}$$
It is well known that many esters can form additive compounds with sodium ethoxide, and, therefore, presumably with ethyl alcohol, although compounds of the latter type have not been isolated. Pechmann (Ber. 1898, 31, 503) has been able to show that the esters of diortho-substituted benzoic acids cannot yield additive compounds with sodium ethoxide, probably owing to the space filling (steric hindrance) of the group in the ortho- position ; by analogy, the diortho- substituted acids would not yield the orthocarboxylic acid derivative at all readily, and this would account for the fact that diortho-substituted benzoic acids are not readily esterified.

Catalytic esterification. According to Michael, the processes of direct and catalytic esterifica-tion are essentially different ; the former is a reaction between the organic acid and alcohol, and the latter a reaction between the organic acid and an additive compound of the alcohol and catalyst (Ber. 1909, 42, 312). This reaction does not consist of addition to the carbonyl-group of the acid, but in union of the acid with the alcohol-catalyst complex to form a large ' double molecule,' which decomposes immedi-ately into ester, water, and catalyst. The fact

that esterification is facilitated by the presence of the catalyst is accounted for by the assump-tion that the alcohol-catalyst complex contains a greater store of energy, is therefore more re-active than the alcohol itself, and can more quickly develop the maximum entropy of the alcohol-acid system. It is questionable whether these views are in harmony with the facts estab-lished by Wegscheider, viz. that the same acid ester is obtained from an unsymmetrical dibasic acid, whether the direct or catalytic method of esterification is adopted, provided that anhy-dride formation is excluded. Goldschmidt also comes to the conclusion that the two processes are essentially different (Zeitsch. Elektrochem. 1909, 15, 4). He claims to have shown that the presence of sodium trichloracetate does not depress the velocity of esterification of trichlor-acetic acid by the direct method, and, therefore, the direct esterification cannot be a simple case of hydrion catalysis. Later experiments of Sudborough and Turner show that the presence of salts of trichloracetic acid does diminish the rate of esterification of the acid, and hence Goldschmidt's conclusion is not justified. The fact that in direct esterification the strength of the acid is an important factor is compatible with the view that the organic acid itself plays the same part in direct esterification that the catalyst does in catalytic esterification. This view agrees again with the fact that the reaction in certain cases of direct esterification is bimolecular (Goldschmidt, Ber. 1896, 29, 2208), provided the reaction is not between the ions of acid and alcohol.

Kailan (Monatsh. 1908, 29, 799) is also of opinion that the processes of direct and catalytic esterification are not analogous, since the addition of a small amount of water increases the rate of esterification of trichloracetic acid by the direct method, but diminishes the activity of trichloracetic acid when it is used as a catalyst.

Various views are held with regard to the function of the catalyst. Goldschmidt and Uddy (Zeitsch. physikal. Chem. 1907, 60, 728 ; comp. also Ber. 1906, 39, 711, and Zeitsch. physikal. Chem. 1910, 70, 627) conclude that the hydrions of the catalyst are the active agents, since the activity of different acids is in the order of their relative strengths, *e.g.* the relative values of the acids hydrochloric, picric, trichloracetic, and dichloracetic as catalysts are indicated in the order given, and the addition of salts of the acid used as catalyst diminishes the activity of the catalyst. They further conclude that the hydrions unite with the alcohol, and that the complex ion $(C_2H_6O,\overset{+}{H})$ is the active agent. They suggest the following modified formula for calculating the velocity constant :—

$$K \cdot c = \frac{1}{t}(n+r+a) \, \log_e \frac{a}{a-x} - x$$

where c = concentration of catalyst, n = concentration of water, and r = hydrolytic constant of the complex alcohol ion for

$$(C_2H_6O,\overset{+}{H}) \quad r = 1 \cdot 5.$$
The constants obtained by means of this equation agree better, and do not show the tendency to decrease as t increases, a tendency which is marked when the constants calculated

by means of the ordinary equation for a unimolecular reaction are used.

A marked exception to the depressing effects of the addition of salts is met with in the case of hydrogen chloride, where the addition of chlorides such as calcium chloride, tetramethyl-ammonium chloride, and aniline hydrochloride, have no appreciable effect on the catalytic activity of hydrogen chloride (Goldschmidt ; Sudborough).

Many chemists are of opinion that in catalytic esterification, as in catalytic hydrolysis of esters by means of mineral acids (see art. on HYDRO-LYSIS), a complex is formed between the substance transformed (acid in esterification and ester in hydrolysis) and the catalyst. This compound is probably an oxonium salt containing quadra-

valent oxygen, e.g. $R \cdot C \underset{OH}{\overset{O \underset{Cl}{\overset{H}{\diagup}}}{\diagdown}}$. The salt,

only small amounts of which may be present, is ionised into $(R \cdot CO_2H_2H)$ and $\overset{+}{Cl}$, and the esterification proceeds by the reaction of the complex cation with the alcohol (Acree and Johnson, Amer. Chem. J. 1907, 38, 334) ; e.g. :

$$(R \cdot CO_2H_2H) + C_2H_5OH = R \cdot CO_2Et + H_2O + \overset{+}{H}$$
and not with the ions of the alcohol as suggested by Lapworth. This reaction is more rapid than the simple reaction between the acid and alcohol, and in this way the accelerating effect of the catalyst is accounted for.

The retarding effects produced by small amounts of water are, according to Lapworth (Chem. Soc. Trans. 1908, 93, 2167, 2196), due to the water competing with the organic acid for the catalyst, and giving rise to the complex ion (H_2O,H), which is not catalytically active. The fact that in alcohol containing water, the velocity of esterification at constant volume decreases more rapidly than the concentration of the catalyst (Goldschmidt and Uddy, Zeitsch. physikal. Chem. 1907, 60, 735 ; Kailan, Monatsh. 1906, 27, 543, 997 ; Annalen, 1907, 351, 186), is also held to be opposed to the view that a complex hydrion is formed with the alcohol.

Work on the catalytic activity of strong acids tends to show that this activity is exerted in two ways : (a) by means of hydrions ; (b) by the non-ionised acid, and that the effect due to the non-ionised acid is greater for highly ionised than for slightly ionised catalysts. In methyl and ethyl alcohol the retarding influences of water on esterification is of much the same magnitude for different acids, and this is held to support the view that an intermediate compound of alcohol and catalyst plays a most important part in the change (Goldschmidt and Thuesen, Zeitsch. physikal. Chem. 1912, 81, 30).

Compare also Snethlage, ibid. 1913, 85, 211 ; 1915, 90, 91 and 139 ; Acree, Amer. Chem. J. 1912, 48, 352 ; Dawson and others, Chem. Soc. Trans. 1913, 103, 2135 ; 1914, 105, 1093 ; 1915, 107, 1426 ; 1916, 109, 1262 ; McBain and Coleman, ibid. 1914, 105, 1517 ; H. S. Taylor, Zeitsch. Electro. Chem. 1914, 20, 201.

(For the conversion of acid amides into esters, and for the transformation of methyl into ethyl VOL. II.—T.

esters, both processes of alcoholysis, see art. HYDROLYSIS.) J. J. S.

ESTON. Trade name for basic aluminium acetate. Used as an antiseptic powder in dressing wounds.

ESTORAL v. SYNTHETIC DRUGS.

ESTRAMADURITE v. FERTILISERS.

ETA (E) ACID. 1-Naphthylamine-3 : 8-disulphonic acid v. NAPHTHALENE.

ETELEEN. Trigallic acetal.

ETHAL v. WAXES.

ETHYL C_2H_5 or $CH_3—CH_2$ is a univalent basylous radical not known in the free state, the body C_4H_{10} or $(C_2H_5)_2$ which was named, ethyl (afterwards diethyl) by its discoverer, Frankland (Chem. Soc. Trans. 2, 263), being now regarded as butane.

Ethyl acetamide v. Ethylamine (infra).

Ethyl acetate v. ACETIC ACID.

Ethyl acetoacetate v. KETONES.

Ethyl alcohol v. ALCOHOL.

Ethyl antimonite $(C_2H_5O)_3Sb$; b.p. 115°-120° ; from action of C_2H_5OH upon Sb_2O_3 in presence of anhydrous $CuSO_4$; colourless liquid (McKey, Chem. Soc. Trans. 1909, 95, 604).

Ethyl arsenite $(C_2H_5O)_3As$. A liquid formed by action of C_2H_5OH upon As_4O_6 in presence of anhydrous $CuSO_4$, the yield being 4·5 p.c. (Lang, McKey, and Gortner, Chem. Soc. Trans. 1908, 93, 1368). According to Crafts (Bull. Soc. chim. 1870, ii. 14, 99), it is obtained in very small yields by

(1) Action of Et_3SiO_3 upon As_4O_6 at 200° ;
(2) Action of Ag_3AsO_3 upon EtI at 150° ;
(3) Action of $AsBr_3$ upon NaOEt.

Auger (Compt. rend. 1906, 143, 907) obtained a yield of 1·2 p.c. by heating EtOH and As_4O_6 in a sealed tube far above the boiling-point of the alcohol.

Ethyl arsenate. A liquid boiling above 200° with partial decomposition. Decomposed by water immediately. Formed by heating together in sealed tubes at 100° Ag_3AsO_4 and EtI (Crafts, Bull. Soc. chim. 1870, ii. 14, 99).

Ethyl boride $(C_2H_5)_3B$. Triethyl boride, Borethyl ; b.p. 95° ; sp.gr. 0·696 at 23° ; V.D. at 132° = 3·581 ; at 101·6° = 3·76 ; calc. = 3·399. From action of $Zn(C_2H_5)_2$ upon $(C_2H_5)_3BO_3$, or from BCl_3 and $Zn(C_2H_5)_2$ (Frankland, Trans. Roy. Soc. 1862, 167 ; Proc. Roy. Soc. 1876, 25, 165).

A spontaneously inflammable, colourless liquid burning with green flame ; decomposed by HCl, evolving C_2H_6, and forming $B(C_2H_5)_2Cl$. Is slowly decomposed by water, and destroyed by HNO_3, with formation of boric acid. Absorbs NH_3, forming an oily liquid $NH_3B(C_2H_5)_3$ of an aromatic odour, which is fairly stable even in contact with O. $B(C_2H_5)_3$ absorbs O and forms $B(C_2H_5)_3O_2$; b.p. 125°. This, by the action of water, yields ethylboric acid $B(C_2H_5)(OH)_2$, a crystalline solid resembling naphthalene in appearance ; can be sublimed at 40° ; has a sweet taste, and acid action, but does not combine with bases. By action of $Zn(C_2H_5)_2$ upon this body we get $B(C_2H_5)(OC_2H_5)_2$ and $B(OC_2H_5)_3$; b.p. 112° ; V.D. (dissoc.) 2·78. By further action of $Zn(C_2H_5)_2$ upon ethylboric acid we get $B(C_2H_5)_2OC_2H_5$; b.p. 102° ; V.D. = 3·914. Water converts this into $B(C_2H_5)_2OH$, a spontaneously inflammable liquid, which absorbs oxygen, yielding $B(C_2H_4O)C_2H_5 \cdot OH$; m.p. 8°.

Ethyl bromide C_2H_5Br. *Hydrobromic* or *Bromhydric ether*; m.p. $-116\cdot0°$ (Ladenburg and Krugel, Ber. 32, 1818), $-125\cdot5°$ (Schneider, Zeitsch. physikal. Chem. 22, 233); b.p. $38\cdot22°$ (corr.) (Thorpe and Rodger, Phil. Trans. 1894, A, 11, 472); sp.gr. $1\cdot4189$ at $15°$ (Mendéleeff), $1\cdot4733$ at $0°$ (Pierre), $1\cdot4685$ at $13\cdot5°$; crit. temp. $236°$ (Pawlewski, Ber. 16, 2633).

Preparation.—1. By action of P and Br upon alcohol (Serullas, Ann. Chim. Phys. [2] 34, 99). 40 parts red P and 160 parts absolute alcohol are slowly mixed with 100 parts Br, kept cool until all action is over; the mixture is then distilled, and the distillate purified by washing with water and rectification (Personne, Compt. rend. 52, 468).—2. Absolute alcohol is heated with Br and distilled, and the distillate is freed from excess of Br by washing with KOH and redistillation (Lowig, Annalen, 3, 288).—3. 4 parts KBr and 5 parts of a mixture of 2 parts H_2SO_4 and 1 part alcohol of 96 p.c. are distilled, and distillate purified as above (De Vrij, J. 1857, 441, Tabourg, Bull. Soc. chim. 1911, [iv.] 9, 124). Weston (Chem. Soc. Trans. 1915, 108, 1489) has given details of a modification of De Vrij's method, using sodium bromide in place of potassium bromide and paying attention to the rate of heating, whereby yields of 80–90 p.c of the theoretical amount of pure ethyl bromide can be obtained (*cf.* Holt, Chem. Soc Trans. 1916, 109, I.).—4. C_2H_4 in presence of $AlBr_3$ at $0°$ combines with HBr to form C_2H_5Br (Gustavson, J. Russ. Phys. Chem Soc 16, 95). To prepare pure C_2H_5Br, the commercially pure bromide is shaken with H_2SO_4 and allowed to separate. It is then shaken with dilute alkali and distilled with 10 p.c of sweet almond oil (Adrian, Chem. Zentr. 1895, i. 20).

Ethyl bromide is a colourless liquid with a sweet taste, and burning after-taste. Its vapour has anæsthetic properties (Robin, Compt. rend. 34, 649; Webster, Bio. Chem. J. 1906, i 328; Cole, J. Physiol. 29). It is slightly soluble in water, and miscible with alcohol and ether. The vapour is decomposed by heat, yielding C_2H_4 and HBr, or, if the temperature be higher, C is deposited (Löwig). Burns in air with a green flame, evolving HBr. By introduction of Cl two isomeric bodies of the composition C_2H_4ClBr, b.p. $84\cdot5°$ and $104°$-$108°$, and 2 isomerides of composition $C_2H_3Cl_2Br$, b.p. $137°$, $151°$ (Lescœur, Bull. Soc. chim. 1878, 29, 483) are obtained. At $100°$ Br reacts, forming $CH_2Br\cdot CH_2Br$, whilst at $200°$ $CH_3\cdot CHBr_2$ is the product (Meyer and Müller, Ber. 24, 4247; J. pr. Chem. [2] 46, 161). By action of Br and P upon alcohol. we get, further, $C_2H_4Br_2$, b.p. $160°$; $C_2H_3Br_3$, b.p. $180°$; $C_2H_2Br_4$, b.p. $196°$-$200°$ (Bertrand, Finot, Bull. Soc. chim. 34, 28) (*v. Ethylene bromide*). Heated with $AlBr_3$, yields successively $C_2H_4Br_2, C_2H_2Br_4$, and C_2Br_6 (Mouneyrat, Compt. rend. 127, 109). With ammonia it yields $NH_4(C_2H_5)$,HBr; and with ethylamine, diethylammonium bromide $NH(C_2H_5)_2$,HBr; similarly, with diethylamine, it yields $N(C_2H_5)_3$HBr.

Ethyl chloride C_2H_5Cl. *Chlorhydric* or *Hydrochloric ether*; m.p. $-142\cdot5°$ (Schneider, Zeitsch. physikal. Chem. 22, 233); b.p. $12\cdot5°$ (Regnault, J. 1863, 67); crit. temp. $187\cdot2$; crit. press. $51\cdot7$ atm. (Berthoud); sp.gr. $0\cdot9214$ at $0°$; $0\cdot9176$ at $8°$, $0\cdot920$ at $0°$ (Pierre), $0\cdot851$

at b.p. (Ramsay, Chem. Soc. Trans. 35, 470); S.V. $75\cdot8$ (Kopp). (Robiquet and Colin, Ann. Chim. Phys. [2] 1, 343; Regnault, *ibid.* 71, 355; Kühlman, Annalen, 33, 108; Löwig, Pogg. Ann. 14, 346; Gm. 7, 367; Gerh. 11, 308.) For a table of its vapour pressure between $-30°$ and $+100°$, see Henning, J. Soc. Chem. Ind. 1920, I. T

Known as far back as 1500, and its preparation described by Glauber in 1648. From alcohol by the action of S_2Cl_2 or metallic chlorides (Rouelle [1759]); from alcohol and HCl (Basse [1801]). Composition first ascertained by Robiquet and Colin. Also formed by action of Cl upon C_2H_6 (Darling, Annalen, 150, 216), and of HCl upon ether in sealed tubes (Berthelot).

The action of HCl upon alcohol gives a very poor yield of C_2H_5Cl, unless $ZnCl_2$ is added to the alcohol before passing in HCl (Groves, Chem. Soc. Trans. 1874, 636). Krüger (J. pr. Chem. [2] 14, 193) recommends that a mixture of 1 part of $ZnCl_2$ in 82 parts of alcohol should be saturated with HCl gas in the cold, and then heated to boiling, HCl being passed in during distillation. A reflux condenser stops the alcohol vapour, and the C_2H_5Cl passes on and is collected in a well-cooled receiver.

The formation of C_2H_5Cl in this process is partly due to the action of HCl upon alcohol, and partly to the union of the nascent C_2H_4 with HCl (Schorlemmer, Chem. Soc. Trans. 1875, 308); this view is sustained by the fact that if amyl alcohol be thus treated, both primary and secondary amyl alcohol are produced, and the latter can only be formed from the radical C_5H_{10}. Ethyl chloride is also formed by the action of PCl_5 upon alcohol, and also, to some extent, by the action of Cl upon alcohol. Hence the formation of ethyl chloride in the manufacture of chloral.

It is a colourless mobile liquid; has a pungent ethereal smell, and a sweetish taste, is inflammable and burns with a green-edged flame, evolving HCl. It is sparingly soluble in water (1 part in 3000), but mixes readily with alcohol and ether. It dissolves phosphorus, sulphur, fats, oils, and many resins. It combines with many metallic chlorides—*e.g.* $SbCl_5$, Fe_2Cl_6 —to form crystalline compounds. Mainly used for Ethylation in the manufacture of dye stuffs and drugs, and as a refrigerant and solvent.

It is used in medicine like ether, but, on account of its volatility, it is mixed with an equal volume of alcohol, and is then known as 'alcoholised muriatic ether, B.P.' It is decomposed at a red heat into C_2H_4 and HCl; at higher temperatures carbon separates, and CH_4,H, and HCl are set free. Strong HNO_3, when boiling, liberates HCl and forms $C_2H_5NO_2$ in small quantity (Thénard, Boullay). SO_3 absorbs it, forming $SO_3\cdot C_2H_5Cl$, a fuming liquid, b.p. $130°$ —probably the three isomerides $C_2H_4O\cdot SO_3\cdot Cl$, $CH_3\cdot ClCH_2\cdot SO_2\cdot OH$, and $CH_2(OH)\cdot CH_2SO_2\cdot Cl$ (Purgold, Zeitsch. Chem. 1868, 669; Ber. 6, 502). When vapour of C_2H_5Cl is passed through boiling H_2SO_4, HCl is evolved (Thénard), also C_2H_4 and SO_2 (Boullay). When the vapour is led through a tube containing heated soda-lime, a mixture of CH_4 and H is evolved, and $NaC_2H_3O_2$ and Na_2CO_3 are formed (L. Meyer, Annalen, 139, 282), while, according to Dumas and Stas, C_2H_4 and NaCl are formed. On

AgNO$_3$,C$_2$H$_5$Cl has no action until after prolonged contact, but even after some months only a very small quantity of AgCl is formed (Thénard, Boullay) ; but AgCl is rapidly thrown down when C$_2$H$_5$Cl is heated with a solution of AgNO$_3$ in sealed tubes (G. C. Foster).

Heated with bromine and iron wire at 100°, C$_2$H$_5$Br and ethylene dibromide are formed (V. Meyer and Petrenko-Kritschenko, Ber. 25, 3307).

NH$_3$ has only a slight action at ordinary temperatures, but on heating a mixture of NH$_3$ and C$_2$H$_5$Cl, ethylene and a deposit of NH$_4$Cl are formed (Dumas and Stas, Ann. Chim. Phys. 73, 154). When a mixture of ethereal NH$_3$ and C$_2$H$_5$Cl is exposed to sunlight, crystals of ethyl-amine hydrochloride separate (Stas). When heated with alcoholic NH$_3$ to 100° in sealed tubes, NH$_2$(C$_2$H$_5$),HCl is also produced, together with traces of NH(C$_2$H$_5$)$_2$,HCl and N(C$_2$H$_5$)$_3$,C$_2$H$_5$Cl (Groves, Chem. Soc. Trans. 1861, 13, 331). KOH slowly removes Cl from C$_2$H$_5$Cl, yielding (in aqueous sol.) alcohol and KCl. Alcoholic KOH and C$_2$H$_5$Cl heated to 100° in sealed tube deposits KCl and forms (C$_2$H$_5$)$_2$O (Balard, Ann. Chim. Phys. [3] 12, 302). Passed into heated sol. of K$_2$S, ethyl sulphide is formed ; with alcoholic KHS, mercaptan is formed (Regnault).

Chlorine in the sunlight yields di-, tri-, tetra-, penta-, and hexa- chloro- derivatives of ethane (Regnault) ; of the dichloro- derivatives CH$_3$·CHCl$_2$ is the main product. If, however, ethyl chloride is heated with a halogen carrier, CH$_2$Cl·CH$_2$Cl is the chief product (D'Ahns and Kautzsch, J. pr. Chem. [2] 1909, 80, 305 ; Staedel ibid. 303 ; Ber. 6, 1403 ; Meyer and Muller, J. pr, Chem. [2] 46, 161).

Trichlorethane C$_2$H$_3$Cl$_3$.

1. *Chlorethylene chloride* CH$_2$Cl·CHCl$_2$; b.p. 115° (Pierre, Annalen, 80, 127), 113·7° at 760 mm. (Stadel, Ber. 15, 2563), 113·5°–114° at 753·2 (Schiff, Annalen, 220·97) ; sp.gr. 1·4223 at 0° (P.), 1·4577 at 9·4°/4°, 1·2945 at 113·5°/4° (Schiff, 1·4406 at 25·6° ; μ$_A$=1·4719 at 22° Rα=42·26 (Kanonnikow), from C$_2$H$_3$Cl (Regnault, Ann. Chim. Phys. [2] 69, 151), or CHCl$_2$·CH$_3$ (Meyer and Muller, J. pr Chem. [2] 46, 174), and SbCl$_5$.

2. *Ethenyl trichloride* CH$_3$·CCl$_3$; b p. 74·5° (Geuther, J. 1870, 435) ; 74·1° at 760 mm. (Städel, Ber. 15, 2563) ; sp.gr. 1·3465 at 0° (Pierre, Annalen, 80, 127), 1·372 at 16° (Regnault, Annalen, 33, 317), 1·3657 at 0°, 1·3249 at 26° ; μ$_A$=1·4199 at 21° ; Rα =42·0 (Kanonnikow) ; by the chlorination of ethyl chloride (Regnault, ibid. 33, 317). Decomposed by sodium ethoxide, giving C$_2$H$_3$Cl·O·C$_2$H$_5$, C$_2$H$_3$(O)$_2$, and CH$_3$(OEt)$_3$.

Tetrachlorethane C$_2$H$_2$Cl$_4$.

1. *as-*CH$_3$Cl·CCl$_3$; b.p. 135° (Regnault, Ann. Chim. Phys. [2] 69, 162), 138·6° (Pierre, Annalen, 80, 130), 135·1° (corr.) (Geuther, Brockhoff, J. 1873, 317) ; sp.gr. 1·6116 at 0° (P.), 1·576 at 19° (R.), 1·5825 at 0°, 1·5424 at 26° ; . μ$_A$ at i°=1·4772−0·0004371 ; Rα =50·72 (Kanonnikow). Formed by chlorination of ethyl chloride (Laurent, Annalen, 22, 292) ; or action of Cl upon CH$_2$Cl CHCl$_2$ (Regnault) ; by heating at 110° acetylene tetrachloride and AlCl$_3$ (Mouneyrat, Bull. Soc. chim. 1898, 19, 499).

Decomposed by sodium ethoxide into C$_2$HCl$_3$·O·C$_2$H$_5$ and CH$_2$(OC$_2$H$_5$)CO$_2$Na.

2. *s-*CHCl$_2$·CHCl$_2$; b.p. 147·2° ; sp.gr. 4°/4°=1·6208, 17°/17°=1·6013 ; μ$_D$ at 17°=1·495587±0·000006 (Veley, Proc. Roy. Soc. 1910, B 82, 217) ; Rα =50·6 (Kanonnikow). From C$_2$H$_2$ and SbCl$_5$ (Berthelot, Jungfleisch, Annalen, Suppl. 7, 264), from dichloraldehyde and PCl$_5$ (Paternò, Pisati) ; from ethylene chloride and AlCl$_3$ at 75° if Cl and C$_2$H$_2$ be led into the mixture (Mouneyrat) ; by long heating yields HCl and C$_6$Cl$_6$.

If S$_2$Cl$_2$ and 1 p.c. of its weight of reduced iron be saturated with Cl, and if the excess Cl be removed with CO$_2$, and then dry acetylene be passed in at a temperature of 40°, and the cycle repeated until no more C$_2$H$_2$ is absorbed, *sym*-tetrachloroethane, pentachloroethane, and hexachloroethane are produced, the two latter in small quantity (Michel, Zeitsch. angew. Chem. 1906, 19, 1095). The *sym*-tetrachlorethane is distilled off from the mixture, either alone or in steam (D. R. P. 174068 ; Chem. Soc. Abstr. 1906, i. 169).

Pentachlorethane CHCl$_2$ CCl$_3$; b.p. 159·1° (corr.) ; 161·7° at 760 mm. (Stadel) ; m.p. −18° ; sp.gr. 1·7089 at 0°, 1·6926 at 10·15°/4° (Thorpe, Chem. Trans. 37, 192) ; μ$_A$ = 1·4871 at 25·1° ; Rα = 59·05 (Kanonnikow). By action of chlorine upon C$_2$H$_5$Cl also from chloral and PCl$_3$ (Paternò, Annalen, 151, 117), or AlCl$_3$ (Mouneyrat, Bull Soc. chim. 1898, 19, 260).

Hexachlorethane CCl$_3$·CCl$_3$ (*v. Carbon trichloride*, art. CARBON).

(For mixed halogen derivatives of ethane, see Mouneyrat, Bull. Soc. chim. 1898, 19, 499 ; Swartz, Rec. trav. chim. 17, 234 and 235 ; Bull. Acad. Roy Belg. 36, 519 ; ibid. 1909, 60 and 728 ; ibid. 1899, n. 281 ; Elbs and Newmann, J. pr. Chem. 1898, 58, 245 ; Biltz, Ber. 1902, 35, 3524 ; Lemoult, Compt rend. 1903, 136, 1333 ; Besson, Bull. Soc. chim. [3] 11, 920 ; Nef, Annalen, 298, 353, 354, 358, and 360 ; Thele and Peter, ibid. 369, 149 ; Lawrie, Amer. Chem. J. 1906, 36, 487.)

Ethyl *iso*cyanate. *Ethyl carbimide,* C$_2$H$_5$N : C : O ; b.p. 60° ; sp.gr. 0·8981 ; heat of formation (Lemoult, Compt. rend. 1898, 126, 43) ; absorption spectrum (Hartley, Dobbie and Walker, Chem. Soc. Trans. 1901, 856). By the action of dry KCNO upon KC$_2$H$_5$SO$_4$ at 180°–250° (Wurtz, Ann. Chim. Phys. 1854 [3] 42, 43) ; distillate is a mixture of *iso*cyanate and *iso*cyanurate, which can easily be separated by distillation. By passing CNBr into absolute alcohol and ether (Ponomarew, Ber. 1882, 15, 515 ; Mulder, Rec. trav. chim. 1, 210 ; 2, 133) ; by passing CNBr (Mulder, ibid. 3, 306) or CNCl (Cloez, Compt. rend. 44, 428 ; Annalen, 102, 355) into C$_2$H$_5$ONa in absolute alcohol ; by the action of diazomethane on *sym*-ethylnitrourea (Degner and Pechmann, Ber. 1897, 30, 653) ; by heating the mercuric chloride derivative of ethyl thiolcarbamate (Anschütz, Annalen, 1908, 359, 202).

In 1895 Nef (ibid. 287, 310) showed that the compound hitherto known as ethyl cyanate was ethyl *iso*cyanate. Ethyl *iso*cyanate is a mobile liquid having a suffocating smell. It is decomposed by water into diethylcarbamide, and by ammonia into ethylcarbamide.

Ethyl cyanide. **Propionitrile** C$_2$H$_5$·C : N,

m.p. ⌐103·5° (Schneider, Zeitsch. physikal. Chem. 22, 233); b.p. 98·1° (corr.) (Engler, Annalen, 133, 153); 97·08°‚ (corr.) (Thorpe, Chem. Soc. Trans. 37, 205); sp.gr. 0·8010 at 0°, 0·7938 at 7·36°/4° (Thorpe), 0·7015 at 97°/4° (Schiff, Ber. 19, 567); H. C. 446·7 Cals. (Berthelot and Petit, Compt. rend. 108, 1217); latent heat of vapourisation (Louguinine, Chem. Zentr. 1900, i. 451); molecular refraction 25·10 (Brühl, Zeitsch. physikal. Chem. 16, 214; Eykman, Rec. trav. chim. 12, 172; Costa, J. 1891, 336); magnetic rotation (Perkin, Chem. Soc. Trans. 55, 701); crit. temp. 291·2°; crit. density 0·2401 (Ter-Gazarian, J. Chim. Phys. 1906, 4, 140).

From Ba(C₂H₅SO₄)₃ and KCN (Pelouze, Annalen, 10, 249), from cyanogen chloride and Zn(C₂H₅)₂ (Gal, Zeitsch. Chem. 1868, 252), from Zn(C₂H₅)₂ and (CN)₂ (Frankland and Graham, Chem. Soc. Trans. 37, 740), from propionamide and P₂O₅ (Dumas, Malaguti and Leblanc, Annalen, 74, 329). By heating ethyl *isocyanide* to 240° (Nef, *ibid.* 280, 296).

Preparation.—By heating C₂H₅I with pure KCN and alcohol to 180°; C₂H₅Cl dissolved in three times its weight of alcohol is heated with KCN to 100° or 150° (Rossi, Annalen, 159, 79). C₂H₅I is heated with KCN in closed tubes to 180°, and the product distilled, and the distillate is freed from excess of C₂H₅I by means of a solution of CaCl₂, upon which the C₂H₅CN swims, while the heavier C₂H₅I sinks to the bottom (Williamson, Phil. Mag. [4] 2, 205; Gauthier, Ann. Chim. Phys. [4] 17, 180).

It is a mobile colourless liquid with an agreeable odour, soluble in water, from which CaCl₂ or NaCl causes it to separate; miscibility with water (Rothmund, Zeitsch. physikal. Chem. 26, 453); V.D. 1·928. It combines with the hydracids, e.g. HCl; the product C₂H₅NHCl forms monoclinic prisms soluble in water and melting at 121° (Gauthier). HCl gas passed into a well-cooled solution of the cyanide in acetic acid gives acetyl chloride and C₂H₅CONH₂,HCl (Colson, Bull. Soc. chim. [3] 17, 57). Chlorine combines with C₂H₅N to form dichloropropionitrile CH₃·CCl₂·CN, a liquid body, b.p 103°–107°, which polymerises on standing to a solid (C₃H₃(Cl₂N)₃. Propionitrile also forms compounds with metallic chlorides and with cyanogen chloride. C₂H₅N·CNCl is a liquid decomposed by water; b.p. 60°–68° (Hencke, Annalen, 106, 280). Compounds with AlCl₃ (v. Perrier, Compt. rend. 1895, 120, 1423). Propionitrile is hydrolysed by acids or alkalis yielding propionic acid; electrolytic reduction yields* n-propylamine (Ahrens, Zeitsch. Elektrochem 1896, 3, 99). By the action of metallic sodium, polymerisation ensues, the products being sodium cyanide, ethane, and α-iminopropionylethyl cyanide (Meyer, J. pr. Chem. [2] 38, 326; 45, 63).

Ethyl isocyanide, Ethyl carbylamine C₂H₅N : C; b.p. 79°; sp.gr. 0·759 at 4°, 0·7150 at 44·5° (Gauthier, Ann. Chim. Phys. [4] 17, 233); molecular refraction 16·26 (Costa, Gazz. chim. ital. 22, i. 104). By the interaction 'of C₂H₅I and AgCN (Gauthier, Annalen, 151, 239); by distilling KCN with KC₂H₅SO₄, propionitrile also being formed; by digesting ethylamine with chloroform and alcoholic potash (Hofmann, *ibid.* 147, 107).

It is a colourless liquid having a very repulsive smell. It is transformed into propionitrile by heating at 240°; by heating with alcoholic H₂S ethylthioformamide is produced; with sulphur and CS₂ ethylthiocarbimide; combines with CNCl; with C₂H₇Cl at −10° yields C₂H₅N(Cl)O·C₂H₅ (Nef, *ibid.* 280, 296). HgO oxidises it to C₂H₅N : C : O. Yields a chloride C₂H₅N : CCl₂, by treatment with SO₂Cl in ether at −15°; an oil, b.p. 102° (Nef, l.c.). Yields a bromide, C₂H₅N : CBr₂, with bromine in CHCl₃. This gives ethylamine dibromide with water, ethyl *isocyanide* dibromide hydrobromide and ethylthiocarbimide with H₂S, ethyl *iso*cyanide dibromide hydrochloride with dry HCl, an oily ethniodide with ethyl iodide, and diphenylethylguanidine with aniline (Guillimand, Bull. Soc. chim. 1904, iii. 31, 605; 1905, iii. 33, 652). Compounds with cobaltous, ferrous, and ferric chlorides (v. Hofmann and Bugge, Ber. 1907, 40, 3759). (For further reactions, v. Nef, l.c.)

Ethyl derivatives of cyanuric acid. Although cyanuric acid exists in only one modification, probably the *iso*-(II.) esters derived from the tautomeric forms (I. and II.) are known.

$$
Ethyl cyanurate (C₂H₅OCN)₃; m.p. 29°, b.p. 275° (Claesson, J. pr. Chem. [2] 33, 131). By action of CNCl on C₂H₅ONa (Hofmann, Ber. 19, 2061); also from C₂H₅ONa (3 mols.) and trimethyl cyanurate (H); from CNI or CNBr and C₂H₅I (Ponomarew, Bull. Soc. chim. [1.] 41, 315); by heating the lead salt of the diethyl ester (P.); together with ethyl *iso*cyanurate by treating silver cyanurate with C₂H₅I (C., P.); from di-potassium cyanurate and C₂H₅I (P.).

Only liquid readily soluble in alcohol, ether, CHCl₃ and CS₂, sparingly so in water. Converted into ethyl *isocyanurate by long heating at 180°–200°; yields cyanuric acid with HCl, cyanuric chloride with PCl₅, melamine with strong ammonia and the diethyl ester with baryta water.

Diethyl cyanurate, Diethylcyanuric acid HO(CN)₃(C₂H₅)₂ (Ponomarew, Ber. 18, 3267; Hofmann, *ibid.* 19, 2077). By warming ethyl cyanurate with concentrated baryta water; by treating methyl cyanurate or mono-potassium cyanurate with C₂H₅I.

Thick plates from water, insoluble in ether, sparingly soluble in alcohol. Decomposes on heating into diethyl, *iso*cyanurate; yields cyanuric acid on warming with HCl. Pb salt and C₂H₅I yield triethyl cyanurate, but if C₂H₅I contains free I, triethyl *isocyanurate also formed.

Ethyl isocyanurate, •Triethylcarbimide (C₂H₅NCO)₃. m.p. 95°; b.p. 276°; absorption spectrum (Hartley, Dobbie and Walker, Chem. Soc. Trans. 1901, 849); heat of formation (Lemoult, Compt. rend. 125, 869). By polymerisation of C₂H₅NCO (H. D! and W.); also from potassium cyanate or cyanurate, or from

Pb salt of the diethyl ester and KC_2H_5SO ; by heating ethyl cyanurate at 180°-200° ; together with ethyl cyanurate from silver cyanurate and C_2H_5I (Habich and Limpricht, Annalen, 109, 102).

Rhombic prisms (Rammelsberg, J. 1857, 273 ; Foek, Ber. 19, 2076) moderately soluble in hot water, 'readily so in alcohol. KOH yields $N(C_2H_5)H_2$ and K_2CO_3.

Diethyl isocyanurate, Diethylcyanuric acid $H(NCO)_3(C_2H_5)_2$, m.p. 173°. Obtained in preparing the triethyl ester (Habich and Limpricht, *l.c.*) ; together with cyanuric acid by heating anhydrous mono-potassium cyanurate with C_2H_5I at 170°-180° (Ponomarew, Ber. 18, 3270) ; by heating diethyl cyanurate (Hofmann, *ibid.* 19, 2078).

Hexagonal columns, readily soluble in hot water, alcohol, and ether, sparingly so in cold water. Yields CO_2 and $N(C_2H_5)H_3$ by heating in a sealed tube at 100°. Pb salt and C_2H_5I yield ethyl *iso*cyanurate.

Ethyl diketobutyrate *v.* KETONES.

Ethyl ferrocyanide $(C_2H_5)_4Fe(CN)_6$. From $Ag_4Fe(CN)_6$ and C_2H_5I (Freund, Ber. 21, 935). Rhombic crystals from $CHCl_3$, easily soluble in water and alcohol, insoluble in ether, ligroin, and CS_2. Decomposed at 212°-214°, with formation of ethyl *iso*cyanide. The aqueous solution gives a deep violet tint with $FeCl_3$, and a white precipitate with $HgCl_2$. Molecular weight by cryoscopic method indicates the monomolecular formula (Buchbock, Zeitsch. physikal. Chem. 23, 157).

Ethyl fluoride C_2H_5F. Obtained impure by action of CaF_2 and H_2SO_4 upon C_2H_5OH (Reinsch, J. pr. Chem. 1840, 19, 314) ; by heating $KC_2H_5SO_4$ and $KF·HF$ (Fremy, Compt. rend. 1854, 38, 393). Prepared pure from AgF and C_2H_5I (Moissan, Ann. Chim. Phys. 1890, [6] 19, 272) Colourless gas with ethereal odour, liquefying at −32° under atmospheric pressure. Burns in air with a blue flame. Readily soluble in C_2H_5Br, C_2H_5I, C_2H_5OH, and ether. Decomposed at 100° by heating with KOH in a sealed tube into KF, C_2H_5OH, and ether.

Ethyl formamide $H·CONHC_2H_5$; b.p. 199° ; sp.gr. 0·952 at 21°. By distilling an aqueous solution of $H·COONH_3(C_2H_5)$; separates from distillate upon addition of KOH (Linnemann). By action of $NH_2(C_2H_5)$ upon $CCl_3·CHO$ (Hofmann, Ber. 5, 247) ; a thick colourless liquid.

Ethyl formate $H·CO_2C_2H_5$; b.p. 54·4° at 760 mm., sp.gr. 0·9376 at 0°/4° ; b.p. 53·4°-53.6° at 754·4 mm., sp.gr. 0·8731 at 53·4°/4° (R. Schiff, Annalen, 220, 106) ; b.p. at 760 mm. 54·3°, sp.gr. 0·9480 at 0°/4° ; critical temperature, 235·3° ; critical pressure, 35,550 mm. (Young and Thomas, Chem. Soc. Trans. 1893, 1193). Capillarity constant at boiling-point, a^2 = 4·528 (Schiff, Annalen, 223, 75) ; H.C. p. 388 cals. (Berthelot, Ogier), 391·7 (Delépine).

By distilling a mixture of 6 parts alcohol (90 p.c.), 7 parts sodium formate and 10 parts (conc.) H_2SO_4 (Liebig) ; by distilling a mixture of ethyl oxalate with oxalic acid (Löwig, J. 1861, 599) ; by heating a mixture of glycerol, oxalic acid, and alcohol in a reflux condenser, and then distilling (Lorin, Bull. Soc. chim. [ii.] 5, 12). On the large scale a mixture of 9 parts of starch and 29 parts of MnO_2 (of 85 p.c.) is heated with 28

parts of H_2SO_4, 5 parts H_2O, and 15 parts of alcohol (85 p.c.) (Stinde, Dingl. poly. J. 181, 402).

A mobile colourless liquid with a pleasant aromatic smell ; is used for flavouring arrack and rum ; is decomposed by water, for which it has strong affinity. Sodium in absolute ether decomposes it into CO_2H and C_2H_5ONa (Freer and Sherman, Amer. Chem. J. 18, 581). Cl forms with it in sunlight *dichlorethyl formate* $H·CO_2C_2H_5Cl_2$, a colourless oily liquid, decomposed on heating, and which by action of alkalis is decomposed into acetic, formic, and hydrochloric acids. By further action of Cl in sunlight, *perchlorethyl formate* $Cl·CO_2C_2Cl_5$, b.p. 200°, sp.gr. 1·705 at 18°, is formed (Cloëz, Ann. Chim. Phys. [3] 17, 297)

Ethyl hydrate *v.* ALCOHOL.

Ethyl hydride, Ethane, *Dimethyl* C_2H_6 (Frankland and Kolbe, Chem. Soc. Trans. 1, 60) ; m.p. −171·4° ; b.p. at 749 mm. −85·4° (Ladenburg and Krügel, Ber. 32, 1821), −172·4° and −84·1° (Cardoso and Bell, J. Chim. Phys. 1912, 10, 497), −88·5° (Maass and McIntosh, J. Amer. Chem. Soc. 1914, 36, 737), −89·3° (Burrell and Robertson). Gas : sp.gr. 1·036, condensed at 4° and 46 atmospheres pressure (Cailletet, J. 1877, 68) ; critical constants (*v.* Hainlen, Annalen, 282, 245 ; Olszewski, Ber. 1894, 27, 3306 ; and Keunen, Chem. Zentr. 1897, ii. 540 ; Cardoso and Bell, *l.c.*) ; heat of vaporisation $14·6+10^{10}$ ergs per mol. ; density at the b p. 0·5490 (Maass and McIntosh, *l.c.*) ; sol. in water at $t°$

$$(1) \quad \frac{9·4556 - 0·35324t + 0·006278t^2}{100}$$

$$(2) \quad \frac{8·710 - 0·33242t + 0·00603t^2}{100}$$

(1) Schockendants (Annalen, 109, 116), (2) Bunsen (Gasometry). Sol in alcohol=1·5 (Berthelot, J. 1867, 344) ; H.C. p. 373·3 Cals. (Th.)=372·3 (Berthelot, Ann. Chim. Phys. [6] 30, 559) ; H.F. (from amorphous C)=11·7 Cals. (B.) ; occurs in crude petroleum.

Pittsburg gas consists of ethane mixed with a little CH_4 and CO_2, and is used for smelting and lighting purposes.

By action of K upon C_2H_5CN, also by action of water upon $Zn(C_2H_5)_2$ (Frankland and Kolbe, Chem. Soc. Trans. 3, 338) ; by action of Zn upon C_2H_5I in presence of water ; by electrolysis of acetic acid or acetates (Kolbe, Annalen, 69, 279) ; by heating 9 parts of C_2H_5I with 2·6 parts of $AlCl_3$ to 140° or 150° (Köhnlein, Ber. 16 562) ; by action of $Hg(C_2H_5)_2$ upon H_2SO_4 (Schorlemmer, Annalen, 132, 234) ; by heating an excess of BaO_2 with acetic anhydride and sand (Schützenberger, Zeitsch. Chem. 1865, 703 ; Darling, Annalen, 150, 216) ; by the action of nascent H (from ZnCu couple or Zn dust) upon a mixture of C_2H_5I and C_2H_5OH (Sabanejeff, Ber. 9, 810). By combining C_2H_4 or C_2H_5 with H in presence of reduced Ni (Sabatier and Senderens, Compt. rend. 124, 1360 ; 128, 1173). Ethane is now produced on an industrial scale by means of this reaction carried out under pressure. For details of the process, *see* Sprent (J. Soc. Chem. Ind. 1913, 171). From EtI and potassium hydride in sealed tubes at 180°-200° (Moissan, *ibid.* 134, 389). Reduced Ni at 395° breaks ethane up into C and C_2H_4 (Berthelot).

Ethyl iodide C_2H_5I (Gay-Lussac, Ann. Chim. Phys. [1] 91, 89 ; Serullas, *ibid.* [2] 25, 323 and 42, 119 ; Frankland, Chem. Soc. Trans. 2, 263 ; 3, 32) ; m.p. −118° (Schneider) ; b.p. 72·34° (Linnemann, Annalen, 160, 204), b.p. 71·3° (Andrews), 72·57° (corr.) (Thorpe and Rodger), 71·9°−72° (Linebarger) ; sp.gr. 1·9444 at 14·5° (L.), 1·9755 at 0° (Pierre), 1·9309 at 15° (Mende-léeff), sp.gr. 1·1810 at 72·2°/4° (Schiff), sp.gr. 1·9053 at 4°, 1·9433 at 15°, 1·9243 at 25° (Perkin) ; V.D. 5·417 (Marchand).

From alcohol and HI (Gay-Lussac) ; from alcohol, iodine, and phosphorus (Serullas). Per-sonne (Compt. rend. 42, 468) suggested the use of red P, and, according to Beilstein (Annalen, 126, 250), 1 part red P and 5 parts of alcohol (90 p.c.) are placed in a retort, and 10 parts of iodine slowly added. After 24 hours the C_2H_5I is distilled off, washed with NaOH solution and with water, and dried over $CaCl_2$. Crismer (Ber. 1884, 649) dissolves 1 in liquid paraffin adds yellow P and then alcohol. Walker (Chem. Soc. Trans. 1892, 717 ; *cf. ibid.* 1905, 1596) obtained a 93 p.c. yield from alcohol, iodine, and equal parts of red and yellow phos-phorus (*cf.* Adams and Voorhees, J. Amer. Chem. Soc. 1919, 41, 789). Prepared in quantitative yield by adding Et_2SO_4 slowly to a warm con-centrated aqueous solution of KI (Weinland and Schmid, D. R. P. 175209). Also from action of HI upon ether (Cottrel Rogers), and together with iodoform and NaI by electrolysis of a solu-tion of 20 grams C_2H_5COONa, and 20 grams KI in 20 c.c. of water (Miller, Hofer, and Reindel).

C_2H_5I is a colourless, pleasantly smelling liquid, almost insoluble in water, but miscible with alcohol and ether. It precipitates silver from its solutions in the cold, easily forms double compounds with silver salts, metals, and am-monia. Br displaces the I, and forms C_2H_5Br ; Cl forms C_2H_5Cl (Dumas, Stas, Annalen, 35, 162) ; ICl forms C_2H_5Cl and I_2. HCl has no action, but, on the contrary, C_2H_5Cl is decom-posed by HI into C_2H_5I and HCl (Lieben, Zeitsch Chem 1868, 712). By action of KI at 150°, ethane and iodine are formed. HNO_3 also causes the separation of I (Marchand, J. pr. Chem 1884, 33, 186). Metallic Ag abstracts I, and leaves butane (C_4H_{10}) By heating with water to 150°, we get alcohol (Reynoso, J. 1856, 567) ; with excess of alcohol yields ether and some C_2H_4 (Lieben, Rossi, Annalen, 158, 166). Is gradually turned brown by exposure to light, owing to formation of free I and liberation of butane (Frankland, Chem. Soc. Trans. 3, 322). In presence of mercury the reaction is much more rapid, owing to combination of the liberated I with Hg. Is used largely for the preparation of other ethyl compounds.

Ethyl nitrate $C_2H_5\cdot O\cdot NO_2$, *Nitric ether* ; m.p. −112° (Schneider) ; b.p. 86·3° at 728·4 mm. ; sp.gr. 1·1322 at 0°, 1·1123 at 15·5° (Kopp, Annalen, 98, 367) ; b.p. 87·6° ; sp.gr. 1 1305 at 4°, 1·1159 at 15°, 1·1044 at 25° (Perkin) ; H.F.p. = 40,870 ; H.F.v. = 38,750 ; H.C. = 325, 690 (Th. 4, 214). Obtained from alcohol by the action of nitric acid in presence of some substance which will destroy nitrous acid, *e.g.* urea (Millon, Ann. Chim. Phys. [3] 8, 233).

Preparation.—400 grams of pure nitric acid (sp.gr. 1·40) previously heated with 1 p.c. of urea in order to destroy lower oxides of nitrogen)

are mixed with 300 grams absolute alcohol and 100 grams of urea nitrate, and distilled ; when half the liquid has distilled off, a mixture of 400 grams of nitric acid and 300 grams of alcohol is allowed to drop into the retort and the distil-lation continued (Lossen, Annalen, Suppl. 6, 220).

Silver nitrate, heated with ethyl iodide (or bromide) and alcohol, yields, not ethyl nitrate, but the nitrite, together with aldehyde (Bertrand, Bull. Soc. chim. 33, [ii.] 566). If, however, EtI be added gradually to powdered $AgNO_3$, kept cool, a theoretical yield of $EtNO_3$ is formed (Von Biron, J. Russ. Phys. Chem. Soc. 30, 667).

Ethyl nitrate is a colourless liquid with pleasant odour and taste ; almost insoluble in water, but miscible with alcohol and ether. Ammonia forms ethylamine nitrate ; nascent hydrogen yields hydroxylamine and other bases (Lossen). Sulphuretted hydrogen yields mer-captan (Kopp, Annalen, 64, 320). Alcoholic potash decomposes it with separation of crystals of potassium nitrate.

Ethyl nitrite $C_2H_5\cdot O\cdot NO$, *Nitrous ether* ; b.p. 16·4° (Liebig), 17° (Mohr, J. 1854, 561 ; Brown, Pharm. J. 15, 400), 17·5° (Dunstan and Dy-mond, *ibid.* 18, 861) ; sp.gr. 0·900 at 15·5° (Br.) ; 0 917 at 0°/0° (D. and D.) ; H.F.p. = 30,610 ; H.F.v. = 28,870 (Th. 4, 217).

This body was discovered in 1681 by Kunckel. Obtained from alcohol by action of nitric acid, especially in presence of some oxidisable matter, *e.g.* copper.

Preparation.—500 grams of potassium nitrite and 1 litre alcohol (45 p.c.) are mixed and cooled by means of ice ; a mixture of sulphuric acid (500 grams), water (500 grams), and alcohol (500 grams) is then slowly dropped in, the heat produced volatilises the ether, which is con-densed in an efficient condenser (Feldhaus, Annalen, 126, 71). Dunstan and Dymond (*l.c.*) recommend that 34·5 grams sodium nitrite in 120 grams water be slowly mixed with a mixture of 13·5 grams of sulphuric acid with 32 grams alcohol and about 75 c c. water kept cool by ice. The ethyl nitrite separates out as a layer floating on the surface. As thus prepared, the liquid contains only traces of alcohol, from which it is freed by shaking with water. Alkali ethyl sulphates react with alkali nitrites, yielding nitrous ester and nitroethane (Ray and Neogi, Chem. Soc. Trans. 1906, 1900). Also formed by the interaction of $MgSO_4$, $NaNO_2$, and C_2H_5OH (Matuschek, Chem. Zeit. 1905, 29, 115).

Ethyl nitrite is a mobile liquid with a plea-sant ethereal smell and taste, liable to undergo decomposition, especially in presence of water. It can be preserved if mixed with alcohol and a small quantity of glycerol. It is decomposed by sulphides in accordance with the following equation :

$$C_2H_5NO_2 + 3H_2S = NH_3 + C_2H_6O + H_2O + 3S$$

(Kopp, Annalen, 64, 321).
It is slightly soluble in water and miscible with alcohol. Mixed with alcohol it constitutes the ' sweet spirit of nitre,' *spiritus ætheris nitrosi*, of the British Pharmacopœia, which is thus pre-pared : To 4000 millilitres of alcohol (90 p.c.) add gradually 100 millilitres of sulphuric acid, and then 125 millilitres of nitric acid, stirring constantly. Transfer the mixture to a retort or

flask, in which 100 grams of copper in fragments have been placed, and to which is attached an efficient condenser with a receiver containing 1000 millilitres of 90 p.c. alcohol. Surround the receiver with ice-cold water and distil gently at a temperature which is at first about 77°, and rises to 80°, but does not exceed 82°, until the volume of liquid in the receiver has been increased to 1600 millilitres. Then allow the contents of the retort to cool. add 25 millilitres of nitric acid, and resume the distillation until the liquid in the receiver is increased to 1700 millilitres. Mix this liquid with 1000 millilitres of the alcohol so as to make the whole contain 2·66 p.c. of ethyl nitrite.

Ethyl oxalylsuccinate v. KETONES.

Ethyl oxide $(C_2H_5)_2O$, **Ether**, *Ethyl ether*, *Vinic ether*; formerly called *Sulphuric ether*, *Phosphoric ether*, &c., according to the acid used in its preparation ; m.p. $-117 \cdot 6°$ (Archbald and McIntosh), m p. $-112 \cdot 6°$ (Ladenburg, and Krugel) ; b.p, $34 \cdot 97°$ (Regnault), $34 \cdot 6°$ at 762 mm.ₐ (Schiff, Annalen, 220, 332), $34 \cdot 9°$ (Kopp) ; sp.gr. 0·7360 at 0°, 0·7185 at 17·5° (Hager), 0·6950 at 34·6°/4° (Schiff), 0·7024 at 15°, 0·7099 at 25°/25°, 0·7201 at 15°/15° (Perkin, Chem. Soc. Trans. 45, 474), sp.gr. 0·71982 at 15°/15° (Wade and Finnemore), sp.gr. 0·7183 at 17·1° (Brühl), sp.gr. 0 70942 at 25° (Linebarger) ; M.M. = 4 777 at 20° . freezes at −129° to a crystalline mass, which melts at −117·4° (Olzewski, Monatsh. 5, 128) ; capillarity constant at b.p. $a^2 = 4 \cdot 521$ (Schiff) ; fl. at 17·5° = 8 ; critical temperature, 194° ; critical pressure, 35·61 atmospheres (Ramsay and Young). ·Vapour tension 67·49 mm. at −23°; 182·34 mm. at 0° ; 286·4 mm. at 10° ; 433·2 at 20° ; 636·3 at 30°.

The preparation of ether from alcohol and sulphuric acid was first described by Valerius Cordus (1540), and the method of making this ' oleum vitroli dulce ' was published in 1552 by Conrad Gessner. Frobenius, 1730, named it sulphuric ether. Val. Rose (Scher. J. 4, 253) showed that it contained no sulphur, but its composition was first made out by Saussure and also by Dumas and Boullay (Ann. Chim. Phys. [2] 36, 294). Its constitution was first studied by Liebig (Annalen, 60, 31 ; 23, 39) and Regnault (Ann. Chim. Phys. [2] 71, 352). Williamson, in 1850-51 (B. A. 1850, 65, and Phil. Mag. [3] 37, 350), established the views now held as to its constitution and formation.

Formation.—From alcohol, by action of phosphoric or arsenic acid (Boullay) ; by action of boron fluoride (Desfosses, Ann. Chim. Phys. [2] 36, 294) ; of $ZnCl_2$ (Masson, Annalen, 31, 63) ; of $SnCl_4$, and other metallic chlorides (Kühlmann, *ibid.* 33, 97, 192). From alcohol by heating with dry NH_4Cl to 260°-400° (Berthelot, Annalen, 83, 110). From C_2H_5NaO and C_2H_5I (Williamson). From alcohol and HCl, HBr, or HI at 200° or 240°, or by heating alcohol with $ZnCl_2$, $SnCl_4$, $CaCl_2$, $MgSO_4$, or chrome alum to 300° (Reynoso, Ann. Chim. Phys. [3] 48, 385). Also from C_2H_5Br or C_2H_5I and HgO (Reynoso), or from C_2H_5I and Na_2O (Green, Bull. Soc. chim. [ii.] 29, 458).

The continuous method now adopted is due to Boullay (J. Pharm. Chim. 1, 97), and the true explanation of the action was first given by Williamson (*l.c.*). The alcohol and sulphuric acid

first form $C_2H_5HSO_4$ and H_2O, and then, by the action of $C_2H_5HSO_4$ upon more alcohol, $(C_2H_5)_2O$ and H_2SO_4 are formed. That this is true Williamson proved by using amyl sulphuric acid and ethyl alcohol, when amyl-ethyl ether was produced (*cf.* Prunier, J. Pharm. Chim. 1897, 5, 513). Addition of $Al_2(SO_4)_3$ increases rate of production of ether owing to catalytic action (Senderens, Compt. rend. 1910, 151, 392).

Preparation.—Boullay's method is usually employed. A mixture of 9 parts H_2SO_4 with 5 parts of alcohol (90 p.c.) is placed in a retort, and alcohol is slowly dropped in and the temperature is maintained between 130° and 140°. An iron retort lined with lead is usually employed, and the ordinary mercurial thermometer, which is, of course, liable to fracture, is replaced by a bulbed tube containing some non-drying oil. The tube is then either exhausted by the air-pump, and hermetically sealed, or its open end is closed by a plug of cotton wool, and two marks are made on the tube corresponding to positions of the surface of the oil at 130° and 140° respectively. In order to avoid risk of explosion by contact of the vapour with direct flame, coils of lead tubing, conveying superheated steam or the vapour of some liquid of high boiling-point (*e.g.* coal-tar phenol), are used as a source of heat. The distillate is treated with milk of lime or solution of soda in order to remove the SO_2 which is always simultaneously formed. It is then rectified in an apparatus devised by Mohr, which consists of a still from which the vapour is led through a vessel kept at 38° by warm water. Here the alcohol and water vapours are condensed, and the ether passes over, and is condensed in an efficient condenser.

By means of an apparatus devised by Soubeiran, ether can be prepared in a fairly pure state by one operation. A mixture of about 30 lbs. of H_2SO_4 with 20 lbs. of alcohol of 85 p.c. is heated rapidly to 130° in a copper still, to the bottom of which two tubes convey alcohol from a tinned copper reservoir. The neck of the retort (which is of lead) is connected with the first condenser, which is a copper vessel kept warm by allowing the waste water from the worm tub (where the ether is condensed) to flow over the outside of it. Here the steam and vapour of alcohol are condensed, and the liquid formed can be drawn off from below by means of a stopcock. The ether vapour then passes on to the purifier, which consists of a vessel filled with wood charcoal saturated with a solution of caustic soda, which not only removes the SO_2, but also absorbs the oil of wine. The pure ether passes on, and is condensed in a well-cooled worm. The greatest yield of ether is obtained at 140°-145° ; below this temperature the yield is less, and above this much SO_2 is evolved (Prescott and Norton, Amer. Chem. J. 6, 243). Other apparatus have been described by Annaratone (Fr. Pat. 408089 ; J. Soc. Chem. Ind. 1910, 592), Fritzsche (Zeitsch. anal. Chem. 1897, 36, 298), Barbet et fils et Cie (Fr. Pat. 479435, 1914). Sulphuric acid has been largely replaced by benzenesulphonic acid in this preparation (Krafft, Ber. 26, 2831 ; D. R. P. 69115 ; Frdl. iii. 11).

Commercial ether contains water, alcohol, aldehyde, methyl compounds, ketones, and vinyl alcohol. A. J. Jones (Pharm. J. 1919, 103, 71)

found that in commercial samples, methyl compounds range from 0·02 to 0·06 p.c., sp.gr. 0·7182-0·7211, and ketones (as acetone) from 0·09 to 5·0 pts. per 10,000. Vinyl alcohol may be removed by shaking with water or treatment with bromine, phenylhydrazine, or potassium hydroxide (Poleck and Thümmel, Ber. 22, 2863), and the other impurities by treatment with dry $Fe(OH)_2$, prepared from crystallised $FeSO_4$, and an equimolecular weight of powdered lime (Gaborini, Bull. Assoc. Chim. Sucr. Dist. 1909, 26, 1165); by treatment with potassium hydroxide and powdered potassium permanganate, and finally drying with calcium chloride (Fierz; Wade and Finnemore, Chem. Soc. Trans. 1909, 1842; François, Chem. Zentr. 1897, ii. 144; Fritsch, Chem. Zeit. 1909, 33, 759). Phosphorus pentoxide may be substituted for calcium chloride (Lieben, Annalen, Suppl. 7, 218). (For other methods, v Guigues, J. Pharm. Chim. 1906, 24, 204; and Ekenberg, Zeitsch. anal. Chem. 36, 245.)

According to the B.P., 1914, ordinary ether should have a sp.gr. of 0·726, 15°/15°, and boil between 34° and 36°. Purified ether (Æther purificatus of the B.P.) should give no yellow colouration with solid potassium hydroxide in the dark, or with a solution of freshly prepared solution of potassium iodide. To test for presence of methyl compounds shake 2 vols. of the ether with 1 vol. of 20 p.c. alcohol and 1 vol. of water, allow the mixture to separate, and draw off the lower layer. Mix 5 millilitres of this lower layer with 2·5 millimetres of an aqueous solution (1 in 50) of potassium permanganate and 0·2 millilitre of sulphuric acid. At the end of 3 minutes add 0·5 millilitre of an aqueous solution (9·6 in 100) of oxalic acid, followed by 1 millilitre of sulphuric acid, and then by 5 millilitres of decolourised solution of fuchsin, and mix thoroughly. No violet colour should be produced within 20 minutes.

Wade and Finnemore (l.c.) find that ether and water form a binary mixture, b.p. 34·15°, containing 1·3 p.c. water, and that slight traces of alcohol greatly increase the solubility of water in ether. 1 gram ether dissolves 0·023 gram water at 15°–20° and 0·019 at 10° (cf. Schunke, Zeitsch. physikal. Chem. 14, 331; Napier, Bull. Soc. chim. 29 [ii.] 129); 1 gram water absorbs at 0°, 0·12465; at 10°, 0·09599; at 20°, 0·07487; at 30°, 0·06370 gram ether (Schunke, l.c.; Tolloczko, Ber. 28, 808; Klobbie, Zeitsch. physikal. Chem. 24, 615; Osaka, J. Soc. Chem. Ind. 1909, 625). If ether be shaken with an equal volume of CS_2, a turbidity is produced if water be present. A better test is with anhydrous copper sulphate or amalgamated aluminium.

Decompositions.—Pt black, CrO_3 or HNO_3 oxidise ether to acetic acid; ozone produces ethyl peroxide. Ether vapour and air at 100°, in the presence of a copper catalyser and platinum-black, yield acetaldehyde and formaldehyde (Orlow, J. Russ. Phys. Chem. Soc. 1908, 40, 799; cf. Legler, Annalen, 217, 392). When ozonised oxygen is passed into ether, a solution is obtained containing $C_2H_6O_4$, $C_2H_6O_2$, and H_2O_2, also a small quantity of CH_2O_2 (A. W. Wright). Ether combines with H_2SO_4 to form $C_2H_6HSO_4$; by action of SO_3 we first get $(C_2H_5)_2SO_4$, but by excess of SO_3, $C_2H_4HS_2O_7$ and a small quantity

of a body of the composition $CH_2(SO_3C_2H_5)_2$ are formed. When ether is heated with water and a small quantity of H_2SO_4 to 150°-180°, alcohol is formed (Erlenmeyer, Zeitsch. Chem. 1868, 343). According to Lieben (Annalen, 165, 136), the reaction goes on, though very slowly, without H_2SO_4, and at the ordinary temperature. Ether combines easily with HI and yields C_2H_5I (Silva, Ber. 8, 903), and is decomposed by heating with zinc-dust into C_2H_4 and water (Jahn, Monatsh. 1, 675); bromine and aqueous ether yield bromacetaldehyde (Maugin, Compt. rend. 1908, 147, 747).

Instances of the spontaneous explosion of ether on heating are not unknown, due probably to the presence of ethyl peroxide produced by autoxidation. Ether occasionally contains hydrogen peroxide and acetaldehyde and a relatively large amount of vinyl alcohol (Kassner, Arch. Pharm. 1912, 250, 436). Hydrogen peroxide may be detected by the immediate red colouration produced when 5 c.c. is treated with 1 c.c of $N/10$ potassium thiocyanate solution and 2 drops of a 5 p.c. freshly prepared acidified solution of ferrous ammonium sulphate (Dietze, Apoth. Zeit. 1915, 30, 165). There should be no liberation of iodine when 2 c.c. of a 10 p.c. solution of cadmium potassium iodide are shaken with 10 c.c. of the sample. Peroxides or peroxidised compounds may be formed in ether when improperly stored. The degree of oxidation is dependent upon the nature of the container, the purity of the ether, the amount of air present, and, in the case of glass containers, the intensity of the light which accelerates the oxidation. Peroxides may be removed by means of ferrous hydroxide or by shaking with mercury.

Mixtures of ether vapour and air explode when heated to about 190° if the amount of ether in the gaseous mixture reaches 1 gram per litre.

A hydrate $(C_2H_5)_2O,2H_2O$ is known; it is a solid body, which only exists below $-3\cdot5°$, and is obtained by the rapid evaporation of aqueous ether on filter paper (Tanret, Bull. Soc. chim. 30, 505; Compt. rend 87, 765). Dry ether and chlorine at $-80°$ yield a white crystalline chloride $(C_2H_5)_2OCl_2$, m.p. $-51°$; bromine similarly yields a reddish-yellow bromide $(C_2H_5)_2OBr_2$, m.p. $-40°$ (McIntosh, Chem. Soc. Trans. 1905, 789). A bromide $(C_2H_5)_2OBr_2$, red plates, m.p. 22°, is also known (Schutzenberger, Annalen, 167, 86).

Ether combines with various metallic salts and forms crystalline bodies, e.g. $BeCl_2$, $2(C_2H_5)_2O$, large prisms (Atterberg, Ber. 9, 856); $HgBr_2,3(C_2H_5)_2O$ (Nicklès, J. 1861, 200); $AlBr_3,(C_2H_5)_2O$ (N.). $TiCl_4(C_2H_5)_2O$; crystalline; m.p. 42°-45°; b.p. 118°-120°, decomposes into $TiCl_2(OC_2H_5)$ (Bedson, Annalen, 180, 236; Chem. Soc. Trans. 1876, 1, 311).

Properties.—A colourless mobile liquid with pleasant smell. Volatilises very quickly, and by so doing produces great cold. It is extremely inflammable, and its vapour, which is very heavy, forms an explosive mixture with air. Ether is readily soluble in concentrated HCl solution (Dräper, Chem. News, 35, 87), and in concentrated H_2SO_4, from which it is separated by addition of ice (Riedel, D. R. P. 52982, Frdl. ii. 551). It is miscible with almost all

organic liquids, and with liquid CO_2. It is a good solvent for resins, fats, alkaloids, &c., and sulphur and phosphorus dissolve in it to a small extent. It also dissolves I and many salts, e.g. Fe_2Cl_6, $HgCl_2$, $PtCl_4$, and many gases, notably ammonia.

In laboratories ether should always be kept over mercury or sodium in completely filled, well-stoppered bottles, preferably made of blue, green, or brown.glass, in cool places excluded from the. light (cf. Baskerville and Hamor, J. Ind. Eng. Chem. 1911, 3, 301 et seq.; J. Soc. Chem. Ind. 1911, 830).

Its vapour when inhaled produces insensibility (Faraday, 1818), and it is used as an anæsthetic in surgery. It is also occasionally used in surgery for producing local anæsthesia; this is done by directing a spray of ether upon the skin, when the extreme cold produced by evaporation produces complete insensibility.

It is also used as a solvent in the preparation of collodion, in the extraction of tannic acids, of several alkaloids, &c.

Chlorine acts v olently upon ether, setting fire to it, and liberating carbon (Cruikshank) If the ether be kept cool by ice, and in the dark, substitution products are obtained. The Cl replaces the H atom by atom from one ethyl group first, in the following order: $CHHHCHHOC_2H_5$

$$\begin{array}{ccccc} & 2 & 3\ 4 & 1 & 5 \end{array}$$

(Liebou, Annalen, 111, 121; 146, 180; Abeljanz, 164, 197; Jacobsen. Ber. 4, 215; also Liebig, Annalen, 1, 220; Malaguti, Ann. Chim. Phys. [2] 70, 338; [3] 16, 5; Fritsch and Schumacher, Annalen, 279, 302).

Monochlorether, *Monochlorethyl oxide*

$CH_3 \cdot CHCl \cdot O \cdot C_2H_5$;
b p. 97°-98°; by the chlorination of ether (Lieben); by saturating a mixture of aldehyde and alcohol with HCl (Frapolli, Wurtz, Annalen, 108, 226); by the action of PCl_5 upon acetal (Bachmann, ibid. 218, 39). It is decomposed by H_2SO_4 into HCl, C_2H_4O, and $C_2H_5 \cdot OH$. C_2H_5ONa forms NaCl and acetal; water decomposes it into HCl, aldehyde, and alcohol (Laatsch, Annalen. 218, 36).

Dichlorether, *Dichlorethyl oxide*

$CH_2Cl \cdot CHCl \cdot O \cdot C_2H_5$;

b.p. 140°-145°; sp.gr. 1·174 at 23°; by action of Cl upon ether (Malaguti, Annalen, 32, 15; Wildman and Gray, J. Amer. Chem. Soc. 1919, 41, 1122); by action of HCl upon a mixture of chloraldehyde and $C_2H_5 \cdot OH$ (Natterer, Monatsh. 5, 496); by action of HCl upon chloracetal (N.).

Dichlorether is decomposed on heating in a tube into C_2H_5Cl and other products. C_2H_5ONa forms first *chlordacetal* $CH_2Cl \cdot CH(OC_2H_5)_2$. By heating with excess of C_2H_5ONa in sealed tubes, *ethyl glycol acetyl* $CH_2(OC_2H_5)CH(OC_2H_5)_2$ is formed. In ethereal solution, $Zn(C_2H_5)_2$ yields *ethyl chlorether* $CH_2Cl \cdot CH(C_2H_5)OC_2H_5$; b.p. 141°; sp.gr. 0·9735 at 0°. With excess of $Zn(C_2H_5)_2$ we get $CH_2(C_2H_5)CH(C_2H_5)OC_2H_5$; b.p. 131·4° at 749·6 mm.; sp.gr. 0·7865 at 0° (Lieben, Annalen, 178, 14). Strong caustic potash forms alcohol, a body $C_8H_{16}Cl_2O_3$, a little glycollic acid, and two isomeric bodies of the composition $C_4H_9ClO_2$ (Abeljanz, ibid. 164, 218): α-$C_4H_9ClO_2$, *chloraldehyde alcoholate* $CH_2Cl \cdot CH(OH)O \cdot C_2H_5$, b.p. 93°-95°; and β-$C_4H_9ClO_2$ *oxychlorether* $CH_2OH \cdot CHCl \cdot O \cdot C_2H_5$,

also formed by chlorination of ether (Jacobsen, Ber. 4, 217), b.p. 151°-155°. With $NH_3 \cdot OH$ yields glyoxime (Hantzsch and Wild, Annalen, 289, 293). It is decomposed by water, and in presence of marble yields monochloracetaldehyde alcoholate, which, on distillation, gives monochloraldehyde and monochloracetal (Fritsch and Schumacher, ibid. 279, 301).

Trichlorether $CHCl_2 \cdot CHCl \cdot O \cdot C_2H_5$; b.p. 167°-168°, 155°-158° (Copaux), 170°-175° (Oddo and Mameli); sp.gr. 1·3303 at 14° (O. and M.). By the action of PCl_5 upon dichloracetal $CHCl_2 \cdot CH(OC_2H_5)_2$ (Krey, J. 1876, 475); by hydrolysis of the compound formed by action of chlorine on triethyl boric ester (Copaux, Compt. rend. 127, 721); by chlorinating αβ-dichloroethyl ether with 1 molecule of Cl at temperature of boiling saturated salt solution. At 230°-240° in a sealed tube, yields dichloroaldehyde and C_2H_5Cl. HCl at 110° for 6 hours, and distillation with concentrated H_2SO_4, yield the same products. Conversely, dichloroaldehyde in alcohol with HCl yields trichloroether. Boiled with water, trichloroether yields acetaldehyde, dichloroacetaldehyde hydrate (m.p. 55°-56°, b p. 96·5°-97·5°), dichloroacetal, and other very complex compounds (Oddo and Mameli, Gazz. chim. ital. 33, ii. 373; also ibid. 36, i 480); decomposed by heating with C_2H_5ONa, yielding *dichloracetal*.

Tetrachlorether $CCl_3 \cdot CHCl \cdot O \cdot C_2H_5$; b.p. 189·4° at 749·1 mm., 79° at 16 mm., 189·7° at 758·7 mm.; sp.gr. 1·4225 at 18°/4° (Weber and Foster, J. Amer. Chem. Soc. 31, 1410); sp.gr. 1·4379 at 0°, 1·4182 at 15 2°. Formed by action of Cl upon monochlorether in contact with I (Wurtz, Vogt, Zeitsch. Chem. 1871, 689), or of chloral alcoholate $CCl_3 \cdot CH(OH)O \cdot C_2H_5$ upon PCl_5 (Henry, Ber. 5, 101, 435; Paternò, Pisati, J. 1872, 303). From *trichlorvinyl ethyl ether* and chlorine (Godefroy). A liquid with a camphor-like smell, decomposed by heating with water into C_2H_4OH, HCl, and chloral. Alcoholic KOH forms with it *trichlorvinyl ethyl ether* $CCl_2 : CCl \cdot O \cdot C_2H_5$. Heated with alcohol, forms trichloracetal (Pergami).

Pentachlorether. Two isomerides:
(1) $CCl_3 \cdot CCl_2 \cdot O \cdot C_2H_5$; b.p. 190°-210° with decomposition; sp.gr. 1·645 (Jacobsen, Ber. 4, 217); by action of Cl upon trichlorvinyl ethyl ether (v. supra) (Busch, Ber. 11, 445).
(2) $CCl_3 \cdot CHCl \cdot O \cdot CH_2 \cdot CH_2Cl$; b.p. 235°; sp.gr. 1·577 at 80°. By action of PCl_5 on a compound of chloral and glycol chlorohydrin

$CCl_3 \cdot CH(OH)O \cdot CH_2 \cdot CH_2Cl$
(Henry, Ber. 7, 763).

Hexachlorether $CHCl_2 \cdot CHCl \cdot O \cdot CHCl \cdot CHCl_2$; b.p. 250°; by action of PCl_5 upon dichloraldehyde saturated with HCl (Paternò, Pisati, J. 1871, 508).

Octochlorether $C_4H_2Cl_8O$; from ethylidene oxychloride and Cl in sunlight (Roth, Ber. 8, 1017). Camphor-like smelling, volatile crystals.

Perchlorether $(C_2Cl_5)_2O$ (Regnault, Annalen, 34, 27); sp.gr. 1·900 at 14·5° (Malaguti, Ann. Chim. Phys. [3] 16, 4); the ultimate product of the action of Cl upon ether in sunlight, is a solid, forming orthorhombic scales, m.p. 69°, which possesses a smell like that of camphor. Decomposed by heating at 300° into C_2Cl_6 and $CCl_3 \cdot COCl$; with H_2S yields perchlorvinyl ether

$(C_2Cl_3)_2O$; with liberation of S (Malaguti, Ann. Chim. Phys. [3] 16, 19). This body is a liquid, b.p. 210°, sp.gr. 1·652 at 21°, which combines with Cl in sunlight to form $(C_2Cl_5)_2O$, or with Br yielding $(C_2Cl_3Br_2)_2O$.

Ethyl peroxide $(C_2H_5)_4O_3$, produced by leading dry ozone into absolute ether (Berthelot, Bull. Soc. chim. ii. 36, 72), is a thick syrup which does not solidify at −40°, is partially volatile on heating, but easily explodes ; is miscible with water, by which it is decomposed into C_2H_5OH and H_2O_2.

Ethyl phosphates.

1. *Normal ethyl phosphate* $(C_2H_5)_3PO_4$; b.p. 215° ; sp.gr. 1·072 at 12°. By action of heat on lead diethyl phosphate $Pb(C_2H_5)_4(PO_4)_2$ (Vogeli, Annalen, 69, 190) ; from C_2H_5I and Ag_3PO_4 (Clermont, Ann. Chim. Phys. [3] 42, 330) : from $POCl_3$ and C_2H_5ONa (Lamprecht, Annalen, 134, 347) ; from P_2O_5 and absolute alcohol (Carius, *ibid.* 137, 121). Colourless liquid, miscible with and slowly decomposed by water, forming diethyl phosphoric acid.

2. *Diethyl phosphoric acid* $(C_2H_5)_2HPO_4$, a syrupy liquid obtained by action of P_2O_5 upon alcohol. It is a monobasic acid, and forms well-marked salts, *e.g.* $Ca[(C_2H_5)_2PO_4]_2$, crystalline needles ; $Pb[(C_2H_5)_2PO_4]_2$, needles, m·p. 180°, soluble in water.

3. *Ethyl phosphoric acid* $H_2(C_2H_5)PO_4$, an oily liquid decomposed by heating, evolving $(C_2H_5)_2O$, C_2H_5OH, and C_2H_4. Equal parts of alcohol (95 p.c.) and syrupy H_3PO_4 are heated to 60° or 80°, diluted with water and neutralised with $BaCO_3$, filtered, the Ba salt allowed to crystallise, and then decomposed by H_2SO_4 (Pelouze, Ann. Chim. Phys. [2] 52, 37).

Also produced by action of P_2O_5 upon ether or alcohol or of syrupy H_3PO_4 upon ether (Vögeli, J. 1847-48, 694). Forms crystalline salts with the metals ; of these the lead salt is least soluble.

Ethyl phosphites.

1. *Triethyl phosphite* $(C_2H_5)_3PO_3$; b.p. 191° (or 188° in stream of H) ; sp.gr. 1·075 at 15·5° (Railton, Chem. Soc. Trans. 1855, 7, 216) ; from PCl_3 and alcohol or sodium ethoxide.

An ethereal-smelling liquid, which absorbs O and is converted by PCl_5 into $PO(OC_2H_5)Cl_2$, PCl_3, and C_2H_5Cl (Geuther, Hertz. J. 1876, 207). By heating with $NaOC_2H_5$ yields $Na(C_2H_5)_2PO_3$; with $(C_2H_5O)_2O$, gives

$$H_2(C_2H_5)PO_3$$
(Jachne, Annalen, 256, 269).

2. *Diethyl-phosphorous acid* $H(C_2H_5)_2PO_3$; b.p. 184°-185° ; sp.gr. 1·0749 (15·5°/4°). From P_4O_6 and C_2H_5OH (Thorpe and North, Chem. Soc. Trans. 1890, 634) ; from PCl_3 and C_2H_5OH (Levitsky, J. Russ. Phys. Chem. Soc. 1903, 35, 211 ; Milobendzi and Sachnowski, Chem. Soc. Abst. 1918, i. 477) ; from C_2H_5I and $Pb_3(PO_3)_2$ (Michaelis and Becker, Ber. 1897, 1005). Colourless mobile liquid with an alliaceous odour.

3. *Ethyl-phosphorous acid* $H_2(C_2H_5)PO_3$, very unstable syrupy liquid ; obtained by action of PCl_3 upon weak alcohol (Wurtz, Ann. Chim. Phys. [3] 16, 218). The salts do not crystallise well, but are more stable than the acid.

Chloride of ethyl-phosphorous acid $C_2H_5POCl_2$; b.p 117·5° (corr.) ; sp.gr. 1·30526 at 0°/4° (Thorpe, Chem. Soc. Trans. 37, 346) ; from PCl_3

and C_2H_5OH (Menschutkin, Annalen, 139, 343) ; decomposed by water into HCl, C_2H_5OH, and H_3PO_3 ; also by heating to 165° into C_2H_5Cl, P, PCl_3, and P_2O_5 (Chambon, J. 1876, 205).

Diethyl pyro-phosphorous acid is not known, but the zinc salt $(C_2H_5)_2P_2O_5Zn$ is produced when $Zn(C_2H_5)_2$ is heated with P_2O_5 to 140° (Dilling, Zeitsch. Chem. 1876, 266).

Ethyl selenic acid $C_2H_5HSeO_4$, very unstable ; produced from H_2SeO_4 and C_2H_5OH (Fabian, Annalen, Suppl. 1, 244). The salts are also unstable, the most permanent being the strontium salt ; they can be crystallised with the ethyl-sulphuric acid salts.

Ethyl selenhydrate, *Ethyl selenomercaptan* C_2H_5SeH ; b.p. 53·5° ; sp.gr. 24°/4° 1·3954 (Tschugaeff, Ber. 1909, 42, 49). From ethyl iodide and sodium hydroselenide. Nauseous-smelling liquid.

Ethyl selenide, *Selenethyl* $(C_2H_5)_2Se$; b.p. 108° ; discovered by Löwig (Pogg. Ann. 37, 552). By action of K_2Se upon $(C_2H_5)_2C_2O_4$ (L.) ; by action of $KC_2H_5SO_4$ upon K_2Se (Joy, Annalen, 86, 35 ; Rathke, *ibid.* 152, 210) ; the crude product is then distilled again with KOH, $C_2H_5HSO_4$, and a small piece of P or S (Pieverling, *ibid.* 185, 331 ; Ber. 9, 1469). A colourless mobile liquid with a not unpleasant smell, is insoluble in water, acts as a base ; HCl precipitates from a solution in dilute HNO_3 an oily liquid $(C_2H_5)_2SeCl_2$, which gives with aqueous NH_3 a crystalline oxychloride $[(C_2H_5)_2Se]_2OCl_2$. Combines with C_2H_5I to form crystalline $(C_2H_5)_3SeI$ (Peverling). This is a white substance resembling Epsom salts in appearance. The $(C_2H_5)_2SeCl_2$ forms double salts with several metallic chlorides ; *e.g.* :

$$[(C_2H_5)_3SeCl]_2ZnCl_2$$

Ethyl diselenide $(C_2H_5)_2Se_2$; b.p. 186° ; formed as a by-product in the preparation of $(C_2H_5)_2Se$; was first obtained by Wöhler and Dean (Annalen, 97, 1) from $KC_2H_5SO_4$ and K_2Se_2 (Rathke, *ibid.* 152, 212) ; has an intensely disagreeable smell, and acts as a poison (Pieverling). A solution in dilute HNO_3 gives with HCl monoclinic crystals of $(C_2H_5)_2Se_2O_4(OH)_2Cl_2$, which are soluble in water, and are reduced by SO_2 to ethyl diselenide.

Ethoxy-selenyl chloride $C_2H_5O·SeOCl$; m.p. 10° ; b.p. 175°, not without decomposition. From $SeOCl_2$ and absolute alcohol. Heated in a tube to 200° yields Se, C_2H_5Cl, HCl, and H_2O (Michaelis and Landmann, Annalen, 241, 156).

Diethylselenite $SeO(OEt)_2$; b.p. 183°-185°, not without decomposition ; sp.gr. 1·49 at 16·5°. From $SeOCl_2$ and NaOEt in dry ether at 180°-190° ; also from Ag_2SeO_3 and C_2H_5I at 85° in sealed tube. A thick liquid, decomposed by water into C_2H_5OH and H_2SeO_3. Decomposed by heating in a tube at 200° with separation of Se (M. and L.).

Ammonium monoethylselenite

$$C_2H_5O·SeO·ONH_4 ;$$
a crystalline, very hygroscopic acid, formed by action of alcohol and ammonia upon SeO_2 at temperature of melting ice. It is soluble in alcohol, insoluble in ether (Divers and Hada, Chem. Soc. Trans. 75, 538).

Ethyl sulphates.

Mono-ethyl sulphate $C_2H_5HSO_4$ *(Ethylsulphuric acid; Sulphethylic acid; Sulphovinic acid)*; sp.gr. 1·316 at 16°.

First noticed by Dabit (Crell's Ann. [1802] 1, 394); and again by Sertürner (Gilb. Ann. 60, 53; 64, 67, [1818-1820]; *see* also Hoeren, Pogg. Ann. 7, 193; Hennel, Trans. Roy. Soc. 1826; 240, 1828, 365; Serullas, Ann. Chim. Phys. [2] 39, 153; Liebig and Wöhler, Pogg. Ann. 22, 487; Liebig, Annalen, 9, 17, 32; 13, 32, 38; Dumas and Boullay, Ann. Chim. Phys. [2] 36, 300).

Formed by action of sulphuric acid upon alcohol (Dabit, Sertürner, Serullas); also by absorption of ethylene in sulphuric acid (Hennel; Berthelot, Ann. Chim. Phys. [3] 43, 385); by heating ether with strong H_2SO_4 (Hennel; Magnus, Pogg. Ann. 27, 386); from S_2Cl_2 and alcohol (Heusser, Annalen, 151, 249); from $HO\cdot SO_2Cl$ and alcohol in the cold (on heating, this gives $C_2H_5O\cdot SO_2Cl$, Claesson, J. pr. Chem. [2] 19, 245).

Preparation —A mixture of equal parts of absolute alcohol and strong sulphuric acid is heated for 4 hours on the water-bath; by this treatment 59 p.c. of the H_2SO_4 used is converted into mono-ethyl sulphate (Berthelot, Bull. Soc. chim. ii. 19, 295) By using 3 molecules alcohol and 1 molecule H_2SO_4 (*i.e.*, 3 to 2 by weight), 77 p.c. of the sulphuric acid is utilised (Claesson, J. pr. Chem. [2] 19, 246). The mixture is diluted with water and neutralised with lead or barium carbonate, filtered, evaporated to crystallisation, the crystals dissolved in water, and the acid set free by means of H_2SO_4, or, when lead carbonate is used, by means of H_2S. The excess precipitated $BaSO_4$, $PbSO_4$, or PbS is removed by filtration, and the liquid evaporated *in vacuó* over sulphuric acid. Mono-ethyl sulphate is a syrupy liquid, very soluble in water, soluble also in alcohol, but insoluble in ether.

Heated with water, yields alcohol and sulphuric acid; on heating with alcohol to 140°, ether and H_2SO_4 are formed. Oxidising agents, *e.g.* MnO_2 or K_2CrO_4, give aldehyde (Jacquemin and Lies-Bodard, J. 1857, 345) The salts are very soluble in water, and can be heated in dilute solutions without decomposition, though in strong solution, or by prolonged heating, they are decomposed with formation of alcohol, a sulphate, and free H_2SO_4. This decomposition may be diminished by the addition of an alkali hydroxide or carbonate. By dry distillation, the salts yield 'heavy oil of wine,' a liquid containing diethyl sulphate and olefines (*cf.* Kremann, Monatsh. 1917, 38, 53). HCl gas yields C_2H_5Cl and a metallic sulphate (Köhler, Ber. 19, 11, 1929).

By distilling sodium ethyl sulphate in a vacuum, Lilienfeld (Austrian Pat. 63526) obtains ethyl sulphate in 83–90 p.c. yield.

Salts (*v.* Marchand, Pogg. Ann. 32, 456; 41, 595). $LiC_2H_5SO_4,H_2O$; $NaC_2H_5SO_4,H_2O$; $KC_2H_5SO_4$, crystallises in anhydrous monoclinic plates, soluble in 0·8 part H_2O at 17°; (Schabus, J. 1854, 560; Marignac, J. 1855, 608).

$Mg(C_2H_5SO_4)_2,4H_2O$; $Ca(C_2H_5SO_4)_2,2H_2O$ forms monoclinic laminæ, soluble in 0·8 part water at 17° (M.); $Ba(C_2H_5SO_4)_2,2H_2O$, monoclinic plates, sp.gr. 2·080 at 21·7°, soluble in 0·92

parts of water at 17° (M.); $Pb(C_2H_5SO_4)_2,PbO$, large rhombic tables — $Pb(C_2H_5SO_4)_2,PbO$, amorphous; soluble in 0·54 part H_2O at 17°.

Diethyl sulphate $(C_2H_5)_2SO_4$; sp.gr. 1·1837 at 19° (Claesson, J. pr. Chem. [2] 19, 257); b.p. 208° (with decomposition), 113·5° at 31 mm., 118° at 40 mm., 120·5° at 45 mm. (Villiers, Bull. Soc. chim. ii. 34, 26); m.p. about −24·5° (V.); occurs in 'heavy oil of wine.' Formed by leading SO_3 vapour into absolute ether (Wetherill, Annalen, 66, 117); in small quantity by distillation of $C_2H_5HSO_4$; by dropping alcohol into chloride of ethyl sulphuric acid $C_2H_5O\cdot SO_2Cl$, or by action of H_2SO_4 upon alcohol (Claesson); from Ag_2SO_4 and C_2H_5I (Stempnewsky, Ber. 11, 514). A mixture of 1 vol. absolute alcohol and 2 vols. H_2SO_4 is distilled slowly *in vacuó* (Villiers). Absolute alcohol is mixed with Nordhausen sulphuric acid, the ether separated by means of $CHCl_3$, and the product distilled *in vacuó* (Claesson and Lundvall, Ber. 13, 1699).

Is an oily liquid, with an odour like that of peppermint: insoluble in water, and slowly decomposed by that liquid even in the cold; when heated with water, yields alcohol, H_2SO_4 and $C_2H_5HSO_4$. Heated with alcohol, forms ether and $C_2H_5HSO_4$; warm baryta water forms alcohol and $Ba(C_2H_5SO_4)_2$ (Villiers).

Unsaturated hydrocarbons are present to the extent of about 5 p.c. in 'heavy oil of wine.'

Chloride of ethyl sulphuric acid $C_2H_5O\cdot SO_2Cl$; b p 151°–154° (corr) (Claesson, J. pr. Chem. [2] 19, 248), with slight decomposition; 93°–95° at 100 mm. (Muller, Ber. 6, 227). From C_2H_5Cl and SO_3, together with isomerides (*v. Ethyl chloride*); by dropping alcohol into SO_2Cl_2 (not *vice versá*; diethyl sulphate is then formed) (Behrend, J. pr. Chem. [2] 15, 28); from a salt of ethyl sulphuric acid and PCl_5 (Purgold, Ber. 6, 505); from ethyl chloroformate $ClCO_2C_2H_5$ and fuming sulphuric acid (Wilm, Ber. 6, 505); by passing C_2H_4 into HSO_3Cl, $SO_4H\cdot C_2H_4\cdot SO_2Cl$ is also produced (Müller, *ibid.* 6, 227).

A liquid with an irritating smell, exciting tears, and decomposed by contact with water into HCl, H_2SO_4 and alcohol. When the chloride is added to methyl alcohol or ethyl alcohol, ethyl sulphuric acid and CH_3Cl or C_2H_5Cl are produced; with amyl alcohol, amyl sulphuric acid and ethyl chloride are formed (Müller). If, on the other hand, absolute alcohol is dropped into the chloride, diethyl sulphate is produced (Claesson).

Bromethyl sulphuric acid

$CH_2Br\cdot CH_2\cdot OSO_2OH(?)$;
from ethylene bromide and SO_3 (Wroblewski, Zeitsch. Chem. 1868, 563). The barium salt is anhydrous, and is decomposed by continued heating with water, with separation of $BaSO_4$ and formation of glycol (Beilstein and Wiegand, Ber. 15, 1370). An isomeric body

$CH_3\cdot CHBr\cdot OSO_2\cdot OH(?)$
is formed by acting upon ethylene bromide with Ag_2SO_4 and water (B. and W.); the barium salt is very soluble in water, and its solution decomposes on warming into $BaSO_4$, HBr, and glycol.

Dibromo-diethyl sulphate $(CH_2Br\cdot CH_2)_2SO_4$; by action of ethylene bromide upon Ag_2SO_4 in

presence of benzene (Beilstein and Wiegand, Annalen, 15, 1369); a heavy oil insoluble in water, soluble in benzene and ether, decomposed on heating. Heated with water, yields bromide of ethyl sulphuric acid, and finally HBr, H_2SO_4, and glycol.

Ethyl sulphites.

Mono-ethyl sulphite $C_2H_5O \cdot SO \cdot OH$, *Ethyl sulphurous acid, Hyposulphethylic acid.* The potassium salt $KC_2H_5SO_3$ is obtained by passing SO_2 into a well-cooled solution of $NaOC_2H_5$ in absolute alcohol (Rosenheim and Liebknecht, Ber. 1898, 408). The ammonium salt is prepared by passing NH_3 followed by SO_2 into absolute alcohol (Divers and Ogawa, Chem. Soc. Trans. 1899, 535). The alkali salts are very unstable in the solid state decomposing with evolution of SO_2. Dilute mineral acids bring about this change in solution; ethyl iodide and alcohol at 150° yield ethyl sulphonate (*q.v.*). By treatment with PCl_5, diethyl sulphite yields the *chloride of ethyl sulphurous acid* $C_2H_5O \cdot SOCl$ which boils at 122°, is decomposed by water into HCl, SO_2, and alcohol, and gives, by further action of PCl_5 at 180°, thionyl chloride, C_2H_5Cl, and $POCl_3$ (Michaelis and Wagner, Ber. 7, 1074). Ethyl sulphurous acid is isomeric with ethyl sulphonic acid $C_2H_5 \cdot SO_2 \cdot OH$ (*q.v.*).

Diethyl sulphite $C_2H_5O \cdot SO \cdot OC_2H_5$; sp.gr. 1·1063 at 0° (Carius, J. pr. Chem. [2] 2, 279); b.p. 161·3°. From alcohol and S_2Cl_2; 18 parts of absolute alcohol are mixed with 50 parts of S_2Cl_2, previously warmed to 60°; the mixture is kept at this temperature for an hour, and then distilled: the portion boiling above 150° is redistilled (Warltz, Annalen, 143, 74).

A colourless liquid, with mint-like odour, miscible with alcohol and ether; insoluble in water. Decomposed by water; with PCl_5, yields a chloride C_2H_5OSOCl, which, on distillation, splits up into C_2H_5Cl and SO_2 (Geuther, Annalen, 224, 223; Michaelis and Wagner, Ber. 7, 1074). Decomposed by KOH into potassium ethyl sulphonate (Rosenheim and Liebknecht, *ibid.* 31, 405). Decomposes at 200° into SO_2 and ether (Prinz, Annalen, 223, 374); or by heating with $SOCl_2$, to 120°, into SO_2 and C_2H_5Cl (Geuther).

Ethyl sulphydrate C_2H_5SH. *Mercaptan, Ethyl mercaptan*; b.p. 36·2° (Nasini, Ber. 15, 2882); sp.gr. 0·83907 at 20°/4° (N.), 0·835 at 21°. By distilling $Ba(C_2H_5SO_4)_2$ with $Ba(HS)_2$ (Zeise, Annalen, 11, 1); by action of KHS upon C_2H_5Cl (Regnault, Ann. Chim. Phys. [2] 71, 390); by heating absolute alcohol saturated with SO_2 in a sealed tube, there are also formed $C_2H_5HSO_4$, $(C_2H_5)_2O$, and H_2SO_4 (Endemann, Annalen, 140, 336); from P_2S_5 and alcohol (Kekulé, Annalen, 90, 310). It is best prepared by saturating a solution of KOH, sp.gr. 1·3, with H_2S, mixing with a solution of $Ca(C_2H_5SO_4)_2$ (also of sp.gr. 1·3), and distilling on water-bath (Liebig, Annalen, 11, 14); according to Claesson (J. pr. Chem. [2] 15, 193), $(C_2H_5)_2S$ is also formed; NaC_2H_5S is prepared from the product of this action, the alcoholic solution evaporated to dryness, the $(C_2H_5)_2S$ removed by means of benzene, and the C_2H_5NaS decomposed by dilute H_2SO_4.

It is a colourless liquid with a penetrating garlic-like smell, slightly soluble in water, from which it crystallises on evaporation with $18H_2O$,

m.p. 12° (Claesson). It gives with bromine C_2H_5Br, HBr, and BrS (Friedel, Ladenburg, Annalen, 145, 189). HNO_3 forms $C_2H_5SO_3 \cdot 8C_2H_5$, or, if the acid is stronger, ethyl sulphonic acid. Treated with Cu powder, loses its disagreeable odour, but is considerably decomposed thereby (Finckh).

It forms crystalline compounds with $SiCl_4$ (Demarcay, Bull. Soc. chim. [2] 20, 127). It absorbs NO, forming a dark-red solution.

The hydrogen of mercaptan is replaceable by metals forming mercaptides; *e.g.* C_2H_5KS and $Hg(C_2H_5S)_2$, transparent plates, m.p. 76°-77° (Otto, Ber. 13, 1290; 15, 125), very slightly soluble in cold alcohol, soluble in 12-15 parts hot alcohol (Liebig, Annalen, 11, 17); gives with HNO_3 the nitrate $Hg(C_2H_5S)NO_3$ (Hofmann and Rabe, Zeitsch. anorg. Chem. 17, 26); $Pb(C_2H_5S)_2$, yellow precipitate, formed when $Pb(C_2H_5O_2)_2$ and C_2H_6HS are mixed in alcoholic solutions. $As(C_2H_4S)_3$, a foul-smelling oil formed from $AsCl_3$ and C_2H_5NaS, decomposed by heat into As and $(C_2H_5)_2S_2$. $Pt(C_2H_5S)_2$ pale-yellow precipitate (Zeise).

Ethyl sulphide $(C_2H_5)_2S$; b.p. 91° (Pierre, J. 1851, 51), 91·9° at 754·7 mm. (Beckmann, J. pr. Chem. [2] 17, 451), 92·2°–93° (corr.) at 754 mm. (Nasini, Ber 15, 2282); 92·1° (corr.) (Thorpe and Rodger); sp.gr. 0·8367 at 0° (Pierre), 0·83676 at 20°/4° (N.). From K_2S and C_2H_5Cl (Regnault, Ann. Chim. Phys. [2] 71, 387); from $Zn(C_2H_5)_2$ and $SOCl_2$ (Gauhe, Annalen, 143, 266); from KHS and $KC_2H_5SO_4$ in alcohol (Hobson, Chem. Soc. Trans. 10, 56); also from P_2S_5 and $(C_2H_5)_2O$ (Beckmann). To prepare the pure sulphide, heat the crude sulphide with Cu powder to 260°-280° (Finckh, Ber. 1894, 1239).

It is a colourless liquid with strong garlic-like smell, insoluble in water. Brühl states that in the pure state it has an ethereal odour. Chlorine acts upon it in the dark, forming substitution products: (1) $(C_2H_4Cl_2)_2S$, yellow liquid, b.p. 167°-172°, sp.gr. 1·547 at 12°; (2) $(C_2H_3Cl_3)_2S$, b.p. 189°-192°, sp.gr. 1·219 at 13·5°; (3) $(C_2HCl_4)_2S$, b.p. 217°-222°. By prolonged action of chlorine, C_2Cl_6 is formed, and possibly $(C_2Cl_5)_2S$ (Riche, Ann. Chim. Phys. [3] 43, 283; Annalen, 92, 358). $(C_2H_4Cl_3)_2S$ also results from action of chlorine upon $(C_2H_5Cl_2)_2S$, which can be obtained from C_2H_4 and Cl_2S_2 (Guthrie, Annalen, 116, 241). Bromine forms $(C_2H_4)_2SBr_2$, a yellowish-red unstable body, which, by the action of KI, yields $(C_2H_5)_2SI_2$, a black liquid (Rathke, Annalen, 152, 214).

Ethyl sulphide combines with many metallic chlorides to form crystalline compounds, *e.g.* $(C_2H_5)_2S \cdot HgCl_2$, white crystals, soluble in alcohol and ether, m.p. 119°; $(C_2H_5)_2S \cdot HgI_2$, yellow needles, m.p. 110°; $2(C_2H_5)_2S \cdot TiCl_3$, dark-red crystals (Demarcay). (For addition compounds, *see* Abel, Zeitsch. physiol. Chem. 20, 268; Werner, Zeitsch. anorg. Chem. 15, 14; 17, 101; Smiles, Chem. Soc. Trans. 1900, 164.)

Nitric acid (of sp.gr. 1·2) forms *ethyl sulphoxide* or *diethyl sulphine oxide* $(C_2H_5)_2SO$, a soluble oily liquid, solid at low temperatures, and decomposed by heating. Fuming nitric acid converts this into *diethyl sulphone* $(C_2H_5)_2SO_2$; b.p. 248°; m.p. 70°-72° (Oefele, Annalen, 127, 370; 132, 88); $R \cdot a = 47·53$ (Kanonnikow, J. Russ. Phys. Chem. Soc. 15

451); also formed from $Pb(C_2H_5)_4$ and SO_3 (Frankland and Lawrence, Chem. Soc. Trans. 35, 244), and from $(C_2H_5)_2S$, and a solution of $KMnO_4$ (O.). Rhombic plates, soluble in 6·4 parts water at 16°.

Triethyl sulphine $(C_2H_5)_3S$ forms compounds in which it plays the part of a univalent radical.

$(C_2H_5)_3SI$ from $(C_2H_5)_2S$, C_2H_5I, and H_2O (Oefele, Annalen, 132, 82); from HI and $(C_2H_5)_2S$ or HI and C_2H_5HS, or C_2H_5I and C_2H_4HS (Cahours, *ibid.* 135, 352; 136, 151); forms rhombic plates of disagreeable odour, and soluble in water. By action of Ag_2O, yields *triethyl sulphine hydroxide* $(C_2H_5)_3SOH$, a strong base; displaces NH_4, and has caustic action on the skin; it forms a crystalline deliquescent mass, which unites with acids to form deliquescent salts yielding double compounds with many metallic salts; *e.g.* :

$$PtCl_4 \cdot 2(C_2H_5)_3SCl$$
dark-reddish prisms, soluble at 20·7° in 30 parts of water (Dehn, Annalen, Suppl. 4, 90; Jorgenson, J. pr. Chem. [2] 6, 82; Kraut, Annalen, 210, 321).

When $(C_2H_5)_2S$ is heated with CH_3I, *diethylmethyl sulphine iodide* $(C_2H_5)_2CH_3SI$, an unstable non crystalline body, is formed, from which other salts can be obtained; the chloride $(C_2H_5)_3SCl$ forms many double salts (Kruger, J. pr. Chem. [2] 14, 196). The isomeride, *ethyl-methylethyl sulphine iodide,* prepared from $C_2H_5CH_3S$ and C_2H_5I, is crystalline (Kruger).

Ethyl disulphide $(C_2H_5)_2S_2$; b.p. 152·8°-153·4° (corr.) at 730 mm. (Nasini, Ber. 15, 2882); sp.gr. 0·99267 at 20°/4° (N.). By distillation of $KC_2H_5SO_4$ with K_2S_2 and water (Zeise, Annalen, 11, 1; Morin, *ibid.* 32, 267; Löwig, Kopp, *ibid.* 35, 345; Cahours, *ibid.* 61, 98); by action of 1 upon a slight excess of a solution of C_2H_5NaS (Kekulé; Linnemann, *ibid.* 123, 279); by action of S upon C_2H_5SNa (Böttger, *ibid.* 223, 348); by distilling liquid thioacetaldehyde (Klinger, Ber. 32, 2195).

A colourless liquid, with garlic-like smell, very slightly soluble in water; with dilute HNO_3, gives $(C_2H_5)_2S_4O_6$, an oily liquid, which may be regarded as the ethyl salt of ethyl thiosulphonic acid $C_2H_5SO_2SC_2H_5$.

Ethyl trisulphide $(C_2H_5)_2S_3$, from K_2S_3 and $KC_2H_5SO_4$ (Cahours, Bull. Soc. chim. [2] 25, 184); also from $(C_2H_5)_2S_2$ and S (H. Müller); a colourless liquid, with unpleasant smell.

Ethyl tetrasulphide $(C_2H_5)_2S_4$; from S_2Cl_2 and C_2H_5SH (Claesson, J. pr. Chem. [2] 15, 214); a heavy oily liquid, with disagreeable smell.

Ethyl pentasulphide $(C_2H_5)_2S_5$; by heating $(C_2H_5)_2S_4$ and S at 150°; a tough elastic solid.

Ethyl sulphinic acid $C_2H_5HSO_2$; by action of $Zn(C_2H_5)_2$ upon SO_2 (Wischin, Annalen, 139, 364; Hobson, Chem. Soc. Trans. 1858, 10, 58); the sodium salt is produced by oxidation of sodium mercaptide by dry oxygen (Claesson, J. pr. Chem. [2] 15, 199). The free acid is a syrupy liquid with a sweet taste; by action of HNO_3, yields ethyl sulphonic acid, and $(C_2H_5SO_2)_2NO$, crystals, m.p. 81·5°, very slightly soluble in water (Zuckschwerdt, Annalen, 174, 308). Forms salts, of which $NaC_2H_5SO_2$, crystallised from alcohol in anhydrous crystals (C.); the lead salt was prepared from $Pb(C_2H_5)_4$

and SO_2, by Frankland and Lawrence (Chem. Soc. Trans. 35, 244).

Ethyl chlorosulphinate $Cl \cdot SO_2 \cdot C_2H_5$. A faintly yellow liquid, b.p. 29°/13 mm., which decomposes at its b.p., 122°, under ordinary pressure, into sulphur dioxide and ethyl chloride, formed by treating well-cooled ethyl alcohol with thionyl chloride (Stähler and Schirm, Ber. 1911, 44, 319).

Ethyl sulphonic acid $C_2H_5 \cdot SO_2 \cdot OH$ by the oxidation of C_2H_5SH (Löwig and Weidmann, Pogg. Ann. 49, 329; Kopp, Annalen, 35, 346), C_2H_5CNS or of $(C_2H_5)_2S_2$ (Muspratt, Chem. Soc. Trans. 1849, 1, 45) by HNO_3; from C_2H_5I and K_2SO_3 (Graebe, Annalen, 146, 37). By heating ethylene sulphonic acid with P and HI at 170° (Kohler, Amer. Chem. J. 20, 688); by oxidation of C_2H_5CNS with hypochlorites (De Coninck, Compt. rend. 126, 838); by action of conc. HNO_3 upon mercury mercaptide nitrate (Hofmann and Rabe, Zeitsch. anorg. Chem 17, 26). The acid is a crystalline deliquescent body; by action of ICl_3 at 150°, we get *dichlorethyl sulphonic acid*; excess of ICl_3 gives C_2Cl_6 (Spring and Wessinger, Ber. 15, 445); unites with bases to form salts. (For halogen derivatives, *see* Kohler, Amer. Chem. J. 19, 737; 20, 690; 21, 361. For salts, *see* Rosenheim and Liebknecht, Ber. 31, 412.)

Ethyl sulphonate $C_2H_5 \cdot SO_2 \cdot OC_2H_5$; b.p. 213·4° (corr.); sp.gr. 1·1712 at 0°/0° 1·1452 at 20°/4° (Nasini, Ber. 15, 2884); by action of ethyl sulphonic chloride $C_2H_5SO_2Cl$ and C_2H_5NaO (Carius, J. 1870, 726; J. pr. Chem. [2] 2, 262); from C_2H_5I and silver sulphite or sodium ethyl sulphite (*q.v.*).

Ethyl sulphonic chloride $C_2H_5SO_2Cl$; b.p. 177·5° (corr.) (Carius), 171° (Otto, Ber. 15, 122); sp.gr. 1·357 at 22·5° (C.); by action of PCl_3 on $NaC_2H_5SO_3$ (Gerhardt and Chancel, Compt. rend. 35, 690); by action of Cl upon ethyl oxysulphide (S. and W. *l.c.*). Colourless liquid, with unpleasant smell.

Ethyl thiocyanate C_2H_5SCN; b.p. 143° (Berthelot, Compt. rend. 130, 444), 146° (corr.) (Buff, Ber. 1, 206); sp.gr. 1·033 at 0°, 1·0126 at 19°, 0·8698 at 146° (B.); by action of KCNS upon $KC_2H_5SO_4$ (Cahours, Ann. Chim. Phys. [3] 18, 264; Annalen, 6,1, 95), or C_2H_5Cl (Löwig, Pogg. Ann. 67, 101), or C_2H_5I (Johnson and Levy. Amer. Chem. J. 1907, 38, 456); from Et_2SO_4 and KCNS, yield 87 p.c. (Walden, Ber. 1907, 3214).

A mobile liquid with unpleasant odour, insoluble in water, miscible with alcohol or ether; by action of sodium forms NaCN and $(C_2H_5)_2S$ (Hofmann, Ber. 1, 184); by heating with solution of KOH, yields $(C_2H_5)_2S_3$, KCN, and KCNO (Brüning, Annalen, 104, 198); with alcoholic KOH, forms $(C_2H_5)_2S_3$, CO_2, NH_3, but no KCNS (Löwig), but with alcoholic KHS yields C_2H_5HS and KCNS (L.). Decomposed by hot solution of bleaching powder, yielding CO_2, N, $EtO \cdot SO_3 \cdot OH$, and H_2SO_4. NaClO and NaOH hot, yield $(EtO)_2SO_2$ and NaCN. Further action gives Et_2S_2, NaCN, and NaCNO, if all the hypochlorite is used up. By action of aqueous NH_3 at 100°, it yields $(C_2H_5)_2S_2$, NH_4CN, urea, oxalic acid, and other products (Kremer, J. 1858, 401; Jeanjean, J. 1862, 364). By passing Cl into it, there results (CNCl), and a liquid $C_2H_5SCl_4$, b.p. 134°-135° (James, J. pr.

Chem. [2] 30, 316). A chlorine substitution product C_2H_4ClSCN was obtained by James (*ibid.* [2] 20, 352) by heating C_6H_4ClBr with KCNS and alcohol; an oil heavier than water, with unpleasant smell; b.p. 202°-203°; m.p. below −20°.

Ethyl thiocyanate forms compounds with HCl, HBr, and HI (Henry, J. 1868, 652; Glutz, Annalen, 153, 312). (For many other compounds, *see* Wheeler and Johnson, Amer. Chem. J. 26, 345; J. Amer. Chem. Soc. 24, 680; Wheeler and Jamieson, *ibid.* 24, 743; Wheeler and Merriam, *ibid.* 24, 439.)

Ethyl *iso***thiocyanate** C_2H_5NCS (L.), *Ethyl-thiocarbimide, mustard oil*; b.p. 134°; sp.gr. 1·0192 at 0°, 0·9972 at 22°, 0·8763 at 133·2° (Buff, Ber. 1, 206); by action of C_2H_5NCO upon P_2S_5 (Michael and Palmer, Amer. Chem. J. 6, 259), also in very small quantity when $Hg(CNS)_2$ is heated with C_2H_5I (Michael, *ibid.* 1, 417), also by heating $CSCl_2$ and $(C_2H_5)NH_2$ (Rathke, Annalen, 167, 211). A solution of ethylamine in alcohol is treated with CS_2, when crystals of ethyl ammonium ethyl dithiocarbamate separate out, $2(C_2H_5)NH_2 + CS_2 = (C_2H_5)NH·CS·S·NH_3(C_2H_5)$. A solution of this body is then treated with $HgCl_2$, when the mercury compound is precipitated:

$(C_2H_5)NH·CS·S·NH_3(C_2H_5) + HgCl_2$
$= 2(C_2H_5)H_3NCl + [NH(C_2H_5)CS_2]_2Hg$
On distillation, this body yields the mustard oil, HgS and H_2S (Hofmann, Ber. 1, 171; 2, 452). Delépine (Compt. rend. 144, 1125) improves the yield of dithiocarbamate by using 1 molecule each of CS_2, amine, and soda, and then distilling with basic lead acetate in place of $HgCl_2$. Mustard oil is a liquid with very disagreeable smell, and in contact with the skin produces a burning sensation (Hofmann, Ber. 1, 26); with absolute alcohol forms monoethyl thiourethane $(C_2H_5)NH·CS·OC_2H_5$, a liquid, b.p 204°-208°; with aldehyde ammonia yields the compound $C_7H_{15}N_3S$, m.p. 135°·136° (Dixon, Chem. Soc. Trans. 1888, 414)

Thiocarbimides react with phenylhydrazine, yielding thiosemicarbazides (Marckwald) With Br in chloroform a ring compound, $C_4OS_2(NEt)_2$, melting at 45°, is formed (Freund and Bachrach, Annalen, 285, 184).

Ethyl thiophens $C_4SH_3(C_2H_5)$.

2-*Ethyl thiophen*; b.p. 132°-134° (corr.), sp.gr. 0·990 at 24°. By action of C_2H_5Br and Na upon C_4SH_3I (Meyer and Kreis, Ber. 17, 1560); also by action of Br upon thiophen, C_2H_5Br and Na (Schleicher, *ibid.* 18, 3015; *ibid.* 19, 671).

3-*Ethyl thiophen*; b.p. 135°-136°; sp¹gr. 1·0012 at 16°. By heating ethyl succinic acid with P_2S_3 (Damsky, Ber. 19, 3284; Gerlach, Annalen, 267, 146).

Di-ethylthiophen; b.p. 181°; sp.gr 0·962 at 14°/14°. An oil obtained by action of Na upon C_2H_5I and iodoethylthiophen (Muhlert, Ber. 19, 633).

Ethyl telluride $(C_2H_5)_2Te$, *Tellurethyl*; b p. 137°-138° (Marquardt and Michaelis, Ber. 21, 2045; Heeren, J. 1861, 565); from K_2Te and $KC_2H_5SO_4$ (Wöhler, Annalen, 84, 69; 35, 111; Mallet, Chem. Soc. Trans. 1853, 5, 71). A heavy, viscid, reddish-yellow liquid, with a very unpleasant smell, burns in air with blue flame, evolving fumes of TeO_2; hardly soluble

in water, and oxidised by exposure to air; is poisonous. HNO_3 forms $(C_2H_5)_2Te.2HNO_3$ (monoclinic prisms). Strong HCl precipitate, the oily compound $(C_2H_5)_2TeCl_2$ from a solution of the nitrate; ammonia converts this into $[(C_2H_5)_2Te]_2Cl_2O$ (hexagonal prisms), which, when treated with Ag_2SO_4, yields

$$[(C_2H_5)_2Te]_2,H_2SO_4$$
(colourless prisms). By action of Ag_2O upon a solution of the chloride, $(C_2H_5)_2TeO$ is produced, which decomposes on concentration.

When $(C_2H_5)_2Te$ is acted upon by C_2H_5I, *triethyl tellurium iodide* $(C_2H_5)_3TeI$ is formed, m.p. 90°-92° (Cahours, Bull. Soc. chim. [2] 4, 40), which crystallises in yellow prisms.

Ethyl ditelluride $(C_2H_5)_2Te_2$ is said to be formed in the preparation of $(C_2H_5)_2Te$, and to be a dark-red liquid, with high boiling-point.

ETHYLAMINES

Compounds in which one or more atoms of H in NH_3 are replaced by C_2H_5.

Ethylamine $C_2H_5·NH_2$; b.p. 18·7°, sp.gr. 0·6964 at 8°, 0·708 at 2° (Hofmann, Ber. 22, 699); m.p. −85·2°, b.p. 19° to 20° (Ladenburg and Krugel); sp.gr. 0·7013 at 4° 0·6892 at 15° (Perkin); crit. temp. 185·2° (Schmidt); 183·2° and crit. press. 55·4 atm. (Berthoud); H C.=408·5 Cals. (Berthelot, Ann. Chim. Phys. [5] 23, 244). From ethyl carbimide and KOH (Wurtz, Annalen, 71, 339; also Compt. rend. 28, 223); from C_2H_5Br and NH_3 (Hofmann, Annalen, 74, 159); by the putrefaction of yeast and of flour (Hesse, J 1857, 403; Sullivan, J. 1858, 231); by heating alcohol with NH_4Cl at 300° (Berthelot, Ann Chim Phys. [3] 38, 63); by action of nascent H upon acetonitrile(Mendius, Annalen, 121, 142). It is also produced in the dry distillation of the residues from beet-root in sugar manufacture (Duvillier and Buisine, Ann. Chim. Phys. [5] 23, 317); by action of $KC_2H_5SO_4$ upon alcoholic NH_3 at 120° (Erlenmeyer and Carl, J. 1875, 617); by action of Na upon $CH_3·CONH_2$ in boiling amyl alcohol (Guerbet, Compt rend 129, 62); from EtOH and phosphates at 225°-250° (Vidal, D. R. P. 64346); by action of Zn filings and HCl in the cold on aldehyde ammonia (Trillat and Fayollat) (Jean); by electrolytic reduction of nitroethane in H_2SO_4 at 70°-75° (Pieron, Bull. Soc. chim. [3], 21, 784)

Preparation.—(1) 1 volume of ethyl nitrate $C_2H_5NO_3$ is treated with 3 volumes of alcoholic ammonia for 12 hours at 100°; the free bases are separated from the NH_3 by neutralising with H_2SO_4 or HCl and extracting with alcohol; the sulphates or chlorides are then decomposed by NaOH, and the free bases combined with picric acid and crystallised. The picrate of $(C_2H_5)_3N$ separates first, in yellow needles, then the $C_2H_5NH_2$ salt in brown prisms; the picrates are then separated and decomposed by HCl, and the bases liberated by KOH (Carey Lea, Chem. News, 5, 118).

(2) Crude C_2H_5Cl, from manufacture of chloral, is heated for an hour with 3 times its volume of alcohol (95 p.c.) previously saturated with ammonia, in an iron vessel heated by a water-bath. On cooling, the NH_4Cl is filtered off, and the remainder distilled until free from NH_3 and alcohol, the residue (hydrochlorides of

mon-, di-, and tri-ethylamine, mixed with a little NH₄Cl) is treated with a strong solution of NaOH, and the liquid drawn off and dried by means of solid NaOH ; it consists of a mixture of the three bases ; ethyl oxalate is then added, and the $(C_2H_5)_3N$, which is unacted upon, is distilled off ; the residue consists of a mixture of solid *diethyl oxamide* $C_2O_2(NHC_2H_5)_2$ and liquid *ethyl diethyloxamate* $C_2O_2N(C_2H_5)_2OC_2H_5$, which are separated and the diethyl oxamide, after recrystallising from hot water, decomposed with KOH (Hofmann, Ber. 3, 109, 776 ; also Duvillier and Buisine, Compt. rend. 88, 31).

According to Garner and Tyrer (Chem. Soc. Trans. 1916, 109, 174), a mixture of mono-, di-, and tri-ethylamine can be separated by fractionating with a 10-bulb column.

(3) By the interaction of ethyl bromide and excess of ammonia in alcoholic solution. By regulating the addition of the ethyl bromide to the ammoniacal solution it is possible to obtain the primary and secondary bases without any sensible admixture of the tertiary base (*see* Werner, Chem. Soc. Trans. 1918, 113, 899).

Properties.—Is a mobile liquid, with strong ammoniacal odour, is strongly caustic, and has an alkaline reaction ; burns with yellow flame, is miscible in all proportions with water, displaces NH_3 from its salts, and, like ammonia, precipitates metallic hydroxides and oxides from salts. It, however, dissolves the hydroxides of Al (Wurtz), Au, and Ru (Carey Lea), and does not dissolve those of Cd, Ni, and Co. The chloride is decomposed on distillation into $C_2H_5NH_2$, $(C_2H_5)_2NH$, NH_3, C_2H_4, and C_2H_5Cl (Fileti and Piccini, Ber. 12, 1508). CrO_3 oxidises ethylamine to aldehyde and N (Carstanjen, J. 1862, 330).

Caro's acid oxidises $EtNH_2$ yielding CH_3COOH, CH_3CN, $CH_3CH:NOH$, nitroethane, and $CH_3C(OH)NOH$ (Bamberger, Ber. 35, 4293). It forms a compound C_2H_5NHK (Titherley).

Salts (*v.* Wurtz, Annalen, 76, 329).— $(C_2H_5)NH_2,HCl$, deliquescent plates ; m.p. 76°–80° ; b.p. 315°–320° (with decomposition) ; sp.gr. 1·2045 at 21°/4° (Schiff and Monsacchi) ; molecular refract. 35·97 (calc. 35·95) (Kanonnikow, J. pr. Chem. [2] 31, 347) ; soluble in alcohol ; soluble in 0·42 part of water at 17° (S. and M. Zeitsch. physikal. Chem. 24, 513). Prepared by heating 1 volume of C_2H_5Cl with 3 volumes alcoholic ammonia to 100° (Groves, Chem. Soc. Trans. 1861, 13, 331). The hydrochloride and hydroiodide exhibit isodimorphism ; both are monoclinic at ordinary temperatures, changing at higher temperatures to uniaxial modifications. $C_2H_5NH_2,HgCl_2$, by action of alcoholic $HgCl_2$ on alcoholic $C_2H_5NH_2$; crystalline precipitate, soluble in hot HCl solution. With excess of $HgCl_2$ in aqueous solution a white precipitate

$$2C_2H_5NH_2,HgCl_2 + 2HgO$$
is thrown down ; by heating $C_2H_5NH_2$ with excess of $HgCl_2$, a yellow precipitate
$$ClHg\cdot OHg\cdot NH\cdot C_2H_5$$

separates, whilst a crystallisable compound $ClHg\cdot NH\cdot C_2H_5$ remains in solution (Köhler, Ber.

12, 2308). $C_2H_5NH_2,PtCl_4$, yellow powder, combines with $(C_2H_5)NH_2$, and forms

$$4C_2H_5NH_2,PtCl_4,2H_2O$$
colourless crystals, soluble in water.

$(C_2H_5\cdot NH_2,HCl)_2,PtCl_4$, orange-yellow flat rhombohedrons (Weltzien, Annalen, 93, 272), hexagonal rhombohedrons (Topsoë, J. 1883, 619) ; sp.gr. 2·255 at 19°/4° (Clarke, Ber. 12, 1399). $C_2H_5NH_2,HCl,AuCl_3$, golden-yellow monoclinic prisms, soluble in water (T.).

$(C_2H_5NH_2)_2,H_2SO_4$, deliquescent body, soluble in alcohol ; forms double salts with other sulphates, *e.g.* ethyl-ammonium alum

$$(C_2H_5NH_2)_2,H_2SO_4,Al_2(SO_4)_3,24H_2O$$
octahedral crystals, soluble at 25° in 6·89 parts of water.

Ethylchloramine C_2H_5NHCl. A very pungent-smelling oil ; sp.gr. 1·067 at 0° ; formed by action of NaClO upon $C_2H_5NH_2,HCl$. Heated with HCl, yields ethylamine (Berg, Ann. Chim. Phys. [7] 3, 319).

Ethyldichloramine, *ethylnitrogenchloride* $C_2H_5\cdot NCl_2$; b.p. 88°–89° at 762 •mm. ; sp.gr. 1·230 at 15° ; by passing Cl through aqueous $C_2H_5NH_2$ (Wurtz, Compt. rend. 11, 810), prepared by distilling a mixture of $C_2H_5NH_2,HCl$ with 2½ times its weight of bleaching powder and a little water (Tscherniak, Ber. 9, 146), a yellow oily liquid with a penetrating smell, insoluble in water and acids, decomposes on long standing into HCl, $NH_2Cl,C_2H_5NH_2,HCl$, $CHCl_3$, CH_3CN, and $CH_3\cdot COCl$ (Köhler, Ber. 12, 1870). The pure substance keeps unchanged for long periods under water (Tscherniak, *ibid.* 12, 2129). Alkalis decompose it into acetic acid and NH_3 ; behaves towards many bodies as free Cl. $Zn(C_2H_5)_2$ forms $(C_2H_5)_3N$ and $ZnCl_2$.

Ethyl di-iodoamine $C_2H_5NI_2$, and *Ethyl dibromamine* $C_2H_5NBr_2$, are formed similarly ; the former is a dark-blue liquid (Wurtz).

Ethyl nitramine $C_2H_5NH.NO_2$; m.p. +6° ; sp.gr. 1·1675 at 15°. A colourless liquid, with an acid reaction, prepared by the action of NH_3 upon diethyl dinitro-oxamide. It gives two classes of alkyl derivatives (Umbgrove and Franchimont, Rec. trav. chim. 16, 388). It is also formed from methyl ethylcarbamate and conc. HNO_3 (Franchimont and Klobbie, *ibid.* 7, 356).

Nitroethylisonitramine $CH_3\cdot CHNO_2\cdot N(OH)NO$ is obtained by the action of NO upon the Na derivative of nitroethane. It forms metallic salts, which are hydrolysed by mineral acids, giving NO and ethylnitrolic acid (Traube, Annalen, 300, 106).

Diethylamine $(C_2H_5)_2NH$; m.p. −40° (Hofmann, Ber. 22, 699) ; b.p. 57·5° (Hofmann, Annalen, 73, 91), 55·5° at 759 mm. (Oudemans, Rec. trav. chim. 1, 59) ; crit. temp. 223·3, crit. press. 36·6 atm. (Berthoud) ; sp.gr. 0·7262 at 0°, 0·7107 at 15° (Hofmann, Ber. 22, 669), 0·7226 at 4°, 0·7116 at 15°, 0·7028 at 25°. From NH_3 and C_2H_5I (Hofmann), or NH_3 and $C_2H_5NO_3$ (Lea, J. 1861, 493 ; *cf.* Garner and Tyrer, *l.c.*). From C_2H_5Br (Werner, Chem. Soc. Trans. 1918, 113, 899). Prepared by the action of KOH upon the $C_2O_2N(C_2H_5)_2OC_2H_5$ obtained in manufacture of ethylamine (*q.v.*).

Also by action of very dilute NaOH solution upon $[(C_2H_5)_2N(NO)]_2,H_2SO_4$ (Kopp, Ber. 8, 622). Also by action of EtOH upon phospham

at 225°–250° (Vidal, D. R. P. 64346). By heating p-toluenesulphodiethylamide with chlorsulphonic acid at 130°–150° (Marckwald and v. Droste-Hülshoff, Ber. 31, 3263). By dissolving 50 grams diethylaniline in 148 grams HCl (sp.gr. 1·1), diluting with 75 c.c. H₂O, adding 32 grams NaNO₂ in 50 c.c. H₂O and pouring slowly through a reflux condenser into a boiling solution of 85 grams NaOH in 2 litres of H₂O (Norris and Kimberley, Amer. Chem. J. 20, 60).

Price, Brazier, and Wood (J. Soc. Chem. Ind. 1916, 35, 147) have described a convenient mode of preparing large quantities of diethyl-amine in the laboratory by a simple modification of this method

$$NO \cdot C_6H_4 \cdot NEt_2 + NaOH$$
$$= NHEt_2 + NO \cdot C_6H_4 \cdot ONa$$
It a colourless, inflammable liquid with strong ammoniacal smell, very soluble in water; is a strong base, and acts like $C_2H_5NH_2$, except that it does not dissolve $Zn(OH)_2$ (Carey Lea). H_2O_2 oxidises it to diethylhydroxylamine (Dunstan and Golding). The nitrate decomposes suddenly at 170°, and yields nitrosodiethyl-amine $(C_2H_5)_2NNO$ (Franchimont, Rec. trav. chim. 2, 95); the hydrochloride $(C_2H_5)_2NH,HCl$ forms non-deliquescent plates; m.p. 215°–217° (Wallach, Annalen, 214, 275); b.p. 320°–330° (W.); sp.gr. 1·0475 at 21°/4° (Schiff and Monsacchi); and combines with many metallic chlorides, e.g. $[(C_2H_5)_2NH,HCl]_2PtCl_4$, orange-yellow monoclinic crystals (Topsoe, J. 1883, 619).

Diethylchloramine $(C_2H_5)_2NCl$. A pungent-smelling oil; b.p. 91°; sp.gr. 0·943 at 0°; formed by action of NaClO upon $(C_2H_5)_2NH$. It decomposes on keeping with formation of $(C_2H_5)_2NH,HCl$ (Berg, Ann. Chim. Phys. [7] 3, 320).

Diethylnitramine $Et_2N \cdot NO_2$; b.p. 206·5° at 757 mm., 93° at 16 mm.; sp.gr. 1·057 at 15°. Formed by action of EtI upon $EtNK \cdot NO_2$; also by action of highest concentrated HNO_3 upon as-diethylurea. It is decomposed by KOH at 150°–160° into $EtNH_2$, HNO_3, and CH_3CHO (Franchimont, Rec. trav. chim 6, 149; F. and Umbgrove, ibid. 16, 396).

Diethylisonitramine. An oil, b.p. 46°–50° at 18 mm.; sp.gr. 1·000 at 15°; formed by inter-action of EtI and $C_2H_5NAgNO_2$. KOH at 100° decomposes it into alcohol, N, and CH_3CHO (U. and F. l.c. 399).

Nitrosodiethylamine $(C_2H_5)_2NNO$; b.p. 176·9° (corr.); sp.gr. 0·951 at 17·5°; V D. = 3·36 (calc. = 3·53) (Knecht, Ber. 10, 979); by distilling neutral solution of $(C_2H_5)_2NH,HCl$ with a concentrated solution of KNO_2 (Geuther, Annalen, 128, 251; J. 1871, 695); also from $(C_2H_5)_2NH$ and NOCl in ether solution at −15° to −20° (Solonina, J. Russ. Phys. Chem. Soc. 30, 431); a yellow oil with aromatic smell, decomposed by HCl into $(C_2H_5)_2NH$ and HNO_2. Alcoholic KOH at 140° forms NH_3 and $(C_2H_5)NH_2$. Na amalgam forms N_2O and $(C_2H_5)_2NH$.

Triethylamine $(C_2H_5)_3N$; b.p. 89°–89·5° at 736·5 mm. (Bruhl, Annalen, 200, 186), 89°–90·5° at 767·8 mm. (Hofmann); sp.gr. 0·735 at 15° (Hofmann, Ber. 22, 700), 0·7426 at 4°, 0·7331 at 15°, 0·7527 at 25° (Perkin); crit. temp. 267·1° (Pawlowski, Ber. 16, 2633); remains liquid at −75° under 40 mm. pressure (H.). By the

action of NH_3 upon C_2H_5I (Hofmann, Annalen, 73, 91, or upon $C_2H_5NO_3$ (Carey Lea).

Preparation.—(1) Crude ethylamine (from C_2H_5Cl and NH_3) in alcoholic solution is treated with C_2H_5Cl (Duvillier and Buisine); (2) by distillation of $(C_2H_5)_4N \cdot OH$.

Properties.—An oily liquid with strong ammoniacal smell, slightly soluble in water; strong base. On strongly heating its salts, $(C_2H_5)_3N$ is destroyed, with formation of a little $(C_2H_5)_2N \cdot NO$ (Geuther, Zeitsch. Chem. 1886, 513).

The hydrochloride forms feathery non-deliquescent scales, and combines with many metallic salts to form double compounds. $N(C_2H_5)_3,HCl$, sp.gr. 1·06885 at 21°/4°. 1 part of water dissolves 1·5 parts salt (Schiff and Monsacchi). $(C_2H_5)_3N,HNO_3$, m.p. 98°–99° (Franchimont, Rec. trav. chim. 2, 339).

Tetra-ethylammonium hydroxide

$$(C_2H_5)_4N \cdot OH$$

formed from the iodide $(C_2H_5)_4NI$ by the action of Ag_2O. It forms very deliquescent needles, is a strong base, which eagerly absorbs CO_2, displaces NH_3, precipitates metallic hydroxides, and gives a blue solution with sugar and $CuSO_4$; is decomposed by dry distillation, forming triethylamine, ethylene, and H_2O; when heated with C_2H_5I, gives $(C_2H_5)_4I$ and alcohol.

Salts.—$(C_2H_5)_4NCl$, forms deliquescent crystals, sp.gr. 1·0801 at 21°/4° (Schiff and Monsacchi), and yields many double salts, e.g. $[(C_2H_5)_4NCl]_2HgCl_2$, tetragonal crystals; $(C_2H_5)_4NCl,HgCl_2$, triclinic crystals (Topsoe, J. 1883, 620); $[(C_2H_5)_4NCl]_2PtCl_4$, orange-yellow, crystalline (monoclinic (T)), difficultly soluble in water, almost insoluble in alcohol; $(C_2H_5)_4NBr$, light-orange needles, m.p. 78°, combines with Br to form an unstable pentabromide (Marquart, Ber. 3, 284); gives with alcoholic I solution a precipitate of $(C_2H_5)_4NI_3$, quadratic prisms (Weltzien, Annalen, 91, 33), which is also formed along with iodoform when the monoiodide is electrolysed between platinum electrodes (Goecke, Zeitsch. Elektrochem. 10, 249); the monoiodide $(C_2H_5)_4NI$ forms large crystals soluble in cold water and in alcohol, insoluble in ether; sp.gr. 1·559 (Schroder, Ber. 12, 562).

a-Ethyl hydroxylamine $C_2H_5O \cdot NH_2$; b.p. 68°; sp.gr. 0·8827 at 7·5° (Gurke, Annalen, 205, 277); by the action of HCl upon benzoyl ethylhydroxyl-amine ethyl ether $C_6H_5CO \cdot NC_2H_5 \cdot OC_2H_5$, or upon the ethyl ether of benzaldoxime

$$C_6H_5 \cdot CH : NOC_2H_5$$
(Lossen and Zanni, ibid. 182, 223).

A strongly smelling inflammable liquid, miscible with water, alcohol, or ether; gives with $AgNO_3$ a white precipitate, which, on heating, is changed to metallic silver; with acids, forms salts, e.g. C_2H_5ON,HCl, scaly plates, m.p. 128°, decomposed by heating with HCl to 150° into C_2H_5Cl, NH_3O, HCl, and NH_4Cl; unites with $PtCl_4$ to form $(C_2H_5ON,HCl)_2PtCl_4$; prismatic crystals, soluble in water and in absolute alcohol (Lossen and Zanni). The sulphate $(C_2H_7ON)_2H_2SO_4$ crystallises with difficulty, and is soluble in water and in alcohol.

β-Ethyl hydroxylamine $C_2H_5NH \cdot OH$; m.p. 59°–60°, with decomposition; sp.gr. 0·9079 at 63·0° (Bruhl). Formed by heating for 8 hours at 140°, β-ethyl-a-benzylhydroxylamine

with conc. HCl (Behrend and Leuchs, Annalen, 257, 228); from hydroxylamine and EtI (Lobry de Bruyn, Rec. trav. chim. 13, 48; Hantzsch and Hilland, Ber. 31, 2065; Dunstan and Golding, Chem. Soc. Trans. 75, 807); by heating 1 part *m*-nitrobenzylaldoxime-N-ethyl ether with 7 parts conc. HCl (Kjellin, Ber. 26, 2378); by electrolytic reduction of nitroethane in H₂SO₄ solution at 15°-20° (Pierron, Bull. Soc. chim. [3] 21, 784).

It is very easily soluble in water or alcohol, less so in ether, benzene, or cold ligroin. It reduces Barreswil's solution, and is reduced by HI to C₂H₅NH₂.

ββ-Diethyl hydroxylamine (C₂H₅)₂N·OH ; b.p. 130°-134°. with decomposition (Dunstan and Golding, b.p. at 15 mm. 47°-49° (Lachman) ; sp.gr. 0·8771 at 15°/15° (D. and G.), 0·8784 (L.). An oil formed by action of EtI upon NH₄OH, and also from (C₂H₅)₂NH and H₂O₂ (D. and G. Chem. Soc. Trans. 75, 800). From addition product of diphenylnitrosamine and Zn(Et)₂ by decomposition with water, along with diphenylamine and Zn(OH)₂ (Lachman, Ber. 33, 1022).

Is a feeble base, soluble in water, alcohol, or ether. Reduces AgNO₃ and Hg Cl₂, and, on heating, CuSO₄. Reduced with HI, yields (C₂H₅)₂NH.

αβ-Diethyl hydroxylamine C₂H₅NH·O C₂H₅ ; b.p. 83° ; sp.gr. 0·829 at 0° ; formed by interaction of α-ethylhydroxylamine and EtBr. It is easily soluble in water, alcohol, or ether. Heated with conc. HCl at 200°, yields HN₂(C₂H₅) and C₂H₅Cl (Lossen, Annalen, 252, 230).

The hydrochloride C₄H₁₁NOHCl of an isomeric compound is obtained by action of Sn and HCl upon C₂H₅NO₃ (Lossen, *ibid.* Suppl. 6, 238). The salts are more soluble in water than those of hydroxylamine. The free base is a syrup, easily soluble in water, and has strong basic properties. The platinum salt is in the form of orange-yellow plates, soluble in warm alcohol and in water.

Triethyloxamine (C₂H₅)₃NO is a colourless crystalline mass obtained from ββ-diethylhydroxylamine and EtI. Also from NEt₃ and H₂O₂ (Dunstan and Golding ; Lachman).

It is very easily soluble in water, less so in CHCl₃ and insoluble in ether. Decomposes on heating. Reduces Barreswil's solution on heating. It gives a precipitate with CuSO₄ and AgNO₃. On reduction, yields triethylamine.

Triethyl methyl ammonium iodide

N(C₂H₅)₃CH₃I
obtained by action of N(C₂H₅)₃ upon CH₃I (Hofmann, Annalen, 78, 277) (for other *Salts*, *v.* Topsoë, J. 1883, 620). The picrate melts at 267°-268° (Lossen, Annalen, 181, 374).

Diethyl dimethyl ammonium iodide, obtained from N(CH₃)₂H and C₂H₅I ; or from N(C₂H₅)₂H and CH₃I (V. Meyer and Lecco, Annalen, 180, 177) (for other *Salts*, *v.* Topsoë, *l.c.*). The picrate melts at 285°-287° (Lossen, Annalen, 181, 374).

Ethyl trimethyl ammonium iodide is formed from (CH₃)₃N and C₂H₅I (Müller, *ibid.* 108, 1) (for other *Salts, v.* Topsoë). The picrate melts at 299°-300° (Lossen).

Triethyl propyl ammonium iodide

N(C₂H₅)₃(C₃H₇)I
crystallises in large needles (Mendius, Annalen, 121, 136).

Diethyl *iso*amylamine N(C₂H₅)₂(C₅H₁₁) ; b.p. 154°; from the distillation of N(C₂H₅)₂(C₅H₁₁)OH (Hofmann) ; [N(C₂H₅)₂C₅H₁₁,HCl]₂PtCl₄, yellow needles.

Triethyl *iso*amyl ammonium iodide

N(C₂H₅)₃(C₅H₁₁)I
formed by the action of N(C₂H₅)₃ upon C₅H₁₁I (Hofmann, Chem. Soc. Trans. 1852, 4, 313 ; Annalen, 78, 279) ; the hydroxide decomposes on heating as follows :—

C₅H₁₁(C₂H₅)₃N·OH
    = N(C₅H₁₁)(C₂H₅)₂+C₂H₄+H₂O
Diethyl methyl *iso*amyl ammonium iodide

N(C₂H₅)₂CH₃(C₅H₁₁)I
is formed from N(C₂H₅)₂(C₅H₁₁) and CH₃I (Hofmann).

Ethyl-methyl-*iso*amylamine

NC₂H₅(CH₃)(C₅H₁₁)
b.p. 135° ; is obtained by distillation of the hydroxide of the radical of the preceding compound (Hofmann).

Acetethylamide CH₃·CONHC₂H₅ ; b.p. 205°, sp.gr. 0·942 at 4·5° (Wurtz) ; b.p. 204°-205° (Titherley) ; from ethyl acetate and ethylamine (Wurtz, Ann. Chim. Phys. [3] 30, 491 ; Compt. rend. 36, 180 ; Annalen, 76, 334) or from C₂H₅NCO and HC₂H₃O₂ (Wurtz, *ibid.* 88, 315) ; from CH₃CONHNa and EtI at 150°. The hydrochloride forms deliquescent needles, melting at 60°. With NaNH₂ yields CH₃CONNaC₂H₅, which, with KMeSO₄, gives CH₃CONMeEt, an oil boiling at 180°, and soluble in water (Titherley, Chem. Soc. Trans. 1901, 393). By action of Cl yields *ethyl acetyl nitrogen chloride* NClEt(C₂H₃O) (Norton, Tcherniak, Bull. Soc. chim. [ii.] 30, 106 ; Compt. rend. 86, 1409), an oily unstable liquid, slightly soluble in water.

Acetdiethylamide N(C₂H₅)₂C₂H₃O ; b.p. 185°-186° ; sp.gr. 0·9248 at 8·5° (Wallach, Annalen, 214, 235).

Diacetylethylamide NC₂H₅(C₂H₃O)₂ ; b.p. 185°-192° (Wurtz) ; sp gr. 1·0092 at 20° (W.) ; by heating EtNCO with (C₂H₃O)₂O to 200° (Wurtz, Ann. Chim. Phys. [3] 42, 43).

Ethyl hydrazines ; Ethylamide.

1. *Ethyl hydrazine* C₂H₅HN·NH₂ ; b.p. 99·5° at 709 mm., is prepared by reducing nitrosodiethyl urea N(C₂H₅)H·CO·N(NO)C₂H₅ by means of zinc-dust and acetic acid ; this yields ethyl hydrazine urea (semi-carbazide) N(C₂H₅)H·CO·N(NH₂)C₂H₅, and this, by action of HCl, forms C₂H₅HN·NH₂, CO₂, and C₄H₅NH₂ ; by passing in HCl the chloride separates out, which is then decomposed by strong KOH solution and solid KOH, and the resulting oily liquid distilled over BaO (Fischer, Annalen, 199, 287) ; also by reducing ethylnitramine with Zn and HCl (Thiele and Meyer, Ber. 29, 963).

Is a colourless liquid, with faintly ammoniacal odour ; has great affinity for water, in which it is soluble, as also in alcohol, ether, chloroform, and benzene ; fumes in air and destroys cork and caoutchouc ; reduces Barreswil's solution in the cold. Br water liberates N. It precipitates metallic oxides, and gives the isonitrile reaction with KOH and CHCl₃. Forms two chlorides: (1) C₂H₆N₂,2HCl, white needles, very

soluble in water and alcohol ; on heating to 110°
yields (2) $C_2H_8N_2$,HCl, an amorphous horny
deliquescent body. The sulphate crystallises
from alcohol in thin plates, and is very soluble
in water. By heating $C_2H_8NH\cdot NH_2$ with $K_2S_2O_7$
at 80°–100°, potassium ethyl hydrazine sulpho-
nate $C_2H_5NH\cdot NHSO_3K$ is obtained ; this forms
fine needles, very soluble in water, much less
soluble in alcohol or ether (Fischer).

2. as-Diethylhydrazine $(C_2H_5)_2N\cdot NH_2$; b.p.
96°–99° ; prepared by action of zinc-dust and
acetic acid upon a solution of nitrosodiethyl-
amine $(C_2H_5)_2(NO)N$; 30 grams $(C_2H_5)_2(NO)N$
dissolved in 300 grams water are mixed with
150 grams Zn dust and 150 grams C_2H_4O (of
50 p.c.) kept at 20°–30°, and, towards the end, at
40°–50°. Excess of Zn is then dissolved by HCl,
an excess of NaOH added, and the mixture
distilled ; the distillate is neutralised with HCl
and NH_4Cl separated by crystallisation. From
the mother liquor $(C_2H_5)_2N_2H_2$ mixed with
$(C_2H_5)_2HN$ is freed by solid KOH. By the
action of HCNO diethylhydrazine urea (semi-
carbazide) $NH_2\cdot CO\cdot NH\cdot N(C_2H_5)_2$ is formed. 4
grams of this compound are heated with 15
grams of HCl in a sealed tube at 100°, diluted
and the NH_4Cl separated ; on treatment with
KOH, pure $(C_2H_5)_2N_2H_2$ is obtained (Fischer,
Annalen, 199, 308).

Is a colourless liquid with a faintly am-
moniacal smell, very hygroscopic and soluble
in water, alcohol, ether, chloroform, and ben-
zene ; reduces Barreswil's solution only on
warming ; is monobasic ; the salts are soluble in
water and alcohol, and difficult to crystallise.
$[(C_2H_5)_2N_2H_2\cdot HCl]PtCl_4$ forms fine yellow
needles, soluble in water. With $SOCl_2$ in ice-
cold ether, yields $(C_2H_5)_2N\cdot NSO$, an aromatic
oil, b.p. 73° at 20 mm. It is slowly hydrolysed
by water (Michaelis and Storbeck, Ber. 26,
310).

3. sym-Diethylhydrazine $C_2H_5\cdot HN\cdot NH\cdot C_2H_5$;
b.p. at 758 mm. 84°–86°. Formed by heating
at 100° for 3 hours 1 part sym-diethyl-diformyl-
hydrazide and 2 parts fuming HCl ; an oil ;
heated with conc. HCl, at 155°, yields NH_4Cl
and C_6H_5Cl. With yellow HgO forms $HgEt_2$.
With HNO_2 yields ethyl nitrite. The hydro-
chloride melts at 160° with decomposition
(Harries, Ber. 27, 2279).

Triethyl-azonium iodide $(C_2H_5)_3NNH_2I$ is
formed by action of diethylhydrazine upon 1½
times its weight of C_2H_5I (Fischer, Annalen,
199, 316). It forms needles very soluble in
water and in hot alcohol ; insoluble in ether and
strong alkalis. By action of Ag_2O, gives the
strongly alkaline free base, which, on heating,
yields $(C_2H_5)_2N\cdot NH_2$ and C_2H_4. By the action
of nascent H (Zn and H_2SO_4), the iodide yields
HI, NH_3, and $(C_2H_5)_3N$.

Tetra-ethyltetrazone $(C_2H_5)_2N\cdot N:N\cdot N(C_2H_5)_2$;
by the action of yellow HgO upon a cold aqueous
solution of $(C_2H_5)_2N\cdot NH_2$ (Fischer, Annalen, 199,
319) ; is an oily liquid with a disagreeable smell,
not volatile without decomposition, and which
does not freeze at −20°. When decomposed
by heat, yields N and $(C_2H_5)H_4N$. Forms an
explosive oily compound with I. Is a strong
base, though its salts are very unstable. It re-
duces silver solutions with formation of a mirror.
The solution decomposes on heating, yielding
N, $N(C_2H_5)_2H$, and aldehyde. The Pt double

salt $[(C_2H_5)_4N_4,2HCl]_2PtCl_4$ forms yellow prisms
soluble in water.

Ethylene C_2H_4, Olefiant gas, Heavy car-
buretted hydrogen, Bicarburetted hydrogen,
Elayl, Ethene, Etherin, discovered by Deiman,
Van Trootswyk, Bondt, and Lauwerenburgh
(Crell's Ann. 1795, [2] 195, 310, 430). Obtained
by action of H_2SO_4 upon alcohol ; the addition
of $Al_2(SO_4)_3$ increases the rate of production
(Senderens, Compt. rend. 1910, 151, 392).
The sulphuric acid can be replaced by syrupy
phosphoric acid, sp.gr. 1·75 (Newth, Chem. Soc.
Trans. 1901, 915) ; or alcohol vapour may be
passed over heated phosphoric acid, or over
thin layers of aluminium sulphate at 350°–400° ;
by the dry distillation of many organic bodies
(hence occurs to the extent of 4 or 5 p.c. in coal
gas). Also formed when CS_2 and H_2S (or PH_3)
are led over heated copper (Berthelot, Annalen,
108, 194). To prepare the gas, a mixture of
25 parts (by weight) of alcohol and 150 parts
sulphuric acid is heated to 170°, and a mixture
of 1 part of alcohol and 2 of H_2SO_4 is allowed to
drop slowly into the vessel by means of a funnel.
The gas is passed through H_2SO_4,NaOH solu-
tion, and then again through H_2SO_4. For the
preparation of small quantities of pure gas, an
alcoholic solution of $C_2H_4Br_2$ is warmed with
granulated Zn (Sabanejeff, J. Russ. Phys. Chem.
Soc. 9, 33). Equal volumes of CO and H led
over coke impregnated with reduced Ni and
Pd heated at 95°–100°, yield 8·3 p.c. C_2H_4
(Orloff, ibid. 40, 1588).

Ethylene is produced on an industrial scale
by the method of Maihle by passing the vapour
of alcohol over amorphous alumina heated to
360°. For details, see Spreut, J. Soc. Chem.
Ind. 1913, 171.

Properties.—A colourless gas, liquefied by a
pressure of 42½ atmospheres at −1·1° ; b.p.
−105° (Cailletet, Compt. rend. 94, 1224).
−102°–103° (Wroblewsky, Olszewsky, Monatsh.
4, 338), −103·9° (Burrell and Robertson) ;
m.p. −169°, b.p. at 757 mm. −104·3°, sp.gr.
0·6095 at −102·7° (Ladenburg and Krugel,
Ber. 32, 49, 1821) ; −102·5°, sp.gr. 0·565
(Maass and McIntosh, J. Amer. Chem. Soc.
1914, 36, 737) ; crit. temp. 9·5° ; becomes
liquid at 1° and 45 atmospheres, at 4° and 50
atmospheres, at 8° and 56 atmospheres, and at
10° and 60 atmospheres (C.) ; $L_D = 1\cdot26031$
(Batuecas, Helv. Chim. Acta, 1918, 1, 136).
1 volume of water absorbs at t°,

$$0\cdot25629 - 0\cdot009136t + 0\cdot0001881t^2$$

volumes C_2H_4 (Bunsen). Alcohol (of sp.gr. 0·792
at 20°) absorbs $3\cdot59498 - 0\cdot05772t + 0\cdot00681t^2$
volumes (Carius, Annalen, 94, 133) ; H.C.p.
$= 341\cdot4$ Cals. ; H.F. (from amorphous C) $= -9\cdot4$
Cals. (Berthelot, Ann. Chim. Phys. [5] 23, 180).

Ethylene forms an explosive mixture with
oxygen, and explodes, even in the cold, in con-
tact with ozonised oxygen (Houzeau and
Renard, J. 1873, 319). Led through a hot tube,
it splits up into C, H, CH_4, C_2H_6, and C_6H_6
(Berthelot, Annalen, 139, 277 ; Bone and
Coward, Chem. Soc. Trans. 1908, 1197). When
heated in an iron tube under a pressure of about
70 atmospheres it undergoes rapid polymerisa-
tion at 380°–400°. The liquid polymerisation
products consist of mixtures of saturated,
ethylenic, and polymethylene hydrocarbons ; viz.

iso-pentane, hexane, heptane, octane, nonane, amylene, hexylene, nonanaphthene, and $a\beta$ decyl, thene, hen-, deca-, dodeca-, tetradeca-, and pentadeca-naphthenes. At atmospheric pressure ethylene does not polymerise, even at 600° (Ipatieff, Ber. 1911, 44, 2978). Decomposed by leading over reduced Ni at 300° into C, C_2H_6, CH_4, and H (Sabatier and Senderens, Compt. rend. 124, 616, 1358). By the action of the electric spark it forms C_2H_2 and H, and then C and H (Wilde, Zeitsch. Chem. 1866, 735). It combines with H to form C_2H_6, when the mixture is passed through a hot tube (Ann. Chim. Phys. [4] 9, 431 ; Bull. Soc. chim. [ii.] 39, 145), or when in contact with Pt black in the cold (Wilde, Ber. 7, 354). By heating a mixture of C_2H_4 and CO_2 at 400°, aldehyde is formed (Schützenberger, Bull. Soc. chim. [ii.] 31, 482). CrO_3 converts it into aldehyde at 120° (Annalen, 150, 373). Fuming sulphuric acid absorbs readily large quantities of C_2H_4 at ordinary temperatures, as does also common H_2SO_4 at 160°-170° (Butlerow, Ber. 6, 193), forming $C_2H_5HSO_4$ (Faraday). C_2H_4 combines at 100° with strong HI or HBr solution, but not with HCl (Berthelot, Annalen, 104, 184 ; 115, 114). With bromine water forms a mixture of ethylene bromohydrin and ethylene dibromide (Read and Williams, Chem. Soc. Trans. 1917, 111, 240). N_2O_4 reacts with ethylene to form ethylene nitrosite, and N_2O_5 to form ethylene nitrate (Demjanow, Chem. Zentr. 1899, i. 1064). In presence of $AlBr_3$, HBr unites at 0° with C_2H_4, forming C_2H_5Br. With Cl_2O, *chlorethyl chloracetate* $CH_2Cl·CO·C_2H_4Cl$ is formed, whilst ClO_3 yields $CH_2Cl·CO_2H$. C_2H_4 combines with BF_3 in sunlight to form $C_2H_3BF_2$ (Landolph, B r. 12, 1586), a liquid, b.p. 124°-125°, sp.gr. 1·0478 at 23°. Ethylene acts as a divalent radical, and forms salts with most of the acids.

Ethylene acetates (Wurtz, Compt. rend. 43, 199 ; Atkinson, Phil. Mag. [4] 16, 433).

1. *Ethylene monoacetate* $C_2H_4(C_2H_3O_2)OH$, *monoacetic glycol* ; b.p. 190°-190·5° (corr.) (Perkin, Chem. Soc. Trans. 45, 505) ; sp.gr. 1·1108 at 15°/15°, 1·1018 at 25°/25° (P.) ; produced by action of $KC_2H_3O_2$ upon $C_2H_4Br_2$ in presence of alcohol (Atkinson, *l.c.* ; *cf.* Seelig, D. R. P. 41507). A liquid not miscible with water ; yields glycol $C_2H_4(OH)_2$ by heating with $C_2H_4Br_2$ and alcohol (Demole, Annalen, 177, 45) ; decomposed by heating with C_2H_3OCl into acetochlorhydrin and ethylene diacetate (Lourenço, *ibid.* 114, 127).

2. *Ethylene diacetate* $C_2H_4(C_2H_3O_2)_2$; b.p. 186°-187° ; sp.gr. 1·128 at 0° ; prepared from $C_2H_4Br_2$ or $C_2H_4I_2$ and $AgC_2H_3O_2$ (Wurtz, Ann. Chim. Phys. [3] 55, 433), or from $C_2H_4Br_2$ and anhydrous $KC_2H_3O_2$ at 150°-200° (Demole).

A liquid soluble in 7 parts of water, isomeric with *ethylidene diacetate* $CH_3·CH(C_2H_3O_2)_2$; b.p. 108·8° ; sp.gr. 1·061 at 12° ; prepared from aldehyde and $(C_2H_3O)_2O$. *Dichlorethylene diacetate* $C_2H_2Cl_2(C_2H_3O_2)_2$; b.p. 120° at 20 mm. ; is produced by action of chloracetic acid upon C_2H_2 (Prudhomme, Zeitsch. Chem. 1870, 397).

Ethylene acetochlorhydrin

$ClCH_2·CH_2·O·C_2H_3O$
b.p. 145° ; sp.gr. 1·1783 at 0° ; by heating a mixture of glycol and acetic acid at 100° with HCl (Simpson, Annalen, 112, 147) ; from C_2H_4

and $CH_2Cl·CO_2H$ (Schützenberger and Lippman, *ibid.* 138, 325) ; insoluble in water ; yields ethylene oxide by action of KOH.

Ethylene acetoiodohydrin $ICH_2·CH_2·O·C_2H_3O$, heavy oil ; and

Ethylene acetobromohydrin

$BrCH_2·CH_2·O·C_2H_3O$
b.p. 161°-163° ; are prepared from

$C_2H_4(C_2H_3O_2)OH$
by action of HI and HBr respectively, the former in the cold in presence of $C_2H_4(OH)_2$ and $CH_3·CO_2H$ (Simpson, Annalen, 113, 123), the latter at 100° (Demole, *ibid.* 173, 120).

Ethylene glycols.

1. **Ethylene glycol** $CH_2OH·CH_2OH$; *glycol* ; m.p. −17·4° ; b.p. 197·37° (Ladenburg and Krugel, Ber. 32, 1821) ; b.p. 197°-197·5° at 764·5 mm. (Wurtz), 196°-199° (corr.) (Perkin, Chem. Soc. Trans. 45, 504), 195° at 751·3 mm. (Pribram and Handl, Monatsh. 2, 673) ; sp.gr. 1·125 at 0° (W.), 1·1279 at 0° (P. and H.), 1·1168 at 15°/15°, 1·112 at 25°/25° (Perkin).

Discovered by Wurtz (Compt. rend. 43, 199 ; Ann. Chim. Phys. [3] 55, 400). Formed by action of ethylene diacetate upon KOH (W.) ; from $C_2H_4Cl_2$ and moist silver oxide at 160°-200° (Simpson, Annalen, Suppl. 6, 253) ; by heating ethylene monoacetate with $Ba(OH)_2$ or with water in sealed tubes (Debus, Annalen, 110, 316) ; by heating a strong aqueous solution of neurine, when glycol and $N(CH_3)_3$ are formed (Wurtz, *ibid.* Suppl. 6, 200) ; by heating ethylene chloride or bromide with PbO and 15-20 times its volume of water at 140°-170° (Eltekow, Ber. 6, 558) ; or with ferric oxide, or with an alkali formate and an alcohol under pressure ; from ethylene bromide and water at 140°-150° (Niederist, Annalen, 186, 393) ; together with polyethylene glycol, by action of C_2H_4O (oxide of ethylene) upon water in sealed tubes (Wurtz, *ibid.* 113, 255).

A mixture of glycols, in which ethylene glycol predominates, may be prepared by decomposing petroleum vapours in an iron tube heated at about 650°, converting the product into dichlorethane, &c., purifying this compound by distillation and treating the distillates with alkali carbonates in a closed vessel (Hibbert, Met. & Chem. Eng. 1918, 19, 571).

Preparation.—1. 600 grams ethylene bromide, 700 grams fused potassium acetate, and 1500 grams alcohol (sp.gr. 0·83) are heated in a flask with reflux condenser until all action ceases ; cooled, filtered from KBr and filtrate distilled ; the portion distilled above 140° is decomposed by slight excess of $Ba(OH)_2$ and heated for 12 hours on water-bath. The excess of baryta is removed by CO_2, the liquid evaporated to one-third its volume, the residue treated with a mixture of alcohol and ether, the liquid removed from the crystals and distilled, first on water-bath, to separate alcohol and ether, then over the flame ; the portion distilling above 185° is then redistilled (Erlenmeyer, Annalen, 192, 244).

2. A mixture of 188 grams ethylene bromide, 138 grams potassium carbonate and 1 litre of water, [or 32 parts $C_2H_4Br_2$, 25 parts K_2CO_3, 350 parts H_2O (Groscheintz, Bull. Soc. chim. [ii.] 31, 203)], is heated with reflux condenser for

10 hours, is then evaporated to small volume on water-bath, the liquid portion poured off the crystals of KBr, the latter are washed with absolute alcohol. The filtrate and alcoholic washings are then distilled as in previous method; a loss owing to formation of C_2H_5Br is experienced by this process (Zeller and Hüffner, J. pr. Chem. [2] 11, 229). Haworth and Perkin (Chem. Soc. Trans. 1896, 175) obtained a 60 p.c. yield by digesting 138 grams K_2CO_3 in 1000 c.c. H_2O with 188 grams $C_2H_4Br_2$ under a reflux condenser. The solution is evaporated very slowly to a syrup, and then extracted with a mixture of alcohol and ether.

3. 1 part of ethylene bromide and 26 parts water are heated to 100° in a sealed vessel for 130 hours. This method gives a yield of over 60 p.c. of the theoretical amount (Niederist, Annalen, 196, 354).

4. Glycol diacetate is decomposed with powdered $Ca(OH)_2$, and the mixture distilled under reduced pressure. The yield of glycol is 93 p.c. of theory (Henry, Rec. trav. chim. 18, 221).

5. It may also be prepared by heating ethylene diacetate with methyl alcohol and hydrochloric acid (Henry, Bull. Acad. Roy. Belg. 1896, 732).

6. 1 mol. of ethylene dichloride, 5 vols. of methyl alcohol and 3 mols. of sodium formate are heated together at 165°–170° in an autoclave for 7 hours. After cooling, the methyl alcohol is separated and distilled at ordinary pressure, the glycol under reduced pressure (Brooks and Humphrey, J. Ind. Eng. Chem. 1917, 9, 750).

Glycol is a colourless, odourless, syrupy liquid with sweet taste, miscible with alcohol and water, but almost insoluble in ether. 100 parts ether dissolve 1·1 part of glycol (Knorr, Ber. 30, 912). It dissolves NaCl, $ZnCl_2$, and many other chlorides; also K_2CO_3, KOH, and $Ca(OH)_2$.

By action of oxidising agents, e.g. platinum black, it forms glycollic acid. Nitric acid converts it into glycollic acid, glyoxylic acid, and oxalic acid (Debus, Annalen, 110, 316). Heated with solid KOH to 250°, glycol yields potassium oxalate and hydrogen (Wurtz). Heated with large quantity of water at 200°–210° yields aldehyde (Nevole, Bull. Soc. chim. [ii.] 25, 289); $ZnCl_2$ at 250° decomposes glycol into aldehyde, crotonaldehyde, and water. By electrolysis of an acid (H_2SO_4) solution of glycol, formic acid, formaldehyde, CO_2, traces of a sugar and a non-volatile acid, not glycollic, are formed. (Löb and Pulvermacher, Zeitsch. Elektrochem. 1910, 16, 1). Chlorine forms a crystallisable halogen compound, m.p. 39°, b.p. 200°; and an oily body, $C_6H_{12}O_4$, b.p. 240° (Mitscherlich, J. 1863, 485). H_2O_2 in presence of ferrous compounds yields glycollic aldehyde (Fenton and Jackson, Chem. Soc. Trans. 1899, 75). Heated with aldehydes, glycol yields ethylene oxide derivatives, e.g. glycol and œnanthaldehyde; heated at 125°–130° for some days yield ethylene œnanthylidene oxide

$$C_6H_{13}\cdot CH<^{OCH_2}_{OCH_2}$$
b.p. 180°; similarly, valeraldehyde and propaldehyde yield $C_4H_9\cdot CH<^{OCH_2}_{OCH_2}>$, b.p. 142°;

and $C_2H_5\cdot CH<^{OCH_2}_{OCH_2}>$, b.p. 105°–107°, respectively (Lochert, Bull. Soc. chim. [4] 3, 337, 716). With Na and EtI, yields glycol monoethyl ether, a liquid boiling under 748 mm. at 134·8°, and having a density of 0·93535 at 15°/15° (Palomaa, Ber. 42, 3873).

Glycol is converted into glycollic acid by the action of Bacterium aceti, provided the acid be neutralised (e.g. by $CaCO_3$) as fast as formed, otherwise after a short time the glycollic acid formed stops the further action (A. J. Brown, Chem. Soc. Trans. 51, 638). NH_4Cl and glycol at 300°–400° form collidine $C_8H_{11}N\cdot HCl$ (Hofmann, Ber. 17, 1905). Phosgene gas at ordinary temperatures converts glycol into glycol carbonate $CO(OCH_2)_2$ (with liberation of HCl), a stable compound, soluble in water, alcohol, and ether, and crystallising in colourless needles (Nemirowsky, J. pr. Chem. [2] 28, 439). Heated with strong formic acid for some time (Henninger, Ber. 7, 263), or with oxalic acid (Lorin, Bull. Soc. chim. [ii.] 22, 104), gives glycol diformin $C_2H_4(CH_2O)_2$, b.p. 174°; in the latter case formic acid is also produced. With mineral acid or dehydrating agents yields acetaldehyde, ethylidene ethylene ether and chiefly diethylene ether $O<^{CH_2\cdot CH_2}_{CH_2\cdot CH_2}>O$ (Faworsky, J. Russ. Phys. Chem. Soc. 1906, 38, 741). By action of sodium on glycol, we get sodium ethylenate $C_2H_4(OH)ONa$, a white crystalline deliquescent body, which, on heating to 190° with more sodium yields disodium ethylenate, a deliquescent mass. The former, with C_2H_5Br in a sealed tube, yields ethylene, glycol, NaBr, and probably $NaCHO_2$ (Wurtz).

De Coninck (Bull. Acad. Roy. Belg. 1905, 360) distinguishes between glycol and glycerol as follows. Uranyl sulphate is dissolved in a small quantity of water, excess of ethylene glycol added, the whole placed in a flask and exposed to sunlight. In 2 hours the liquid is quite green, and in 2½ hours uranous sulphate is precipitated. With glycerol no such colouration or precipitation takes place.

Glycol forms a number of cyclic esters and cyclic compounds analogous to the metallic saccharates (Bischoff, Ber. 40, 2803; Grün and Bockisch, ibid. 40, 2812).

2. Diethylene glycol

$$HO\cdot CH_2\cdot CH_2\cdot O\cdot CH_2\cdot CH_2\cdot OH$$
b.p. 250°, sp.gr. 1·132 at 0°; V.D. = 3·78 at 311° (calc. 3·67) (Lourenço, Ann. Chim. Phys. [3] 67, 275); from ethylene oxide and water, or better, ethylene oxide and glycol at 100° (Wurtz); from glycol and ethylene bromide or bromhydrin at 115°–120° (Lourenço); by action of glycol monoacetate upon sodium glycol at 130°–140° (Mohs, Zeitsch. Chem. 1866, 495).

An oily liquid, soluble in water, alcohol, and ether; concentrated HI at 100° forms $C_2H_4I_2$; oxidised by HNO_3 to glycollic acid, oxalic acid, and diglycollic acid $C_4H_6O_5$. The chlorhydrin $C_4H_9O_2Cl$, b.p. 180°–185° (L.), 190°–200° (W.), is formed by leading HCl into ethylene oxide, or from ethylene oxide and ethylene chlorhydrin at 140° (Wurtz, Ann. Chim. Phys. [3] 69, 338). 1 molecule ethylene chlorhydrin and 2 molecules glycol are heated at 140°, saturated with HCl

and again heated at 100° (Lourenço, *ibid.* [3] 67, 290), a liquid soluble in water.

The *bromhydrin*, b.p. 205°, is prepared from glycol and ethylene bromide at 160° (L.).

3. Tri-ethylene glycol

$$C_6H_4(OH)\cdot O\cdot C_2H_4\cdot O\cdot C_2H_4OH$$
b.p. 290°; sp.gr. 1·138; a liquid miscible with alcohol and water, and oxidised by HNO_3 to *diglycol-ethlenic acid* $C_6H_{10}O_6$ (Lourenço; Wutrz).

The *chlorhydrin* $C_6H_{13}O_3Cl$: b.p. 222°-232°; is a liquid soluble in water (L.).

The *bromhydrin* $C_6H_{13}O_3Br$; b.p. (with decomposition) 250° (L.).

4. Tetra-ethylene glycol $C_8H_{17}O_5$; b.p. 230° at 25 mm. (L.; W.).

The *chlorhydrin* $C_8H_{17}O_4Cl$; b.p. 262°-272°; is soluble in water (L.).

5. Penta-ethylene glycol $C_{10}H_{22}O_6$; b.p. 281° at 25 mm.; a viscid liquid soluble in water, alcohol, and ether (L.).

6. Hexa-ethylene glycol $C_{12}H_{26}O_7$; b.p. 325° at 25 mm.; a very viscid liquid (L.).

Ethylene bromide $C_2H_4Br_2$ or $CH_2Br\cdot CH_2Br$; m.p. 9·975° (Moles, Anal. Fis. Quim. 1912, 10, 131), 10·012° (Biron, Zeitsch. physikal. Chem. 1913, 81, 590); b.p. 131·6° (R.), 129·5° at 745 mm. (Anschütz, Annalen, 221, 137), 130·39° (corr.) (Thorpe and Rodger); sp.gr. 2·1804 at 20° (Biron, *l.c.*), 2·2132 at 0°/4°, 2·1901 at 10·9°/4° (Thorpe. Chem. Soc. Trans. 37, 177); by action of C_2H_4 and Br (Balard, Ann. Chim. Phys. [2] 32, 375); formed together with ethylidene bromide CH_3CHBr_2 by heating C_2H_5Br with Br to 180° (Tawildarow, Annalen, 176, 14). From C_2H_4Cl, Br, and iron wire at 100° (V. Meyer and Petrenkò, Ber. 25, 3307); also from C_2H_5Br, Br, and $AlBr_3$ at 65°-70° (Mouneyrat, Bull. Soc. chim. [iii.] 19, 497).

Preparation.—1. Ethylene, purified by passing through H_2SO_4 and NaOH solution, is led into bromine covered with water, contained in a wide tube, until the colour of the Br disappears; the product is washed with NaOH and water, dried by $CaCl_2$ and distilled (Erlenmeyer and Bunte, Annalen, 168, 64; Erlenmeyer, *ibid.* 192, 244; Prideaux, Chem. News, 1916, 113, 277). 2. By heating together at 150° in glacial acetic acid glycol diacetate and HBr, a quantitative yield of $C_2H_4Br_2$ is obtained (Perkin and Simonsen, Chem. Soc. Trans. 1905, 856).

Is a colourless mobile liquid with a pleasant smell and sweet taste; V.D. 6·485 (Regnault). When heated with water to 150°-160°, it yields, first glycol, and, on longer heating, HBr and aldehyde (Carius, Annalen, 131, 173). Zn acts upon an alcoholic solution of $C_2H_4Br_2$ with formation of C_2H_4 and $ZnBr_2$ (Gladstone, Ber. 7, 364); by heating with KI and water, ethane is produced. Alcoholic KOH yields C_2H_3Br, and in excess C_2H_2. Heated with $AlBr_3$ at 100°-110°, yields C_2H_2 and $C_2H_2Br_4$; with Cl and $AlCl_3$, yields C_2Cl_6 (Mouneyrat).

Aqueous KOH produces, after long contact, C_2H_3Br (Stempnevsky, Annalen, 192, 240). By heating with strong NaOH and KOH solution, glycol and C_2H_3Br are produced. If $C_2H_4Br_2$ be heated with excess of H_2O and PbO to 220°, aldehyde is formed (due to decomposition of $C_2H_4(OH)_2$, first formed, into C_2H_4O and H_2O) (Eltekow, Ber. 6, 558, and Nevole, *ibid.* 9, 447).

Heated with strong HI solution, yields $C_2H_4I_2$ (Sororkin, Zeitsch. Chem. 1870, 519). Heated with Ag_2O and water, aldehyde is produced, and when heated with Ag_2CO_3 and water, yields glycol (Beilstein and Wiegand, Ber. 15, 1368). Treated with Ag_2SO_4 and benzene, yields dibromethyl sulphate $(C_2H_4Br)_2SO_4$; with Ag_2SO_4 and water, bromethyl sulphuric acid $(C_2H_4Br)HSO_4$ (B. and W.).

Bromethylene bromide $CH_2Br\cdot CHBr_2$; b.p. 186·5° (Wurtz, Annalen, 104, 243), 187°-188° at 721 mm. (Denzel, *ibid.* 195, 202), 191° (Tawildarow, *ibid.* 176, 22), 73° at 11·5 mm., 83° at 18 mm., 187°-188° at 751·5 mm. (Anschütz, *ibid.* 221, 138); sp.gr. 2·624 at 16° (T.), 2·620 at 23° (W.), 2·6189 at 17·5°/4°, 2·6107 at 21·5°/4° (A.).

Prepared from monobromethylene and Br (Wurtz); from C_2H_3I and Br (Simpson, J. 1857, 461); from C_2H_3Br and Br at 170° (Hofmann, J. 1860, 364); or from $C_2H_4Br_2$ and Br at 200° (Tawildarow); decomposed by $KC_2H_3O_2$ at 150°, or by H_2O and PbO into dibromethylene and HBr. C_2H_5NaO yields ethylidene dibromide (Gray, Chem. Soc. Trans. 1897, 1024). Alcoholic KOH gives $C_2H_3Br_2$, C_2H_2, and bromacetylene C_2HBr. When heated with excess of absolute alcohol, C_2H_5Br and probably C_2H_3BrO bromaldehyde, are formed (Glöckner, Annalen, Suppl. 7, 110).

The isomeric body CH_3CBr_3 is not known.

Dibromethylene dibromide $C_2H_2Br_4$. Two isomerides are known.

1. *Acetylidene tetrabromide*; $CH_2Br\cdot CBr_3$ boils with decomposition at 200°; b.p. 103·5° at 13·5 mm.; sp.gr. 2·9292 at 17·5°/4°, 2·9216 at 21·5°/4° (Anschütz, Annalen, 221, 140). Formed from *as*-dibromethylene $CH_2 : CBr_2$ and bromine (Lennox, *ibid.* 122, 124; Chem. Soc. Trans. 1862, 206; Reboul, Annalen, 124, 270). From C_2H_5Br and Br at 180° a compound $C_2H_2Br_4$ is produced, which boils with decomposition at 208°-211° (Tawildarow). By heating a mixture of pyrotartaric acid and bromine with water at 150° (Bourgoin, Ann. Chim. Phys. [5] 12, 427).

2. *Acetylene tetrabromide* $CHBr_2CHBr_2$; b.p. 137°-137·2° at 36 mm., 114° at 12 mm., at 15 mm. 124°-126°, at 54 mm. 151°; sp.gr. 2·9710 at 17·5°/4°, 2·9629 at 21·5°/4° (Anschütz, Ber. 12, 2974, and Annalen, 221, 139); decomposes at 190° into HBr, Br, and C_2HBr_3.

By leading C_2H_2 into bromine covered with water (Reboul, Annalen, 124, 269; Berthelot, Bull. Soc. chim. [ii.] 5, 97); the crude $C_2H_2Br_4$ is then reduced by means of alcohol and Zn dust to $C_2H_2Br_2$, when the admixed $C_2H_3Br\cdot Br_2$ is converted into C_2H_2Br; the $C_2H_2Br_2$ is then purified by distillation and treated with bromine (Anschütz, Annalen, 221, 139); by action of Br and $AlBr_3$ at 105°-110° upon $C_2H_4Br_2$ (Mouneyrat, Bull. Soc. chim. [iii.] 19, 498). A liquid smelling of camphor and chloroform; decomposed by heating or by action of Na; by heating with alcoholic KOH, C_2H_2 and C_2HBr are produced. Cl produces $C_2Cl_4Br_2$ (Bourgoin, Bull. Soc. chim. [i.] 23, 4); when heated with Br and water to 180°, yields C_2Br_4 and C_2Br_6 (Anschütz); with C_6H_6 and $AlCl_3$, produces anthracene; heated with aniline, dimethylaniline, or alcoholic NH_3, yields $NHBr : CBr_2$.

Pentabromethane $CHBr_2\cdot CBr_3$; m.p. 56°-57°

(Bourgoin), 54° (Denzel, Ber. 12, 2208), 48°–50° (Reboul); boils with decomposition at 210° (at 300 mm.) (Denzel). From C_2HBr_3 (Elbs and Newmann, J. pr. Chem. [2] 58, 254; Lennox, Annalen, 122, 125) or C_2HBr (Reboul, *ibid.* 124, 268) and bromine. By slow oxidation (by exposure to air) of C_2HBr_3 (Demole, Bull. Soc. chim. [ii.] 34, 204); from $C_2H_3Br_4$ and Br at 165° (Bourgoin, *ibid.* 23, 173). Forms prismatic needles soluble in alcohol and ether.

Perbromethane C_2Br_6 *v.* CARBON TRIBROMIDE.

Ethylene bromolodide; m.p. 28°; b.p. 163°; sp.gr. 2·516 at 29°. From C_2H_3Br and conc. HI at 100° (Reboul, Annalen, 155, 213). From C_2H_4 and 1Br (Simpson, J. 1874, 326). Needles, with alcoholic KOH yields, in the cold, C_2H_3I and HBr, and on warming HBr, HI, and C_2H_2. Forms iodoform with alcoholic CH_3COOK at 100°.

Ethylene bromhydrin $C_2H_4Br·OH$, *Glycol bromhydrin*; b.p. 150°–152°, at 18 mm. 63°–64° (Henry, J. 1889, 1321), 155° (Lourenço, Ann. Chim. Phys. [3] 67, 287); sp.gr. 1·66 at 8° (H.); sp.gr. 1·7195 at 18·6° (H.). From glycol and $C_2H_4Br_2$ at 115°–120° (Lourenço); from glycol and HBr at 100°, and from $CH_2I·CH_2OH$ and bromine (Henry); also from 3 mols glycol and 1 mol. PBr_3 (Demole, Ber 9, 48); from ethylene and HBrO (60 p.c.) (Mokiewsky, J. Russ. Phys. Chem. Soc. 30, 900); with zinc-dust and alcohol is reduced to C_2H_4; together with ethylene dibromide by the action of ethylene on bromine water (Read and Williams, Chem. Soc. Trans. 1917, 111, 240)

Ethylene dichloride, *Elayl chloride*, *Dutch liquid* CH_2ClCH_2Cl; b.p. 84·9° (Pierre, J. 1847–48, 63), 83·5° (corr.) (Thorpe, Chem. Soc. Trans 37, 182), 84·5°–85° at 750·9 mm. (Bruhl, Annalen, 203, 10), 83·3° at 749 mm. (R. Schiff, *ibid.* 220, 96), 84·1° at 760 mm. (Städel, Ber. 15, 2563); sp.gr. 1·2808 at 0°/4° (Thorpe), 1·2803 at 0° (Pierre), 1·2562 at 20° (Haagen, Bull. Soc. chim. ii. 10, 355), 1·2656 at 9·8°/4°, 1·1576 at 83·3°/4° (R. Schiff), 1·2606 at 14·4°, 1·204 at 62·5° (Landolt and John); b.p 83·93° (corr.) (Thorpe and Rodger) refractive index; at $t°$ $\mu_A = 1·441466 - 0·000446t$, mol. refract. $= 34·06$ (Kanonnikow); capill. constant at b.p. $a^2 = 4·198$ (R. Schiff, Annalen, 223, 72). By action of C_2H_4 upon Cl (Deiman, Trootswyk, Bondt, and Lauwerenburgh, Crell's Ann. 1795, 2, 200); by leading C_2H_4 into $SbCl_5$ or into molten $CuCl_2$ (Wöhler, Pogg. Ann. 13, 297); from C_2H_4Cl and $SbCl_5$ at 100° (V. Meyer and Müller, J. pr. Chem. [ii.] 46, 173); also by action of glycol upon PCl_3 (Wurtz) or upon HCl at 100° (Schorlemmer, Chem. Soc. Trans. 1881, 1); from ethylene diamine and NOCl in carefully cooled *m*-xylene solution (Solonina, J. Russ. Phys. Chem. Soc. 30, 606). Prepared best according to Limpricht's method (Annalen, 94, 245). Ethylene is passed into a gently heated mixture of 2 parts manganese dioxide, 3 parts common salt, 4 parts water, and 5 parts sulphuric acid, and when the mass turns yellow it is distilled. It can be prepared in good yield from ethylene and chlorine if the temperature is kept at 0°; at higher temperatures considerable quantities of trichloroethane are formed. It forms an oily liquid, insoluble in water. When heated with alcoholic KOH, it yields KCl and C_2H_3Cl, and with K it forms H_2, KCl, and C_2H_3Cl

(Liebig, Annalen, 14, 37). Heated with $AlCl_3$ to 80°–85° is decomposed into HCl and C_2H_2 (Mouneyrat, Bull. Soc. chim. [iii.] 19, 446). With NH_3 it forms bases, $N_2H_4C_2H_4$, $N_2H_2(C_2H_4)_2$, &c. With ethylamine, it yields *collidine* (*trimethylpyridine* $C_5H_2(CH_3)_3N$), C_2H_5Cl, and also NH_3 and $N(C_2H_5)_3$ (Hofmann, Ber. 17, 1907).

Chlorethylene $CH_2:CHCl$, *Vinyl chloride*; at ordinary temp. a gas; b.p. $-18°$ to $-15°$; by action of alcoholic KOH upon ethylene chloride (Regnault, Annalen, 14, 28), or ethylidene chloride (Wurtz and Frapolli, *ibid.* 108, 224). To prepare it the ethylene dichloride and alcoholic potash are left in contact for 3 or 4 days in the cold, and the mixture is then warmed. Combines with Cl to form $C_2H_3Cl_3$. Polymerises in sunlight, and forms a solid insoluble mass of sp gr. 1 406 (Baumann, Annalen, 163, 317).

Dichlorethylene $C_2H_2Cl_2$.

1. *Dichlorethylene* $CH_2:CCl_2$; b.p. 33·5°–35° (Joetlsch and Faworsky); b.p. 37° (Kramer, Ber. 3, 261); sp.gr. 1·250 at 15°, obtained by action of alcoholic KOH upon $CH_2Cl·CHCl_2$ (Regnault, J. pr. Chem. [ii.] 18, 80). Also by action of Zn shavings in alcoholic solution upon the trichlorethyl ester of acetic acid (Joetlsch and Faworsky, J Russ. Phys. Chem. Soc. 30, 998). Polymerises easily into a solid amorphous insoluble body.

2. *Sym-Dichlorethylene* (*Acetylene dichloride*) $CHCl:CHCl$; b.p. 55°; by distillation of the compound of C_2H_2 with $SbCl_5$ (Berthelot and Jungfleisch, Annalen, Suppl. 7, 253); also by action of Zn upon an alcoholic solution of $CHClBr·CHClBr$, or by leading C_2H_2 into aqueous solution of ICl (Sabanejeff, Annalen, 216, 262).

Trichlorethylene $CHCl:CCl_2$; b.p. 87·4°–87·55°; sp.gr. 1·4904 at 4°/4°, 1·4598 at 25·5°/25·5° (Veley, Proc. Roy. Soc. 1910, B 82, 217), 85·8°–86·0°/741·6 mm., m.p. $-83°$, D_4^{20} 1·4649; D_4^{15} 1·4695 (Erdmann, J. pr. **Chem.** 1912, ii. 85, 78). From isomeric compounds $C_2H_2Cl_4$, and alcoholic KOH (Berthelot and Jungfleisch); also by action of nascent H (Zn and H_2SO_4) upon C_2Cl_6 (Fischer, J. 1864, 481): from anhydrous chloral and P_2S_5 at 160°–170° (Paternò and Oglialoro, Ber. 7, 81); combines with Cl to form C_2HCl_5. By action of ammonia in aqueous solution on tetrachloroethane (Comp. prod. chem. d'Alais; Eng. Pat., 132755).

For observations on its autoxidation, *see* Erdmann (*l c.*).

Tetra-chlorethylene C_2Cl_4 *v. Carbon dichloride*, art. CARBON *Cf.* Weiser and Wightman, J. Phys. Chem. 1919, 23, 415.

Hexachlorethane C_2Cl_6 *v.* Carbon trichloride, art. CARBON.

Ethylene chlorhydrin $HO·CH_2·CH_2Cl.$ *Chlorethyl alcohol*, *Glycol chlorhydrin*; b.p. 128° (Wurtz, Annalen, 110, 125), 132°; 51°–52° at 22 mm.; sp.gr. 1·2005 at 18·6° (Henry, J. 1889, 1321), 1·24 at 8°. From glycol and HCl (gas) at 100° (W.). If excess of HCl be used, $C_2H_4Cl_2$ is produced (Schorlemmer, Chem. Soc. Trans. 39, 143); from glycol and Cl_2S_2 (Carius, Annalen, 124, 257); from C_2H_4 and ClOH (Carius, *ibid.* 126, 197; Butlerow, *ibid.* 144, 40). Dry HCl is led into glycol kept at 148°; the $C_2H_4Cl(OH)$ distils off (Ladenburg, Ber. 16, 1408). A liquid miscible with water;

yields alcohol with Na amalgam and H_2O (Lourenço, Annalen, 120, 92). Oxidised by CrO_3 to chloracetic acid (Kriwaxin, Zeitsch. Chem. 1871, 265); with KOH, yields ethylene oxide. *Cf.* Gomberg, J. Amer. Chem. Soc. 1919, 41, 1414.

Ethylene chlorobromide $CH_2Cl\cdot CH_2Br$; b.p. 107°–108° (Leeocœur, Bull. Soc. chim. [ii.] 29, 484); sp.gr. 1·79 at 0° (L.), 1·705 at 11° (Montgolfier and Giraud, *ibid.* 33, 12), 1·689 at 19°. By action of Br upon $CH_2Cl\cdot CH_2I$ (Henry, Annalen, 156, 14); from $C_2H_4Br_2$ and $SbCl_5$ (Lössner, J. pr. Chem. [2] 13, 421) or $C_2H_4Br_2$ and $HgCl_2$ at 150°–180° (M. and G.); by action of Br upon $C_2H_4Cl(OH)$ at 130° (Demole, Ber. 9, 556). To prepare it, first chlorine and then ethylene is passed into Br, kept under a mixture of equal vols. of strong HCl and water (James, J. pr. Chem. [2] 26, 380; also Simpson, Proc. Roy. Soc. 27, 118); decomposed by alcoholic KOH, with formation of C_2H_3Cl.

Ethylene chloroiodide $CH_2Cl\cdot CH_2I$; m.p. −15·6° (Sehn der, Zeitsch. physikal. Chem. 19, 157), b.p. 140° (Sorokin, Zeitsch. Chem. 1870, 519), 140·1° (corr.) (Thorpe, Chem. Soc. Trans. 37, 189), 137°–138° (Meyer and Wurster, Ber. 6, 964); sp.gr. 2·151 at 0° (S.), 2·16439 at 0°, 2·13363 at 15·3°/0° (T.). From $CH_2I\cdot CH_2I$ and ICl; from C_2H_4 and an aqueous solution of ICl (Simpson, Proc. Roy. Soc 12, 278). Decomposed by alcoholic KOH and HI and C_2H_3Cl; nascent H yields HCl, HI, and C_2H_4; moist Ag_2O at 160° produces glycol (Simpson). Finely divided silver at 160° yields C_2H_4 and $C_2HCl\cdot CH_2Cl$ (Friedel and Silva, Bull. Soc. chim. [ii.] 17, 242). Heated with HI solution, yields C_2H_5I and $C_2H_4I_2$ (Sorokin).

Ethylene cyanhydrin $HO\cdot CH_2\cdot CH_2CN$; b.p. 220°–222° at 723·5 mm.; sp.gr. 1·0588 at 0°. By long digestion of C_2H_4O (ethylene oxide) with anhydrous HCN at 50°–60° (Erlenmeyer, Annalen, 191, 273); miscible with alcohol and water; 100 parts ether dissolve 2·3 parts $C_2H_4(OH)CN$ at 15°; insoluble in CS_2. Forms a chloride with PCl_5, which boils at 174°–176° under 752 mm., and has sp.gr. 1·443 at 18·5° (Henry, Bull. Acad. Roy. Belg. iii. 35, 360).

Ethylene cyanide $C_2H_4(CN)_2$, *Succinonitrile*; m.p. 54·5° (Ngvole and Tscherniak, Bull. Soc. chim. [ii.] 30, 101), 51°–52° (Henry, *ibid.* 43, 618); b.p. 158°–160° at 20 mm. (Pinner, Ber. 16, 360), 265°–267° (H.); sp.gr. 1·023 at 45°. By heating on a water-bath $CH_2Br\cdot CH_2Br$ with KCN and alcohol (sp.gr. 0·84) (Simpson, Proc. Roy. Soc. 10, 574); the liquid is filtered from the KBr, and distilled, when the alcohol is first removed; then the distillation is conducted under diminished pressure; also is produced by electrolysis of potassium cyanacetate (Moore, Ber. 4, 520); is a white amorphous mass soluble in water, chloroform, and alcohol; slightly in carbon disulphide and ether; decomposed when distilled at ordinary pressure. Decomposed by heating with KOH or HCl into NH_3 and succinic acid; with $AgNO_3$ forms plates of $C_2H_4(CN)_2\cdot 4AgNO_3$, which is soluble in water and alcohol, and explodes when heated (Simpson).

Ethylene diamine $NH_2\cdot C_2H_4\cdot NH_2$; m.p. 8·5° (Kraut, Annalen, 212, 263), b.p. 116·5°; sp.gr. 0·9002 at 15° (Kraut). By heating $C_2H_4Cl_2$ or $C_2H_4Br_2$ with alcoholic NH_3 to 100° (Cloëz, J. 1853, 468); by distillation of $\alpha\beta$-diaminopropionic acid (Neuberg and Neimann, Zeitsch. physikal. Chem. 45, 110); by treatment of $C_2H_4(CN)_2$ with Sn and HCl (Fairley, Annalen, Suppl. 3, 372). 42 grams of $CH_2Cl\cdot CH_2Cl$ and 510 c.c. aqueous NH_3 are heated for 5 hours to 115°–120° in a sealed tube; the product is then evaporated until it begins to crystallise, and is then precipitated with 3 times its volume of absolute alcohol; the precipitated $C_2H_4(NH_2)_2,2HCl$ is then washed with alcohol and the base set free by distillation with powdered NaOH (Kraut, *l.c.*; also Hofmann, Ber. 4, 666). The by-product from the manufacture of chloral, consisting of $CH_2Cl\cdot CH_2Cl$, $CH_3\cdot CHCl_2$, &c., can be used. A thick oily liquid, with faint ammoniacal smell, soluble in water, not miscible with ether or benzene; the aqueous liquid, which contains $C_2H_4(NH_2)_2,H_2O$, cannot be freed from water by BaO, but only by distillation over Na. Caro's acid oxidises it to glyoxime (Bamberger and Seligman, Ber. 36, 3831). With HClO and HBrO, yields tetrachloro and tetrabromo derivatives; *e.g.* $Br_2N\cdot C_2H_4\cdot NBr_2$ (Chattaway, Chem. Soc. Trans. 1905, 381). Decomposed by HNO_2 into ethylene oxide and oxalic acid (Hofmann, J. 1859, 386); is a strong base and forms salts; combines with CS_2 to form crystals of
$$C_2H_4(NH_2)_2\cdot CS_2$$

soluble in water, insoluble in alcohol and ether. $C_2H_4(NH_2)_2,2HCl$, long silvery needles insoluble in alcohol. $C_2H_4(NH_2)_2HCl,PtCl_4$, yellow leaflets, slightly soluble in water (Greiss and Martius, Annalen, 120, 327); $C_2H_4(NH_2)_2(HCNS)_2$, large prisms, very soluble in water, m.p. 145° (Hofmann, Ber. 5, 245). Forms many compounds with metallic salts and a periodide $C_2H_4(NH_2)HI\cdot I_4$, which melts at 218°.

Diethylene diamine, *Piperazine*

$$(C_2H_4)_2(NH)_2 \text{ or } C_2H_4\!<\!\!\begin{array}{c}NH\\NH\end{array}\!\!>\!C_2H_4$$
m.p. 104° (Berthelot); b.p. 170° (Hofmann, J. 1858, 343), 145°–146° (Berthelot), 140° (Rosdalsky). From ethylene chloride and alcoholic NH_3 (Cloez; Hofmann, Natanson, Annalen, 98, 291); from sodium ethylene glycollate and acid derivatives of ethylene diamine by heating at 250°–350° (D. R. P. 67811); by heating the sodium compound of *sym*-diacyl ethylene diamine with anhydrous glycol or ethylene bromide at 200° (D. R. P. 73354); by reduction of ethylene oxamide with zinc-dust and KOH (D. R. P. 66461). (For other methods of preparation, *see* D. R. P. 70055, 70056, 73125, 74628, 79121, 9803, 100232.)

Forms a hydrate $C_4H_{10}N_2,6H_2O$; m.p. 44° (Berthelot). Piperazine is not changed by heating with HCl or H_2SO_4 at 200°. With carbonyl chloride it forms tricarbonyl piperazine. It forms a periodide $C_4H_{10}N_2\cdot 2HI\cdot I_4,3H_2O$, m.p. 283°. The anhydrous periodide melts at 280° (Herz, Ber. 30, 1585). Piperazine reacts with 2 molecules HBrO to form an additive compound, which, on treatment with dilute alkali or piperazine solution, yields *n*-dibromopiperazine. This latter can form an additive compound with 2 molecules of HBrO (Chattaway, Chem. Soc. Trans. 1905, 951). Piperazine reacts

with an excess of EtI at temperature of water-bath to form triethyl piperazonium iodide; m.p. 240°. Colourless needles, insoluble in cold water, ligroin, C_2Cl_3, C_6H_6, and CS_2; soluble in warm alcohol (Van Rijn, Chem. Zentr. 1898, 1, 727) (v. *Piperazine*).

sym.Diethylene diethyldiamine

$$(C_2H_4)_2(NH \cdot C_2H_5)_2, H_2O$$
b.p. 165° (Schmidt and Wichmann, Ber. 24, 3247); from $(C_2H_4)_2(NH_2)_2$ and C_2H_5I, or from $C_2H_4Br_2$ and $NH_2 \cdot C_2H_5$ (Hofmann, J. 1859, 389); from piperazine and an excess of $KEtSO_4$ in aqueous solution (Van Rijn, Chem. Zentr. 1898, i. 727). It combines with salts of Cd, Cr, Zn, and Ni.

as.Diethylene diethyldiamine

$$NH_2 \cdot C_2H_4 \cdot N(C_2H_5)_2$$
mobile liquid; b.p. 145°; sp.gr. 0·827 at 18·5°/18·5°; from bromethylphthalimide and diethyl-amine with subsequent hydrolysis, yields a *platinochloride*, m.p. 230°; an *aurochloride*, m p. 161°–163°; and a *picrate*, m.p. 211° (Ristenpart, Ber. 1896, 29. 2526).

Triethylene diamine $(C_2H_4)_3N_2$; b.p. 210°; soluble in water (Hofmann, J. 1858, 343; Harries, Annalen, 294, 350).

Diethylene triamine

$$NH_2 \cdot C_2H_4 \cdot NH \cdot C_2H_4 \cdot NH_2$$

b.p. (with slight decomposition) 208°; formed with other products by action of NH_3 upon $C_2H_4Br_2$; the double salt with $PtCl_4$ being less soluble than that of triethylene triamine, it can be separated from that body (Hofmann, J. 1861, 514).

A strongly alkaline liquid miscible with water and alcohol. Its salts are soluble in water, less so in alcohol, $2[(C_2H_4)_2N_3H_5, 3HCl]3PtCl_4$ forms golden-yellow needles.

Triethylene triamine

$$C_2H_4 \begin{array}{c} \diagup NH \cdot C_2H_4 \diagdown \\ \diagdown NH \cdot C_2H_4 \diagup \end{array} NH$$
b.p. 216° (Hofmann, J. 1861, 514); forms salts; $[(C_2H_4)_3N_3H_5, 3HCl]_2PtCl_4$: long golden-yellow needles moderately soluble in water; with hydrobromic acid gives $(C_2H_4)_3N_3H_5, 3HBr$ from acid solutions: from weaker acid solution $(C_2H_4)_3N_3H_5, 2HBr$.

Tetraethylene triamine $(C_2H_4)_4N_3H_5$; by action of alcoholic NH_3 upon $C_2H_4Br_2$ (Hofmann, Ber. 3, 762); forms 3 series of salts with 1, 2, or 3 molecules of monobasic acid; the hydrobromides are amorphous bodies, almost insoluble in water, alcohol, and ether.

Triethylene tetramine

$$NH_2 \cdot C_2H_4 \cdot NH \cdot C_2H_4 \cdot NH \cdot C_2H_4 \cdot NH_2$$

m.p. +12°; b.p. 266°–267°; sp.gr. 0·9817 at 15°; a strongly alkaline syrup from $C_2H_4Cl_2$ and $C_2H_4(NH_2)_2$, or from $C_2H_4Br_2$ and alcoholic NH_3 (Hofmann, J. 1861, 519); yields

$$C_6H_{18}N_4 \cdot 4HCl \cdot 2PtCl_4$$
a yellow amorphous powder almost insoluble in water.

Ethylene diformin $C_2H_4(CHO_2)_2$; b.p. 174°; by heating glycol with pure formic acid (Henninger, Ber. 7, 263); also by heating oxalic acid with glycol (Lorin, Bull. Soc. chim. [ii] 22, 104). Decomposed when heated at 200° in sealed tube into CO_2, CO, H_2O, and C_2H_4.

Ethylene ferrous chloride $C_2H_4FeCl_2, 2H_2O$; by heating $FeCl_2$ and ether to 150° (Kachler, Ber. 2, 510); forms prisms fairly soluble in water. The corresponding compound

$$C_2H_4FeBr_2, 2H_2O$$
is prepared by leading C_2H_4 into a strong aqueous solution of $FeBr_2$ in sunlight (Chojnacki, Zeitsch. Chem. 1870, 420); forms light-green deliquescent crystals.

Ethylene iodide $CH_2I \cdot CH_2I$; m.p. 81°–82° (Aronstein and Kramps, Ber. 13, 489); sp.gr. 2·07; from C_2H_4 and I in sunlight (Faraday, Gm. 4, 682), also in the shade, especially if warmed (Regnault, Annalen, 15, 67); a mixture of I and alcohol (absolute) is saturated with C_2H_4 with repeated agitation (Semenow, J. 1864, 483).

Crystalline plates or prisms decomposed by heating; when warmed with alcohol to 70°, $IC_2H_4 \cdot OC_2H_5$, is produced; $HgCl_2$ gives in the cold C_2H_4ICl, and on heating $C_2H_4Cl_2$ (Maumené, J. 1869, 345); alcoholic KOH converts it into C_2H_3I (Regnault, Annalen, 15, 63).

Ethylene iodohydrin $CH_2I \cdot CH_2OH$; from $C_2H_4(OH)_2$ and gaseous HI (Simpson, *ibid.* 113, 121); also by heating $C_2H_4(OH)Cl$ with KI (Butlerow and Ossokin, *ibid.* 144, 42).

An oil, b.p. 85°/25 mm.; sp.gr. 2·1649 at 18·6° (Henry, Ber. 24 Ref. 75).

Ethylene nitrate $NO_3CH_2 \cdot CH_2NO_3$; b.p. 114°–116° with explosion (Demjanow, Chem. Zentr. 1899, i. 1064); sp.gr. 1·5099 at 4°, 1·4960 at 15°, 1·4860 at 25° (Perkin). Is formed when glycol is treated with HNO_3 and H_2SO_4, also by interaction of C_2H_4 and N_2O_5 in the cold (Demjanow); an oily liquid which is inflammable, explodes on percussion, and is poisonous; KOH converts it into alcohol (Henry, Ber. 3, 529; also Champion, Compt. rend. 73, 571). On reduction yields CH_3CHO, $C_2H_4(NH_2)_2$, and $H_2N \cdot CH_2 \cdot CH_2OH$.

Ethylene nitrite

$$C_2H_4(NO)_2 \text{ or } NO_2 \cdot CH_2CH_2 \cdot NO$$
m.p. below −15°; b.p. 96·8°; sp.gr. 1·2156 at 0° (Bertoni). Is prepared by distilling glycerol trinitrate with more than an equivalent amount of glycol. Soluble in alcohol to form C_2H_5ONO (Bertoni, Gazz. chim. ital. 15, 353); insoluble in and slowly decomposed by water.

Nitroethylene can be prepared in 50 p.c. yield by the dehydration of β-nitroethyl alcohol by phosphoric oxide or sodium hydrogen sulphate; an almost colourless mobile liquid, b.p. 98·5°; $D^{13·8}$ 1·073. Vapour violently attacks the eyes and throat. Readily undergoes polymerisation; with alkali the change occurs with explosive violence. Combines with bromine in ethereal solution, yielding nitroethylene dibromide, colourless liquid, b.p. 97°/21 mm. With aniline gives N-β-nitroethyl aniline $NHPh \cdot CH_2 \cdot CH_2 \cdot NO_2$, colourless leaflets, m.p. 37° (Wieland and Sakellarios, Ber. 1919, 52, B, 898).

Ethylene passed into an ice-cold mixture of nitric acid (D 1·4) and concentrated sulphuric acid containing 20 p.c. of sulphur trioxide yields on steam-distillation and fractionation under diminished pressure *ethylene dinitrate*, colourless oil, b.p. 105·5°/19 mm. D^{17} 1·433, and *β-nitroethyl nitrate*, colourless, poisonous oil, b.p.

120-122°/17 mm. D^{15} 1·468. The latter is converted by phosphoric oxide into nitroethylene.

β-Nitroethyl alcohol is a colourless odourless liquid, b.p. 103°/11·5 mm. $D13·3$ 1·309, miscible with water, alcohol, and ether obtained by the action of silver nitrite on ethylene iodohydrin (Wieland and Sakellarios, Ber. 1920, [B] 201.

Ethylene oxide $\begin{matrix} CH_2 \\ \diagdown \\ CH_2 \end{matrix}O$; b.p. 12·5° ; sp.gr.

0·8909 at 4°/4° ; 0·8824 at 10°/10° (Perkin, Chem. Soc. Trans. 1853, 488). From $C_2H_4(OH)Cl$ and KOH (Wurtz, Annalen, 110, 125 ; Ann. Chim. Phys. [3] 69, 317) ; also from $C_2H_4(OH)Cl$ and $C_2H_4(OH)ONa$ (Scheitz, Zeitsch. Chem. 1868, 379) ; also from $C_2H_4I_2$ and Ag_2O at 150° ; from $C_2H_4Br_2$ and Ag_2O at 250° ; or from $C_2H_4Br_2$ and Na_2O at 180° (Greene, J. 1877, 522) ; also by treatment of $C_2H_4Cl(OC_2H_3O)$ with KOH (Demole, Annalen, 173, 125) ; by dropping chlorethylacetate on to a cooled mixture of powdered KOH and sand (Roithner, Monatsh. 15, 666).

A pleasant-smelling liquid miscible with water ; when heated with water in a closed tube, yields glycol, and polyethylene glycol. Has strong basic properties, although not an alkaline reaction. It combines with acids, and precipitates metallic hydroxides from solutions of Mg, Al, Fe, and Cu salts. With Na amalgam forms C_2H_6O. Pt black oxidises it to glycollic acid ; PCl_5 produces $CH_2Cl·CH_2Cl$ (Wurtz, Ann. Chim. Phys. [3] 69, 317, and 355).

Equal molecules of C_2H_4O and Br at 0° form $C_2H_4(OH)Br$, $C_2H_4Br_2$ and other bodies (Demole, Ber. 9, 47), but 2 molecules C_2H_4O and 1 molecule Br, on standing, yield large red or small yellow prisms of $(C_2H_4O)_2Br_2$; m.p. 65° ; b.p. with decomposition at 95° ; they are insoluble in water, but soluble in alcohol. H_2S or contact with Hg separates the Br and leaves dioxyethylene (Wurtz, Ann. Chim. Phys. [3] 69, 321). By long contact with $ZnCl_2$ or KHO, a polymeride which melts at 56° and is insoluble in water, is produced (Wurtz, Bull. Soc. chim. [ii.] 29, 530).

Dioxyethylene, *Diethylene dioxide* $\begin{matrix} CH_2·O·CH_2 \\ | \quad\quad | \\ CH_2·O·CH_2 \end{matrix}$;

m.p. 9° ; b.p. 102° ; sp.gr. 1·0482 at 0°. From $(C_2H_4)_2O_2·Br_2$, and Hg by contact at ordinary temperature. The mixture is then distilled, and distillate rectified over KOH (Wurtz, Ann. Chim. Phys. [3] 69, 323) ; has no marked basic properties, but combines slightly with acetic acid on heating to 120°. Lourenço (*ibid.* [3] 67, 288) obtained it by heating $C_2H_4(OH)_2$ and $C_2H_4Br_2$ to 160°, but the product boiled at 95°. Forms an iodide with 2 atoms of I, m.p. 84°, which is decomposed by water and air, but soluble in benzene ; also a sulphate and a picrate melting respectively at 100° and 66°. It also forms a compound with $HgCl_2$, soluble in, but slowly decomposed by, water (Faworsky, J. Russ. Phys. Chem. Soc. 38, 741 ; Paternò and Spallino, Atti. R. Acad. Lincei, [v.] 16, i. 87).

Chlorethylene oxide C_2H_3ClO ; b.p. 70°-80°. By long contact of acetylene chloriodide $CHCl : CHI$ with 40-50 vols. of water at 200°-220° (Sabanejeff, Annalen, 216, 268) ; difficultly soluble in water.

Bromethylene oxide $C_2H_3Br·O$; b.p. 80°-92°. From bromoglycol bromhydrin $CHBr_2·CH_2OH$ and KOH (Demole, Ber. 9, 51) ; soluble in water.

Ethylene phosphides r. PHOSPHORUS, ORGANIC COMPOUNDS OF.

Ethylene selenocyanate $C_2H_4(SeCN)_2$; m.p. 128° (Proskauer), 138° (Hagelberg, Ber. 23, 1092). From $CH_2Br·CH_2Br$ and alcoholic KCNSe (Proskauer, *ibid.* 7, 1281). Colourless needles, insoluble in cold water or ether, difficultly soluble in hot water or cold alcohol ; dissolves unchanged in strong HNO_3, but on heating gives ethylene selenious acid $C_2H_4(SeO_3H)_2$. With alcoholic alkali, yields ethylene diselenide (Hagelberg).

Diethylene disulphide $S\begin{matrix} CH_2·CH_2 \\ \diagup \quad\quad \diagdown \\ CH_2·CH_2 \end{matrix}S$; m.p. 111°-112° ; b.p. 199°-200° ; V.D.=4·28 (Husemann, Annalen, 126, 280). From $C_2H_4Br_2$ and K_2S (Crafts, *ibid.* 124, 110 ; 128, 220) ; also by heating $C_2H_4CS_2$ or $C_2H_4S_2Hg$ with $C_2H_4Br_2$ at 150° (H.).

Crystallises from alcohol in needles or leaflets, from ether in thick prisms which are volatile at ordinary temperatures ; combines with Br and certain salts, but not with NH_3 ; oxidised by HNO_3 to $(C_2H_4)_2S_2O_2$. The bromide

$$(C_2H_4)_2S_2Br_4$$

is a lemon-yellow amorphous body, m.p. 96°, very unstable ; the iodide $(C_2H_4)_2S_2I_4$, m.p. 132°-133°, forms iron-black monoclinic needles, insoluble in water. The oxide $(C_2H_4)_2S_2O_3$ can also be obtained by decomposition of the chloride or bromide ; with water, forms crystals which decompose without fusion on heating, and are soluble in water, almost insoluble in alcohol. The peroxide $(C_2H_4)_2S_2O_4$, obtained by heating $(C_2H_4)_2S_2$ with fuming HNO_3 to 150° (Crafts, Annalen, 124, 124), crystallises from strong HNO_3 in small crystals which are insoluble in water.

Ethylene ethylidene disulphide is obtained by heating ethylene sulphide almost to dull redness in absence of air and in a current of hydrogen sulphide. After being shaken with aqueous alkali is obtained as an almost colourless liquid, b.p. 172-173° (O. Matter, D. R. P. 313650).

Ethylene hydroxysulphide $C_2H_4(OH)SH$ (*Thioethylene glycol*), from $HO·CH_2CH_2Cl$ and alcoholic KHS ; the KCl is filtered off and the filtrate acidified with dilute HCl and evaporated at 30°-40° (Carius, Annalen, 124, 258). Is a heavy liquid, almost insoluble in water, soluble in alcohol ; the salts are fairly soluble in alcohol ; the mercury compound $Hg(C_2H_5OS)_2$ crystallises from alcohol in needles.

Thiodiethylene glycol $(C_2H_4OH)_2S$ is formed when the above compound is heated, H_2S being evolved. It is a crystalline solid ; m.p. under 60°, soluble in alcohol, insoluble in water, forms salts and double compounds with metallic salts.

Ethylene mercaptan $C_2H_4(HS)_2$; b.p. 146° ; sp.gr. 1·123 at 23·5°. From $CH_2Cl·CH_2Cl$ (or bromide, Werner, J. 1862, 424) and alcoholic KHS (Löwig and Weidmann, Annalen, 36, 322). A colourless liquid, soluble in alcohol and alkalis, forms insoluble mercaptides with heavy metals ; $Pb(C_2H_4)_2S_2$ yellow ; $Cu(C_2H_4)_2S_2$ chrome green. *Ethylene dimethyl sulphide* $C_2H_4(SCH_3)_2$, b.p. 183°, from $C_2H_4Br_2$ and CH_3SNa (Ewerlöf, Ber. 4, 716). *Ethylene*

diethyl sulphide $C_2H_4(SC_2H_5)_2$, b.p. 210°-213° (E.) gives on oxidation first $(C_2H_5SO)_2C_2H_4$, m.p. 170°; and next $(C_2H_5SO_2)_2C_2H_4$, m.p. 136·5° (Beckmann, J. pr. Chem. [2] 17, 469).

Ethylene thiocarbonates.

1. *Ethylene dithiocarbonate* $C_2H_4COS_2$, *ethylene oxythiocarbonate*; m.p. 31°; by action of HNO_3 upon $C_2H_4CS_3$ in the cold (Husemann, Annalen, 126, 269); forms long thin tables, insoluble in water, soluble in alcohol, ether, and chloroform.

2. *Ethylene trithiocarbonate* $C_2H_4CS_3$; m.p. 39·5° (Husemann), 33·4° (Konowalow), 39° (Frasetti); sp.gr. 1·4768. From $C_2H_4Br_2$ and Na_2CS_3 in presence of absolute alcohol (Husemann, Annalen, 123, 83); by action of water upon $AlBr_3·C_2H_4Br_2·CS_2$ (Konowalow); by action of alcoholic KOH upon ethylene xanthate

$$C_2H_4(S·CS·OEt)_2 + KOH$$
$$= KS·CO·OEt + C_2H_4CS_3 + EtOH$$
a theoretical yield; it reacts with dil. KOH thus:

$$C_2H_4CS_3 + EtOH + 3KOH$$
$$= KS·CO·OEt + C_2H_4S_2K_2 + 2H_2O$$
(Frasetti, Ber. 38, 488). Forms golden-yellow, rhombic prisms; slowly soluble in alcohol, easily soluble in ether, very soluble in CS_2, $CHCl_3$, and C_6H_6.

$\beta\beta'$-**Dichloroethyl sulphide** $(CH_2Cl·CH_2)_2S$, so-called 'mustard gas,' was apparently obtained by Guthrie (Chem. Soc. Trans. 1860, 12, 116; 1861, 13, 35) and by A. Niemann (Ann. 1860, 113, 288) by passing ethylene into cooled sulphur dichloride:

$$2CH_2 : CH_2 + SCl_2 = (CH_2Cl·CH_2)_2S$$
The conditions for its formation by this reaction have been studied by Myers and Stephen (J. Soc. Chem. Ind. 1920, 39, 65, T), and by Gibson and Pope (Chem. Soc. Trans. 1920, 117, 272). May also be prepared by converting ethylene into ethylene chlorohydrin, thence into thiodiglycol by treatment with sodium sulphide, and thiodiglycol into $\beta\beta'$-dichloroethyl sulphide by the action of hydrogen chloride:

(1) $CH_2 : CH_2 + HClO = CH_2Cl·CH_2·OH$

(2) $2CH_2Cl·CH_2·OH + Na_2S$
$$= (HO·CH_2·CH_2)_2S + NaCl$$

(3) $(HO·CH_2·CH_2)_2S + 2HCl$
$$= (CH_2Cl·CH_2)_2S + 2H_2O$$
(V. Meyer, Ber. 1886, 19, 3260; Clarke, Chem. Soc. Trans. 1912, 101, 1583). For the conversion of ethylene chlorohydrin into dichloroethyl sulphide, *see* Gomberg, J. Amer. Chem. Soc. 1919, 41, 1414.

$\beta\beta'$-Dichloroethyl sulphide is more readily procured by the action of ethylene on sulphur monochloride at about 60°

$$2CH_2 : CH_2 + S_2Cl_2 = (CH_2Cl·CH_2)_2S + S$$

The product has either the constitution

$$(C·H_2Cl·CH_2)_2S : S$$
or is a colloidal solution of S in $(C_2H_4Cl)_2S$. According to Gibson and Pope, Guthrie's compound is a disulphide of the constitution

$$CH_2Cl·CH_2·S·S·CH_2·CH_2Cl$$
(Guthrie, l.c.; Gibson and Pope, l.c.; cf. J. Soc. Chem. Ind. 1919, 38, 348, T, et seq.).

The conditions for its preparation on a technical scale by this reaction were worked out by A. G. Green.

A continuous vacuum still for its manufacture is described by Streeter (J. Ind. Eng. Chem. 1919, 11, 292).

$\beta\beta'$-Dichloroethyl sulphide, when pure, boils at 120°/34 mm., 122·5°/37 mm., and 217°/760 mm. and readily solidifies in cold weather, forming long, colourless needles or prisms, which melt at 13·5° to a liquid of sp.gr. 15°/4°=1·285. It is almost insoluble in water, and is readily hydrolysed by boiling with an alcoholic solution of soda. For other physical properties, *see* Gibson and Pope; for a number of synthetic reactions, *see* Davies (Chem. Soc. Trans. 1920, 117, 297). It causes intense inflammation and suppuration when in contact with the skin or when breathed. First used on account of its physiological and toxic action as an offensive agent by the Germans during an attack on Ypres in June, 1917.

For a method of quantitative estimation of the substance in air, *see* J. Amer. Chem. Soc. 1920, 42, 266.

The existence of the so-called *chloroethylene dithiodichloride* $(C_2H_4Cl)_2S_2Cl_2$ (?), said to be obtained by the action of C_2H_4 upon boiling S_2Cl_2, and described as a light yellow liquid with a pleasant smell, is doubtful.

On treating $\beta\beta'$-dichloroethyl sulphide with concentrated nitric acid it is converted into $\beta\beta'$-*dichloroethyl sulphoxide* $(CH_2Cl·CH_2)_2SO$, colourless plates, m.p. 51°, and afterwards the sulphone $(CH_2Cl·CH_2)_2SO_2$, m.p. 110° (Spica, Gazz. chim. ital. 1919, 49, ii. 299). Treated with bromine the dichloroethyl sulphide yields $(CH_2Cl·CH_2)_2S,2Br_2$, an orange-coloured substance which rapidly loses bromine, and is converted into a bright-yellow solid

$$(CH_2Cl·CH_2)_2S,Br_2$$
m.p. 43°-44° (Gibson and Pope).

Ethylenethiocyanate $C_2H_4(SCN)_2$; m.p. 90°. From $CH_2Cl·CH_2Cl$ and alcoholic KCNS (Sonnenschein, J. 1855, 609; Buff, Annalen, 100, 229); $CH_2Br·CH_2Br$ may be used with advantage (Glutz, *ibid.* 153, 313); forms rhombic plates slightly soluble in cold water, more so in hot, and in alcohol, decomposed by heat, volatile in steam; its vapour excites tears.

Ethylidene acetamide $CH_3CH(NHC_2H_3O)_2$; m.p. 169°; formed by acting on acetamide with aldehyde; forms large prisms decomposed by acids (Tawildarow, Ber. 5, 477).

Ethylidene acetate $CH_3·CH(C_2H_3O_2)_2$; o.p. 169°; sp.gr. 1·061 at 12°. From aldehyde and $(C_2H_3O)_2O$ at 180° (Geuther, Annalen, 106, 249); from alcoholic $C_2H_3O_2K$ and $CH_3CHCl·C_2H_3O_2$ (Schiff, Ber. 9, 304); by passing acetylene into a solution of mercuric oxide in glacial acetic acid to which an alkyl sulphate, particularly methylene sulphate, has also been added (Eng. Pat. 112766, 1918); or β-naphthalene sulphonic acid dissolved in glacial acetic acid may be used instead (Eng. Pat. 112765); has a smell like that of onions, and is decomposed by water into aldehyde and acetic acid.

Ethylidene azine $CH_3CH : N·N : CHCH_3$; b.p. 95°-96° at 760 mm.; sp.gr. 0·832 at 17°. Prepared by shaking an ethereal solution of aldehyde with an aqueous solution of hydrazine hydrate. At 180° it is unchanged, but at a higher tempera-

ture gives off nearly all its N as gas. It is fairly stable to alkalis, but is hydrolysed by acids into aldehyde and hydrazine (Curtius and Linkeisen, J. pr. Chem. 1898, [ii.] 58, 310).

Ethylidene biuret $NH<^{CO \cdot NH}_{CO \cdot NH}>CH \cdot CH_3$, *Trigenic acid*, by leading HCNO into well-cooled aldehyde (Liebig and Wöhler, Annalen, 59, 296), crystallises in small prisms, slightly soluble in water, nearly insoluble in alcohol, has a slightly acid taste. When heated, liberates CO_2, NH_3, and traces of collidine $C_8H_{11}N$ (Herzig, Monatsh. 2, 398). Is hardly decomposed by NaBrO. HNO_3 decomposes it and liberates cyanuric acid. The silver compound $AgC_4H_5N_3O_2$ forms amorphous precipitate, soluble in boiling water.

Ethylidene bromide $CH_3 \cdot CHBr_2$, b.p. 114°–115° (Tawildarow, *ibid.* 176, 12), 109°–110° at 751 mm. (Denzel, *ibid.* 195, 202), 110·5° at 760 mm. (Anschutz, *ibid.* 221, 137), 108°–110° (corr.) (Perkin, Chem. Soc Trans. 45, 523); b.p. 107°–108° (V. Meyer and Muller, J. pr. Chem. [2] 46, 168); sp.gr. 2·129 at 10° (T.), 2·1001 at 17·5°/4° 2·0891 at 20·5°/4° (Anschutz) 2·0822 at 21·5°/4°, 2·1029 at 15°, 2·0854 at 25° (P.). From C_2H_5Br and Br at 170° (Hofmann, Proc. Roy. Soc. 10, 619; Cawentou, Compt. rend. 52, 1330). Is produced by action of PCl_3Br_2 but not of PBr_5 upon aldehyde (Paternò and Pisati, Ber. 5, 289); also by heating $CH_3 \cdot CHBr$ with HBr to 100° (Reboul, Compt. rend. 70, 398). A heavy liquid; alcoholic KHS has no action upon it. On heating with water and PbO to 130°, aldehyde and HBr are produced (T.). With $SbCl_5$ gives $CH_3 \cdot CHCl_2$ (Henry, Bull. Soc. chim. [ii.] 42, 262).

Ethylidene bromiodide CH_3CHBrI; m.p. below $-20°$; b.p. 142°–143°; sp.gr. 2·50 at 1°, 2·452 at 16°. From C_2H_3Br and HI in the cold (Pfaundler, J. 1865, 483; Reboul, Annalen, 155, 212); by shaking CH_3CHI_2 with 1Br solution (Simpson, Bull. Soc. chim. [ii.] 31, 412); decomposed by alcoholic KOH or Ag_2O into HI and C_2H_3Br; Br yields CH_3CHBr_2.

Ethylidene chlorobromide $CH_3 \cdot CHClBr$; m.p. 16·6° (corr.) (Schneider, Zeitsch. physikal. Chem. 19, 157); b.p. 84°–84·5° at 750 mm., 82·7° at 760 mm. (Stadel, Ber. 15, 2563); sp.gr. 1·667 at 16°. From C_2H_4Br and concentrated HCl at 100° (Reboul, Annalen, 155, 215); from C_2H_5Cl and Br in sunlight (Denzel, *ibid.* 195, 193). By action of Cl upon C_2H_5Br (Lescœur, Bull. Soc. chim. [ii.] 29, 483). Is decomposed at ordinary temperature by alcoholic KOH on long standing; with Ag_2O gives aldehyde; and with $AgC_2H_3O_2$ forms $CH_3CH(C_2H_3O_2)_2$ (L.).

Ethylidene chloriodide $CH_3 \cdot CHClI$; b.p. 117°–119°; sp.gr. 2·054 at 19°. By agitating a mixture of CH_3CHI_2 and ICl; formed also from CH_3CHCl_2 and AlI_3 (Simpson, Bull. Soc. chim. [ii.] 31, 411).

Ethylidene or Ethidene chloride $CH_3 \cdot CHCl_2$, m.p. $-101·5°$ (Schneider, Zeitsch. physikal. Chem. 22, 233), b.p. 57·4°–57·6° at 750·9 mm., sp.gr. 1·1743 at 20°/4° (Brühl, Annalen, 203, 11), 1·2124 at 0°, 1·1805 at 22°/0°; refractive index μ_A (at 24·7°) = 1·405724. R_α = 34·1 (Kanonnikow); b.p. 57°–57·7° at 738·7 mm., 2·2013 at 0° (Pribram and Handl, Monatsh. 2, 659); b.p. 56·7°–56·9° at 749·1 mm., sp.gr. 1·1895 at 9·8°/4°, 1·11425 at 56·7°/4° (R. Schiff, Annalen, 220, 96), 57·32° (corr.) (Thorpe

and Rodger); crit. temp. 254·5° (Pawlewsky, Ber. 16, 2633); H.C.p. = 267·1 cals. (Berthelot and Ogier, Bull. Soc. chim. [ii.] 36, 68). From C_2H_5Cl and Cl (Regnault, Annalen, 33, 312); from C_2H_4O and PCl_5 (Beilstein). By action of HCl upon copper acetylene (Sabancjeff, *ibid.* 178, 111). Is prepared by passing a mixture of chlorine and C_2H_5Cl over animal charcoal heated to 250°–400° (Damoiseau, Bull. Soc. chim. [ii.] 27, 113). Is obtained as a by-product in the manufacture of chloral. Is decomposed by alcoholic KOH into HCl and C_2H_3Cl. Sodium produces · at 180°–200° hydrogen, acetylene, ethylene, ethane, and C_2H_3Cl (Tollens, Annalen, 137, 311). By action of Cl, CH_3CCl_3 and $CH_3Cl \cdot CHCl_2$ are produced.

Ethylidene di-*iso*-nitramine is formed by the interaction of $CO(Et)_2$, or $COEtMe$, and NO, in C_2H_5ONa. The lead salt is anhydrous and crystallises in cubes. The dimethyl ether forms rhombic crystals, and melts at 75°. The *iso*-nitramine itself is hydrolysed by mineral acids into acetaldehyde NH_2OH and oxides of N. With Na amalgam, is reduced to hydrazine (Traube, Annalen, 300, 120).

Ethylidene diethyl ether
$$CH_3 \cdot CH(OC_2H_5)_2 \; (v. \; \text{ACETAL}).$$

Ethylidene dimethyl ether $CH_3CH(OCH_3)_2$, *Dimethyl acetal*; b.p. 64·4° (Dancer, Annalen, 132, 240), 62·7°–63·3° at 757·6 mm. (R. Schiff, *ibid.* 220, 104); sp.gr. 0·8787 at 0°, 0·8590 at 14°, 0·8476 at 25° (D.), 0·8013 at 62·7°/4° (S.); capillarity constant at b.p. $a^2 = 4·092$ (Schiff, Annalen, 223, 74); occurs in crude wood spirit (D.): 2 volumes of wood spirit, 1 volume aldehyde, and ½ volume of glacial acetic acid are heated to 100° (Alsberg, J. 1864, 485); also by oxidation of CH_3OH and C_2H_5OH by MnO_2 and H_2SO_4 (Wurtz).

Ethylidene methyl propyl ether
$$CH_3 \cdot CH(OCH_3)(OC_3H_7)$$
b.p. 103°–105° (Bachmann, Annalen, 218, 46).

Ethylidene ethyl propyl ether
$$CH_3 \cdot CH(OC_2H_5)(OC_3H_7)$$
b.p. 124°–126° (Bachmann, *l.c.*).

Ethylidene dipropyl ether $CH_3 \cdot CH(OC_3H_7)_2$; b.p. 146°–148°, sp.gr. 0·825 at 22° (Girard, J. 1880, 695).

Ethylidene methyl *iso*butyl ether
$$CH_3 \cdot CH(OCH_3)(OC_4H_9)$$
b.p. 125°–127° (Claus and Trainer, Ber. 19, 3005; Bachmann, *l.c.*).

Ethylidene ethyl *iso*butyl ether
$$CH_3 \cdot CH(OC_2H_5)(OC_4H_9)$$
b.p. 155° (Claus and Trainer, *l.c.*).

Ethylidene di *iso*butyl ether $CH_3 \cdot CH(OC_4H_9)_2$; b.p. 168°–170°, sp.gr. 0·816 at 22° (Claus and Trainer, *l.c.*; Girard, *l.c.*).

Ethylidene methyl *iso*amyl ether
$$CH_3 \cdot CH(OCH_3)(OC_5H_{11})$$
b.p. 141°–144° (Bachmann, *l.c.*).

Ethylidene ethyl *iso*amyl ether
$$CH_3 \cdot CH(OC_2H_5)(OC_5H_{11})$$
b.p. 165°–167° (Claus and Trainer, *l.c.*).

Ethylidene di isoamyl ether $CH_3CH(OC_5H_{11})_2$
b.p. 210·8° (corr.), sp.gr. 0·8347 at 15° (Claus and Trainer, *l.c.*).

Ethylidene hydramine $CH_3 \cdot CH(OH)NH_2$ v. *Aldehyde-ammonia*, art. ALDEHYDE.

Ethylidene imine $CH_2CH:NH$; m.p. about 85° ; b.p. 123°–124°. If aldehyde ammonia be kept *in vacuo* over H_2SO_4 for several days, the imine is formed. It crystallises in brilliant colourless crystals, which have an odour like acetamide. It is soluble in water, EtOH, CH_3COOH, $CHCl_3$, C_6H_6, and toluene. The vapour density at 260° agrees with the simple formula, but at lower temperatures the V.D. is higher. It forms a picrate, and combines with HCN to form $CH_3 \cdot CH(NH_2)CN$. It polymerises to form trimeric ethylidine imine

$$CHMe \overset{NH \cdot CHMe}{\underset{NH \cdot CHMe}{\overbrace{\hspace{1.5cm}}}} NH$$
which forms a trinitroso- derivative, with N_2O_3 in $CHCl_3$; opaque yellow-white needles, melting at 161° (Delépine, Compt. rend. 1897, 125, 951 ; and 1907, 144, 853).

Ethylidene iodide CH_3CHI_2 ; b.p. 177°–179° ; sp.gr. 2·84 at 0°. By combination of C_2H_2 and HI (Berthelot, Annalen, 132, 122 ; Semenow, Zeitsch. Chem. 1865, 725) ; from CH_3CHCl_2 and Al_2I_6 (Gustavson, J. Russ. Phys. Chem. Soc. 6, 164) ; from C_2H_5Br and HI (Friedel, Ber. 7, 823). Decomposed by alcoholic KOH into HI and C_2H_3I.

Ethylidene malonic acid $CH_3 \cdot CH:C(COOH)_2$; only known in combination, the *ethyl ester* $CH_3CH:C(COOC_2H_5)_2$, b.p. 220°, 115°–118° at 17 mm. ; sp.gr. 1·0435 at 15°. From $CH_2(CO_2Et)_2$ (1 mol.) aldehyde (2 mols.), and $(C_2H_3O)_2O$ (1½ mols.) at 100° (Komnenos, Annalen, 218, 157). An ethereal oil smelling of camphor ; by long contact with $Ba(OH)_2$ in the cold yields ethoxy malonic acid $C_5H_8O_5$, malonic acid $C_3H_4O_4$, and aldehyde.

Ethylidene oxide $CH_3 \cdot CHO$ v. ALDEHYDE.

Ethylidene ethylene oxide

$$CH_3 \cdot CH \overset{OCH_2}{\underset{OCH_2}{\big\langle}}$$
b.p. 82° (Verley, Bull. Soc. chim. [iii.] 21, 276), 82·5° at 765·8 mm. ; sp.gr. 1·002 at 0°. From aldehyde and excess of glycol at 100° (Wurtz, Compt. rend. 53, 378 ; Annalen, 120, 328) ; a liquid with irritating smell, soluble in 1½ vols. water, from which $CaCl_2$ separates it ; with acetic acid gives glycol diacetate.

Ethylidene ethoxyacetate $CH_3CH(OEt)OAc$; b.p. 125°–130° ; sp.gr. 0·941. By heating together acetal and acetic anhydride for 3 hours at 150°. A pleasant-smelling oil, slowly decomposed by cold water into alcohol, aldehyde, and acetic acid, rapidly on boiling.

Ethylidene sulphonic acids.

1. *Ethylidene hydroxysulphonic acid*

$$CH_3CH(OH)(HSO_3)$$
Salts of this acid are formed by action of aldehyde upon alkaline hydrogen sulphites ; they are crystalline bodies, soluble in water, and decomposed on heating into water, aldehyde, and sulphites.

2. *Ethylidene chlorsulphonic acid*

$$CH_3 \cdot CH \cdot Cl(SO_3H)$$
obtained by action of CH_3CHCl_2 upon neutral alkaline sulphites at 140° ; the salts are crystalline, and the acid is fairly stable.

3. *Ethylidene disulphonic acid*

$$CH_3CH(SO_3H)_2$$
By oxidation of trithioaldehyde $(C_6H_6S_3)$ or thialdin by $KMnO_4$ solution (Guareschi, Gazz. chim. ital. 9, 75 ; Annalen, 222, 302). 10 grams thialdin are treated with 30–35 grams $ZnMn_2O_8$ and 300 grams water ; after filtering, BaH_2O_2 is added and excess of Ba precipitated by CO_2 ; the Ba salt is then precipitated by alcohol. It forms a strongly acid oily liquid, very soluble in water and alcohol, and is very stable ; forms stable salts $Na_2C_2H_4S_2O_6,H_2O$, small silky crystals soluble in 6071 parts of alcohol (90 p.c.) at 24·5° ; $K_2C_2H_4S_2O_6,2H_2O$ forms large transparent crystals soluble in 1·56 parts of water at 17°.

ETHYL ACETATE v. *Alkyl acetates*, art. ACETIC ACID.

ETHYL-m-AMINOPHENOL
(1) Prepared by adding monoethyl aniline to fuming sulphuric acid, converting the ethyl aniline-m-sulphonic acid into the sodium salt, melting this with potassium hydroxide at 220°, dissolving the product in water, and acidifying with hydrochloric acid. The filtered solution is neutralised with sodium carbonate, and the mono ethyl-m-amino phenol extracted with benzene (Bad. Anil. und Soda Fabrik. D. R. P. 48151).

(2) Sodium-m-phenylene oxamate

$$C_6H_4(NH \cdot CO \cdot CO_2Na)$$
is mixed with sodium ethyl sulphate, alcohol, and sodium carbonate, and heated in an autoclave fitted with a stirrer to 180°. After distilling off the alcohol, and extracting the mass with water, the residue is boiled with dilute sulphuric acid, and the cooled solution of ethyl-m-phenylenediamine sulphate is mixed with sodium nitrite, warmed, and neutralised with sodium carbonate (*idem.* D. R. P. 76419).

(3) Aniline-2 : 5-disulphonic acid is neutralised with alkali, and the solution diluted, mixed with sodium ethyl sulphate, and heated in an autoclave to 170°–180°. Sodium carbonate is added to the cooled solution which precipitates ethyl-m-aminophenol (Farberfabrik. vorm. F. Bayer & Co., D R. P. 82765) ; m.p. 62° ; b.p. 176°/12 mm.

ETHYLANILINE
Is manufactured by heating aniline hydrochloride with alcohol in an autoclave at 180°. The hydrochloride separates out on cooling. Or aniline hydrochloride may be boiled with diethylaniline under a reflux condenser, hydrochloric acid added, and the hydrochloride separated by crystallisation. The base boils at 206°/760 mm. ; sp.gr. 0·954 at 18°. Yields methyl ethyl aniline on methylation, and benzyl ethyl aniline on benzylation.

ETHYLBUTYLACETIC ACID v. OCTOIC ACIDS.

ETHYL-iso-BUTYLACETIC ACID v. OCTOIC ACIDS.

ETHYL BUTYRATE v. BUTYRIC ACID.

ETHYL DIPHENYLAMINE v. DIPHENYLAMINE.
ETHYLKETENE v. KETENES.

ETHYLKETENECARBOXYLATE v. KETENES.

ETHYLMALONIC ACID v. GLUTARIC ACID and MALONIC ACID.

ETHYLMORPHINE v. OPIUM.

**ETHYLPROPYLACETIC ACID** v. HEPTOIC ACIDS.

ETHYL-o-TOLUIDINE

.⋅CH₃

NH⋅C₂H₅

May be prepared by heating a mixture of o-toluidine, ethyl alcohol, and hydrochloric acid, or a mixture of o-toluidine, ethyl alcohol, and a small quantity of iodine. Boils at 213°–214°; sp.gr. 0·9534.

EUBORNYL. Trade name for bornyl-α-bromo-isovalerate, obtained by brominating chloro-isovaleric acid and esterifying borneol with the product.⋅ A syrupy aromatic liquid; b.p. 175°–178°. Used as a sedative (v. SYNTHETIC DRUGS).

α-EUCAINE. Methyl ester of N-methyl-benzoyl-triacetone-alkamine carboxylic acid. First obtained by Merling (Ber. Deut. pharm. Ges. 1897, 173) by acting on acetone with ammonia to form triacetoneamine, treating this with hydrocyanic acid to form the cyanhydrin,
which by hydrolysis yields triacetone-alkamine-carboxylic acid. On benzoylation and methylation it forms α-eucaine. Formerly employed as a substitute for cocaine. Its use is now superseded by β-eucaine, which is less painful and not so toxic.

β-EUCAINE (benzoyl-vinyl-diacetone-alkamine)

CH—O⋅CO⋅C₆H₅

H₂C   CH₂

(CH₃)₂C   CH⋅CH₂

NH
A local anæsthetic, used chiefly as the lactate or hydrochloride, in 2–3 p.c. solution. Is prepared by condensing acetone with oxalic acid and ammonia to form the hydrogen oxalate of diacetoneamine, condensing this with paraldehyde to produce the cyclic vinyl-diacetoneamine (Harries, Annalen, 1897, 328; 1898, 346), reducing by means of sodium amalgam to a mixture of the cis and trans forms of the trimethyl hydroxy piperidine (D. R. P. 95622), treating with sodium amylate to produce the cis form only of this compound (D. R. P. 95621), and treating with benzoyl chloride (D. R. P. 97672), and finally with hydrochloric or lactic acid to obtain the corresponding salt of β-eucaine.

2 (Acetone + Ammonia) → Diacetoneamine → Vinyl-diacetoneamine ↓ Reduction → Vinyl-diacetone-alkamine

Base of β-Eucaine
EUCAINE, EUCHININ, EUCODIN, EUCOL, EUDOXIN v. SYNTHETIC DRUGS.

EUCAIRITE. Selenide of silver and copper (Ag,Cu)₂Se, crystallising in the cubic system. It is lead-grey, but usually tarnished and dull; sp.gr. 7·5. It is found massive and granular embedded in calcite in the Skrikerum copper mine in Småland, Sweden, and in the Cacheuta mine in the province of Mendoza, Argentina.

L. J. S.

EUCALYPTOL. The volatile oil of the leaves of *Eucalyptus globulus*, consists mainly of a body C₁₀H₁₈O; b.p. 176°–177°; sp.gr. 0·923 at 16°. It is optically inactive, has a camphor-like smell, and is probably identical with cineol and cajeputol (v. OILS, ESSENTIAL).

EUCALYPTUS GUM v. KINO.

EUCALYPTUS MACRORHYNCHA. *Eucalyptus macrorhyncha* (F. v. M.), a fair-sized tree, is the 'red stringy bark' of New South Wales,

and the ordinary stringy bark tree of Victoria (Smith, Chem. Soc. Trans. 1898, 73, 697).

The leaves yield under favourable conditions a very large amount (10 p.c.) of a crystalline glucoside termed by Smith *myrticolorin*, which can be isolated in the crude condition by mere extraction with boiling water. The solution on cooling became semi-solid owing to the separation of crystals, and these can be purified by extraction with ether to remove chlorophyll and crystallisation first from alcohol and subsequently from water. It formed pale-yellow needles, gave on hydrolysis quercetin and glucose, and at first appeared to be a new glucoside of quercetin. Though very similar to rutin its identity with this glucoside was unsuspected in that rutin by hydrolysis was presumed at that time to give quercetin and 2 molecules of rhamnose (Schunck, ibid. 1888, 53, 264). Schmidt in 1908 (Arch. Pharm. 246,

214), however, pointed out that rutin in this manner yields not only rhamnose but glucose, and the probability that myrticolorin—as also viola quercitrin and osyritrin—were identical with rutin was subsequently confirmed by Perkin (*ibid.* 1910, 97, 1776). A. G. P.

EUCALYPTUS OIL *v.* OILS, ESSENTIAL.

EUCALPYTUS RESIN *v.* RESINS.

EUCLASE. Basic silicate of aluminium and glucinum (GlO, 17·3 p.c.) HGlAlSiO₅, crystallising in the monoclinic system. The well-developed crystals have a very perfect cleavage parallel to the plane of symmetry, hence the name, from εὖ, well, and κλάσις, fracture. They are colourless, yellow, green, or blue ; sp.gr. 3·1 (higher than that of beryl) ; H. 7½. The mineral is not attacked by acids, and the water is expelled only at a high temperature. It is found as single isolated crystals in gold washings at Ouro Preto in Brazil, and on the River Sanarka in the southern Urals. Minute crystals have also been found in mica-schist in the Grossglockner district of the Austrian Alps, and in granite in the Fichtelgebirge, Bavaria. The mineral is occasionally cut as a gem-stone, but it has the drawback that it readily splits along the perfect cleavage. L. J. S.

EUCODAL. Trade name for the hydrochloride of dihydrohydroxycodemone. Used as a narcotic.

EUCODEINE. Syn. for codeine methyl bromide.

EUCOL. Trade name for guaicol acetate.

EUCOLITE *v.* EUDIALYTE

EUCRYPTITE. Orthosilicate of aluminium and lithium (Li₂O, 11·9 p.c.) LiAlSiO₄, crystallising in the hexagonal system and belonging to the nephelite group of minerals. It occurs intimately intergrown with albite as an alteration product of spodumene at Branchville, Connecticut. An artificial orthorhombic form of LiAlSiO₄, dimorphous with eucryptite, has been called *pseudo-* or *β-eucryptite* (F. M. Jager and A. Simek, 1914). L. J. S.

EUCUPIN. Trade name for *iso*-amylhydrocuprein.

EUDESMIN C₂₂H₂₆O₆ occurs in the kinos of eucalyptus species, the oils of which contain cineole and pinene, but not phellandrene. It may be obtained by extracting a concentrated aqueous solution of the kino with ether, purifying by treatment with chloroform, and crystallising from methyl alcohol. Colourless prismatic needles, m.p. 107°, $[a]_D^{21}$ −64·1° (in chloroform). Contains 4 methoxy- groups, and is unacted upon by hydroxyl or ketone reagents. Red solution with sulphuric acid. Nitric acid converts it into *dinitroeudesmin*, colourless needles, m.p. 214°. Boiling conc. nitric acid forms 4 : 5-dinitroveratrole (2 mols). Chlorine in acetic acid solution gives *dichloroeudesmin* ; colourless rectangular plates, m.p. 163°. *Dibromoeudesmin*, prepared in like manner, colourless needles, m.p. 172°, $[a]_D^{22}$ +69·4° (in chloroform) ; this, on oxidation with permanganate, gives 6-bromoveratric acid, m.p. 184°. *Diiodoeudesmin*, needles, m.p. 175° (Robinson and Smith, J. Roy. Soc. New South Wales, 1914, 48, 449).

EUDIALYTE. Silicate and zirconate (ZrO₂,

14–16 p.c.) of sodium, calcium, and ferrous iron, occurring as large well-developed rhombohedral crystals. These are brownish-red or rose-red in colour ; sp.gr. 2·9–3·1. The mineral occurs in nepheline- and sodalite syenites in the Julianehaab district in south Greenland, at Magnet Cove in Arkansas, on Sedlovatoi Island in the White Sea, and on the Kola peninsula in Russian Lapland. The name eudialyte, from εὖ, well, and·διαλύειν, to dissolve, refers to the fact that the mineral is readily decomposed by acids.

Eucolite, a closely related variety, differs in being optically negative, instead of positive. This is from the nepheline-syenites of the Langesundsfjord in Norway. L. J. S.

EUDRENINE. A solution containing eucaine and adrenaline.

EUFORMOL. Dextrin formaldehyde.

EUGENOL $(HO)(CH_3O)C_6H_3·CH_2·CH : CH_2$ $(C_3H_5 : CH_3O : HO = 1 : 3 : 4)$ occurs in oil of cloves from the leaves of *Eugenia caryophyllata* (Thunb.) (Bonastre and Ettling, Annalen, 9, 68) ; in the oil from the leaves of the Ceylon cinnamon tree (Stenhouse, Annalen, 95, 103 ; Schimmel & Co., Chem. Zentr. 1902, ii. 1486) ; from *Cinnamomum pedatinervium* (Meissn.) (Goulding, Chem. Soc. Trans 1903, 1101), *C. Tamala* (Nees et Eberm.) (Schimmel & Co., Chem. Zentr. 1910, i. 1720), *C. cassia* (Blume), and *C. zeylanicum* (Nees) (Duyk, Chem. Zentr. 1896, ia. 358 ; Weber, Arch. Pharm. 230, 232) ; ·from the fruit of *Pimenta officinalis* (Lindl.) (Bonastre, *l.c.* ; Oeser, Annalen, 131, 277) ; from the sap of *Acacia Farnesiana* (Willd.) (Walbaum, J. pr. Chem. 68, [2] 235) ; in the oil from *Ocimum Basilicum* (Linn.) (Schimmel & Co., Chem. Zentr. 1900, i. 906) ; in calamus oil (Thoms and Beckstroem, Ber. 1902, 3187) ; in Ylang Ylang oil (Schimmel & Co., Chem. Zentr. 1903, i. 1087 ; ii. 272) : in olive oil from Pugh (Canzoneri, Gazz. chim. ital. 1897, 27, ii. 1) ; in oil of nutmeg (Power and Salway, Chem. Soc. Trans. 1907, 2041) ; in sassafras leaves and bark (Pomeranz, Monatsh. 11, 101 ; Power and Kleber, Chem. Zentr. 1897, ii. 42) ; in the oil from the leaves of the bay tree (Mittmann, Arch. Pharm. 27, [3] 539) ; in oil from Maltese oranges (Gildemeister and Stephan, Arch. Pharm. 235, 583), and in other ethereal oils The methyl ether of eugenol

$$(CH_3O)_2·C_6H_3·CH_2·CH : CH_2$$
occurs in the oil of *Asarum canadense* (Linn.) (Power and Lees, Chem. Soc. Trans. 1902, 67), of *A. arifolium* (Michx.) (Miller, Arch. Pharm. 240, 371) ; in oil from Paracoto bark (Jobst and Hesse, Annalen, 199, 75 ;· Wallach and Rheindorff, *ibid.* 271, 300) ; in Ylang Ylang oil ; in oil from the bark of *Cinnamomum pedatinervium* ; in oil from Maltese oranges (*v. supra*) ; and in oil of citron (Schimmel & Co., Chem. Zentr. 1899, ii. 879).

Oil of cloves, which contains eugenol and a terpene as the chief constituents, is treated with potash ; the potassium salt of eugenol separates, is pressed out, washed with alcohol, and the eugenol set free by the addition of a mineral acid (Wasserman, Annalen, 179, 369). It is obtained by a similar process from oil of cinnamon leaves or from that of *Pimenta officinalis* (Lindl.). Another method consists in separating eugenol from oil of cloves by means of the compound it forms with sodium acetate (Chem.

Werke Byk D. R. P. 100418; Chem. Zentr.
1899, i. 764). In the former process, a residue
is left after treating the oil of cloves with
potash, and by distilling this under reduced
pressure, acetyl eugenol, m.p. 29°, is obtained
(Erdmann, J. pr. Chem. 1897, [2] 56, 146). By
reducing coniferin in alkaline solution with
sodium amalgam, eugenol is formed (Chiozza,
Chem. Zentr. 1888, 443). Methyl eugenol (allyl
guaiacol) has been prepared synthetically by
treating veratrol (dimethylcatechol) with allyl
iodide and zinc-dust (Moureau, Compt. rend.
121, 721).

Pure eugenol is a colourless oil; b.p. 244·5°
(Frankforter and Lando, J. Amer. Chem. Soc. 27,
641), 247·5° (Wassermann, Annalen, 179, 366),
253·5° (corr.) (Perkin, Chem. Soc. Trans. 1896,
1247); sp.gr. 1·0785 at 4°/4°, 1·0734 at 10°/10°,
1·0663 at 20°/20°; specific magnetic rotation,
2·1974; molecular magnetic rotation at 15°,
18·727 (Perkin, l.c.); dielectric constant, 6·0
(Mathews, J. Phys. Chem. 9, 641); μ_D 1·54437;
sp. heat, ·0·5024; mol. heat of combustion,
1304 cals. (F. & L. l.c.). Eugenol reddens
litmus, smells strongly of cloves, and has a
burning taste. It does not reduce Barreswil's
solution, but reduces ammoniacal silver solu-
tions on long standing. Eugenol may be
detected by the following reactions: (i.) ferric
chloride imparts a blue colour to its alcoholic
solution; (ii.) zinc chloride yields a transitory
pale-yellow colour; (iii.) sulphuric acid gives
first a brown colour, changing quickly to purple
and finally to wine-red; (iv.) Burgess (Analyst,
1900, 25, 265) makes use of a reagent prepared
by dissolving 10 grams of mercuric salt in 25 p.c.
sulphuric acid, and making the solution up to
100 c.c. with the latter. By shaking 2 c.c. of
eugenol with 5 c.c. of the reagent, and allowing
the solution to stand, a pale violet colour is
developed. (For estimation of eugenol in oil
of cloves, v. Verley and Bösling, Ber. 1901,
3359; Thoms, Chem. Zentr. 1903, 27, 954;
Arch. Pharm. 241, 592; Spurge, Pharm.
J. 1903, [4] 16, 701, 757; Schimmel & Co.,
Chem. Zentr. 1903, ii. 1124; Reich, Zeitsch.
Nahr. Genussm. 1909, 18, 401.)

Eugenol and its derivatives are readily con-
verted into the corresponding derivatives of
the isomeric isoeugenol (v. infra), which on
oxidation yields vanillin and its derivatives.
Chromic acid oxidises eugenol to acetic acid,
carbon dioxide, and water (Wassermann, l.c.);
chromyl chloride, however, combines with
eugenol, and on decomposing the product with
water, vanillin can be extracted (Novarine,
U.S. Pats. 365918, 365919; Ber. Ref. 1896,
812). Nitric acid oxidises eugenol to oxalic
acid and a resin, but in ethereal solution, 5-
nitro-eugenol is formed (v. infra). Ferric
chloride oxidises it to dehydroeugenol, m.p.
105°–106° (Cousin and Hérissey, Compt. rend.
1908, 146, 1413). Oxidised with potassium
permanganate, eugenol yields homovanillin,
vanillin, and vanillic acid (Erlenmeyer, Ber.
1876, 273). Hydrogenisation of either eugenol
or isoeugenol in the presence of platinum black,
yields dihydroeugenol (propylguaiacol), b.p.
246°–248° (Fournier, Bull. Soc. chim. [4] 7, 23).

5-Nitroeugenol is prepared by acting on
eugenol in ethereal solution with nitric acid.
It forms large triclinic crystals, m.p. 43°–44°

(Weselsky and Benedikt, Monatsh. 3, 388).
With tin and hydrochloric acid, it produces
aminochlorhydroeugenol hydrochloride; amino-
chlorhydroeugenol melts at 97°. Nitroeugenol,
heated with acetic anhydride and sodium acetate,
forms nitro-aceto-eugenol, m.p. 61°, which,
oxidised by potassium permanganate at 70°
(Tiemann, Ber. 1876, 418), yields nitrovanillic
acid $C_6H_2(COOH)(OCH_3)(OH)NO_2$, decom-
posing at 210° without melting.

Acyl and aryl derivatives of eugenol are
obtained by treating eugenol with acyl or aryl
anhydrides in the cold, in presence of some con-
densing agent such as sulphuric acid, zinc
chloride, pyridine, &c. The chlorides may be
substituted for the anhydrides (Merck, D. R. P.
103581, 109445; Chem. Zentr. 1899, ii. 927;
1900, ii. 407; Riedel, D. R. P. 189333; Chem.
Zentr. 1908, i. 185; Pond & Beers, J. Amer.
Chem. Soc. 19, 825). Acetyl eugenol, which
occurs in oil of cloves (Erdmann, J. pr. Chem.
1897, [2] 56, 146), melts at 29°, and boils at
281°–282° (752 mm.) (Freyss, Chem. Zentr.
1899, i. 835); benzyl eugenol has b.p. 235°,
and on heating with potash and subsequently
with potassium dichromate and sulphuric acid,
the benzyl ether of vanillin is obtained (Boeh-
ringer and Sons, D. R. P. 65937; Ber. Ref.
1893, 211). Eugenol carbonate, m.p. 93°–94°, is
obtained by passing phosgene gas into an alkaline
solution of eugenol; on treatment with ammonia,
the carbamate is formed (F. von Heyden Nachf.
D. R. P. 58129; Ber. Ref. 1892, 186); the car-
bonate can also be obtained from eugenol and
the diphenyl ester of carbonic acid (D. R. P.
99057; Chem. Zentr. 1898, ii. 1190). On
adding eugenol to a cooled mixture of pyridine
and chlorsulphonic acid in carbon disulphide,
potassium eugenyl sulphate, m.p. 203°, is ob-
tained; the latter is transformed by heating
with excess of potash into potassium isoeugenyl-
sulphate, m.p. 223°, which, on oxidation with
ozone, yields potassium vanillin sulphate
(Verley, Bull. Soc. chim. 1901, [3] 25, 46).

Eugenyl acetic acid

$$C_6H_3(CH_2 \cdot CH : CH_2)(OCH_3)(OCH_2 \cdot CO_2H)$$
is obtained by heating eugenol with chloracetic
acid in the presence of sodium hydroxide for
20 hours, and decomposing the sodium salt thus
formed with hydrochloric acid; m.p. 75°. By
heating the acid with potash and amyl alcohol
at 150°, isoeugenyl acetic acid, m.p. 92°–94°, is
produced; and oxidation of the latter with
potassium permanganate yields vanillin acetic
acid (Bassmann and Krafft, Ber. 1895, 1870).

Eugenyl phosphoric acid is obtained by
treating eugenol with phosphorus oxychloride
and decomposing the resulting chloride with
water; m.p. of anhydrous acid, 105° (Boehringer
& Sons, D. R. P. 98522; Chem. Zentr. 1898,
ii. 950; Oeser, Annalen, 131, 277). On
heating with alcoholic potash, isoeugenyl
phosphoric acid is obtained, and by heating the
acid sodium salt of the latter to 150°, isoeugenol
is obtained quantitatively.

Eugenyl alcohol is prepared by heating
eugenol in 20 p.c. sodium hydroxide solution
with formaldehyde at 60°; m.p. 37°–38°
(Monasse, Ber. 1902, 3894).

Eugenol glucoside, m.p. 132°, is produced by
the action of acetochlorhydrose on the potassium

salt of eugenol (Michael, Amer. Chem. J. 6, 336).

Eugenol and isoeugenol form compounds with proteins which are stated to be used in the treatment of tuberculosis (Belart, Eng. Pat. 9246, 26075 ; Fr. Pat. 389889 ; J. Soc. Chem. Ind. 1908, 998 ; 1909, 1325).

(For compounds with iodine, v. F. v. Heyden Nachf. D. R. P. 70058 ; Ber. Ref. 1893, 915 ; Ingle, J. Soc. Chem. Ind. 1904, 422.) The N-substituted aminoethyl compounds of eugenol- and isoeugenol- acetamide are stated to be used as local anæsthetics (Einhorn, D. R. P. 208255 ; J. Soc. Chem. Ind. 1909, 491).

Bromine in excess forms with eugenol, di-bromeugenol dibromide, m.p. 118°-119°, which, treated with zinc-dust in alcoholic solution, yields dibromeugenol, m.p. 59° (Chasanowitz and Hell, Ber. 1885, 823 ; Auwers, ibid. 1901, 4266). By treating eugenol with bromine in chloroform at 0°, bromeugenol is formed (Lando, J. Amer. Chem. Soc. 1905, 27, 641). Tribrom-eugenol and other brom- derivatives (v. Lando, l.c. ; Auwers and Müller, Ber. 1902, 35, 114 ; Hell and Anwandter, ibid. 1895, 2085).

Eugenol methyl ether occurs in several ethereal oils, and can be obtained from veratrol (v. supra). It is also obtained by the action of methyl iodide and caustic potash on eugenol (Ciamician and Silber, Ber. 1890, 1164) ; b.p. 247°-248°. It is readily converted into iso-eugenol methyl ether, b.p. 263°, which yields methyl vanillin and veratric acid on oxidation with potassium dichromate and sulphuric acid.

isoEugenol

$(HO)(CH_3O) C_6H_3 \cdot CH:CH \cdot CH_3(C_3H_5:CH_3O:HO=1:3:4)$

occurs in small quantities in oil of nutmeg (Power and Salway, Chem. Soc. Trans. 1907, 2041), and as the methyl ether in the oil from Asarum arifolium (Michx.) (Miller, Arch. Pharm. 240, 371). It is prepared by adding 5 parts of eugenol or an equivalent quantity of oil of cloves to 12·5 parts of potash, dissolved in 18 parts of amyl alcohol, and heating for 16-20 hours at 140°. The product is steam distilled, and the residue acidified with sulphuric acid. The isoeugenol separates out, is washed with sodium carbonate solution, and purified by distillation (Tiemann, Ber. 1891, 2870 ; 1894, 2580 ; Lairi, Eng. Pat. 17547 ; J. Soc. Chem. Ind. 1891, 854 ; Haarmann and Reimer, D. R. P. 57808 ; Ber. Ref. 1892, 94). The amyl alcohol may be replaced by methyl, ethyl, or butyl alcohols (Gassmann, Compt. rend. 124, 38 ; F. von Heyden Nachf. D. R. P. 70274 ; J. Soc. Chem. Ind. 1892, 633). Other methods are to heat eugenol with 4 parts of caustic potash and some water at 220° (Einhorn and Frey, D. R. P. 76982 ; Frdl. iii. 863 ; Ber. 1894, 2455) ; to heat the alkali derivative of eugenol to 200° in the absence of air (Fritzsche, D. R. P. 179948 ; J. Soc. Chem. Ind. 1907, 1216) ; and to heat the acid sodium salt of iso-eugenylphosphoric acid to 150° (v. Eugenyl-phosphoric acid).

isoEugenol forms colourless crystals, m.p. 33°; b.p. 264°-265° (J. Soc. Chem. Ind. 1892, 633), 193·5° (100 mm.), and 266·5°-268·5° (760 mm.) ; sp.gr. 1·0994 at 4°/4°, 1·0944 at 10°/10°, 1·0872 at 20°/20° ; specific magnetic rotation ?·5578 ; molecular magnetic rotation at 15°, 21·469 (Perkin, Chem. Soc. Trans. 1896, 1247). On

oxidation, isoeugenol and its derivatives yield the corresponding derivatives of vanillin. Thus isoeugenol, when treated with sodium peroxide, yields vanillin itself (Haarmann and Reimer, Eng. Pat. 11952, 14925.; J. Soc. Chem. Ind. 1895, 506 ; 1897, 623 ; cf. Majert, D. R. P. 82924 ; Ber. Ref. 1895, 878). Ozone oxidises isoeugenol in the same way, and vanillin is also produced by the electrolysis of the sodium salt of isoeugenol and subsequent addition of acid (Otto and Varley, U.S. Pat. 553039, 553593 ; Ber. Ref. 1896, 249 ; cf. Otto, Ann. Chim. Phys. 1898, [viii.] 13, 120). Ferric chloride oxidises isoeugenol to dehydroisoeugenol, m.p. 133° (Cousin and Hérrisey, Compt. rend. 1908, 147, 247).

isoEugenol is readily polymerised by small quantities of mineral acids, acid chlorides, or metallic haloids, forming diisoeugenol, which crystallises in colourless needles, m.p. 178° (F. von Heyden Nachf. D. R. P. 70274 ; J. Soc. Chem. Ind. 1892, 633), 180° (Puxeddu, Gazz. chim. ital. 39, i. 131). Similarly, the ethyl ether of isoeugenol, when dissolved in alcohol and treated with hydrogen chloride for some hours, polymerises into diethyldiisoeugenol, m.p. 130° (Puxeddu, l.c. ; Wassermann, Annalen, 179, 375).

The acyl and aryl derivatives are obtained by methods similar to those employed for the eugenol compounds, but the solutions must be kept cool to prevent polymerisation taking place ; acetyl isoeugenol, m.p. 79°-80° ; benzoyl iso-eugenol, m.p. 103°-104° ; benzyl isoeugenol, m.p. 48° (Pond and Beers, J. Amer. Chem. Soc. 19, 825 ; Merck, D. R. P. 103581, 109445 ; Chem. Zentr. 1899, ii. 927 ; 1900, ii. 407 ; Haarmann and Reimer, D. R. P. 57568 ; Ber. Ref. 1892, 93). If acetyl chloride is added to isoeugenol at 54°, and the temperature is finally raised to 80°, diacetyldiisoeugenol is obtained, and by hydrolysis with acids, diisoeugenol is formed (Tiemann, Ber. 1891, 2870 ; 1894, 2580). Methylene chloride reacts with an alkaline solution of eugenol forming methylenediisoeugenol, m.p. 50°-52°, which on oxidation yields methyl-enedivanillin (Lesault & Co., D. R. PP. 75264, 76061 ; Ber. Ref. 1894, 812, 928).

5-Nitroisoeugenol is formed by the action of nitric acid on isoeugenol in acetic acid solution ; on recrystallisation from isobutyl or amyl alcohols it forms a reddish-yellow mass, which decomposes at about 150° (Puxeddu and Comella, Gazz. chim. ital. 1906, 36, ii. 450).

isoEugenol carbonate is prepared in the same way as eugenol carbonate (q.v.) (F. von Heyden Nachf. D. R. P. 61848 ; Ber. Ref. 1892, 486).

By adding excess of bromine to isoeugenol, bromisoeugenol dibromide, m.p. 138°-139°, is formed. If only 1 molecule of bromine is added, an unstable isoeugenol dibromide, m.p. 95°, is produced Di- and tri-isoeugenol dibromides have been prepared (Hell and Portman, Ber. 1895, 2088 ; Hell and Bauer, Ber. 1904, 1128 ; Zincke and Hahn, Annalen, 329, 1).

isoEugenol methyl ether occurs in the oil of Asarum arifolium (v. supra). It can be pre-pared by warming eugenol methyl ether with alcoholic potash (Ciamician and Silber, Ber. 1890, 1165) or by treating isoeugenol with dimethyl sulphate and aqueous potash (Mannich, Arch. Pharm. 248, 127) ; b.p. 263°.

*iso*Eugenol is distinguished from eugenol by the following reactions : (i.) ferric chloride gives an olive-green colouration with its alcoholic solution ; (ii.) zinc chloride, a bright rose-pink colour ; (iii.) sulphuric acid, a rose-pink colour changing to light-brown.

EUGUFORM, EUMYRDIN, EUPHTHAL-MIN, EUPORPHIN v. SYNTHETIC DRUGS.

EUKODAL. Oxydihydrocodeinone hydrochloride. Used as a narcotic (Freund and Speyer, Münch. med. Woch. 1917, 64, 380).

EULATIN. Trade name for a mixture of *p*-bromobenzoic acid, *o*-aminobenzoic acid, and antipyrine.

EUONYMUS (*Euonymi Cortex*, B.P.) (deleted from U.S. P. 1916) is the root bark of *E. atropurpureus* (Jaquin), a shrub indigenous to the United States, and known there as ' wahoo ' or ' burning bush.' It is said to contain an amorphous bitter principle and a glucoside *euonymin* : the latter, according to Hans Meyer (*cf.* Schmiedeberg, Arch. exp. Path. Pharm 1883, 16, 163), possesses a digitalis-like action, causing systolic arrest of the frog's heart in very small doses. Nothing is known about it chemically. For an account of earlier investigations, *v.* Rogerson (Chem. Soc. Trans. 1912, 101, 1040), who isolated dulcitol (2·1 p.c. of the bark) and other substances, but could not find any glucoside. The latter negative result may have been due to hydrolysis by the steam distillation employed. The name euonymin is also applied to dried extracts of varying composition, brown euonymin being from the root bark, and green (containing chlorophyll) from the stem bark.

<div align="right">G. B.</div>

EUPAD. An antiseptic consisting of equal weights of chloride of lime and boric acid.

EUPHORBIC ACID, EUPHORBIUM, EUPHORBONE v. GUM RESINS.

EUPHORINE v. SYNTHETIC DRUGS.

EUPHRASIA TANNIN v. TANNINS.

EUPHYLLIN. Trade name for a compound of theophylline with ethylene-diamine. A white crystalline soluble powder, used as a diuretic (*v.* SYNTHETIC DRUGS).

EUPITTONIC ACID, *Eupittone*, *Pittacal*, *Hexamethoxyaurin* $C_{25}H_{26}O_9$

$$O: \langle\!\!\!\!\!\bigcirc\!\!\!\!\!\rangle : C[C_6H_2(OMe)_2OH]_2$$
$$\overset{OMe}{\underset{OMe}{}}$$
Pittacal is a blue colouring matter obtained by Reichenbach in 1835 from the high-boiling portions of beechwood tar. Grätzel also from the same products obtained a brown substance which gave the same blue colour reaction with baryta as the pittacal of Reichenbach. The colouring matter, which only exists in small quantity in this brown substance, was extracted and examined by Liebermann (Ber. 9, 334). It is an orange-red crystalline powder, soluble in alcohol and acetic acid, forming brown solutions. It forms with alkalis purple, and with ammonia blue solutions, from which carbon dioxide precipitates blue salts, soluble in pure water. Calcium, magnesium, barium, and tin salts also give blue precipitates with the alkaline solutions. The calcium and magnesium salts are soluble in water. Hydrochloric and sulphuric acids form red

solutions, and the latter turns pure blue on warming. In acid solutions, it dyes animal fibres orange, in ammoniacal solution especially with tin mordant, blue-violet. Liebermann called this colouring matter *eupittone*, and regarded it as at least closely allied to pittacal (Ber, 11, 1145). Hofmann (Ber. 12, 1371, 2216), by the action of hexachlorethane C_2Cl_6 on dimethyl pyrogallate mixed with alcoholic potash or soda, obtained a substance identical in composition with the eupittone of Liebermann, and strongly resembling it in properties. It is an orange-yellow substance, soluble in acetic acid, and precipitated therefrom by alcohol. It melts at 200° and decomposes partly into a blue sublimate. It forms the same alkali salts and gives the same sulphuric acid reaction as eupittone. This body is hexamethoxy-rosolic acid $C_{19}H_9(OC_2H_3)_6O_3$. Heated with alcoholic ammonia, it yields hexamethoxy-rosaniline

$$OH\cdot C[C_6H_2(NH_2)(OMe)_2]_3$$
which crystallises in broad colourless needles, and has no tinctorial properties. When 2 grams eupittone are heated with 20 c.c. alcoholic methylamine (10 p.c.) at 150°–160° for 2½ hours, it yields hexamethoxydimethylformyl-*paraleucaniline*

$$CH[C_6H_2(OMe)_2NH\cdot CH_3]_2C_6H_2(OMe)_2NHCHO$$

m p. 187° (Liebermann, Ber. 34, 1034). Pyrogallol is produced in attempting to replace the methoxyl groups by hydrogen. Its formation is analogous to that of rosolic acid

$$3C_6H_{10}O_4 + CO_2 - C_{25}H_{26}O_9 + 2H_2O$$
Hofmann terms thus body *eupittonic acid*, and uses the name as synonymous with pittacal and eupittone. Eupittone acid cannot be obtained by heating the sodium derivative of dimethyl pyrogallate or of dimethyl-methyl-pyrogallate separately, in air ; a mixture of the two, however, with excess of soda gives sometimes as much as 10 p.c. of its own weight of the acid. The action is comparable with that in which rosaniline is produced from aniline and toluidine.

$$2C_8H_{10}O_3 + C_9H_{12}O_3 = C_{25}H_{26}O_9 + 3H_2$$
The oxygen necessary to remove the hydrogen is obtained from the atmosphere, as in a closed vessel no such change as the above takes place. Eupittonic acid appears to be dibasic, the sodium and barium salts, $C_{25}H_{24}Na_2O_9$ and $C_{25}H_{24}BaO_9$, have been prepared. Paper steeped in a solution of the acid and dried, is a most sensitive test for free alkalis on account of the blue colour of the alkaline salts of eupittonic acid. Hydrochloric acid, however, produces the same blue colour. With acetic anhydride, a diacetyl derivative, $C_{25}H_{24}O_9(C_2H_3O)_2$, m.p. 265°, is produced, which, curiously, is insoluble in alkalis, although its molecule ought to contain four hydroxyl groups.

The dibenzoyl derivative $C_{25}H_{24}O_9(C_7H_5O)_2$ forms golden needles, m.p. 232° ; the dimethyl ether $C_{25}H_{24}Me_2O_9$ has m.p. 242° ; the diethyl-ether $C_{25}H_{24}Et_2O_9$ has m.p. 201°–202° ; and the iodo compound $C_{25}H_{26}O_9I_4$ forms brown shining prisms.

Eupittone black, noreupittone, hexaoxyaurin $C_{19}H_{14}O_7$ or $[C_6H_2(OH)_3]_2C : C_6H_2(OH)_2 : O$ is formed by adding eupittone to sulphuric acid

at 140°, and keeping the temperature at 125° until the mass is pure blue; it is a dark shining black powder, and dyes mordanted fibres through a dirty violet to a deep black; the hydrochloride $C_{16}H_{14}O_7.HCl,C_2H_6O$ is deep blue (Liebermann and Widermann, Ber. 34, 1033).

EUPNINE. Trade name for a preparation of caffeine and iodine.

EUPORPHINE. Trade name for apomorphine methyl bromide.

EUPYRIN v. SYNTHETIC DRUGS.

EUQUININE. Trade name for quinine ethyl carbonate.

EUREKA v. NICKEL.

EURESOL. Syn. for resorcinol monoacetate.

EURHODINES, EURHODOLS v. AZINES.

EUROBIN. Trade name of a pharmaceutical preparation consisting mainly of the diacetate of chrysarobin (q.v.).

EUROPHEN v. SYNTHETIC DRUGS.

EUROPIUM. Eu = 152 (cf. Urbain and Lacombe, Compt. rend. 1904, 138, 637, and Jantsch, ibid. 1908, 146, 473).

Source.—The oxide of this extremely rare element is present in very small amounts in monazite sand, and is extracted from this mineral in the fraction containing the yttrium earths.

Extraction.—In separating europium from its associates, advantage has been taken of the isomorphism existing between the double nitrates of bismuth and those of the metals of the rare earths.

Bismuth nitrate gives rise to a series of double salts having the general formula

$$3M^{II}(NO_3)_2,2Bi(NO_3)_3.24H_2O$$
where the bivalent metal may be magnesium, zinc, nickel, cobalt, or manganese (Urbain and Lacombe, Compt. rend. 1903, 137, 568). Magnesium bismuth nitrate

$$3Mg(NO_3)_2,2Bi(NO_3)_3.24H_2O$$
is isomorphous with the corresponding double magnesium nitrates

$$3Mg(NO_3)_2,2M^{III}(NO_3)_3.24H_2O$$
where M^{III}=Ce, La, Nd, Pr, Sm, Eu, Gd, and Tb

To a mixture of these metals in the form of their double magnesium nitrates is added a large excess of magnesium bismuth nitrate. When the product is crystallised methodically from nitric acid solution, the double magnesium nitrates of cerium, lanthanum, praseodymium, neodymium, and samarium first separate, followed by the double salt of bismuth, leaving europium and gadolinium in the mother liquors. As the fractional crystallisation proceeds, the rare earths yielding double nitrates less soluble than the bismuth double salt, are gradually eliminated until at a certain point the middle fractions contain no other tervalent metal than bismuth. When this point is reached, all the samarium has been crystallised out, and thus separated from the europium and gadolinium. The bismuth still in solution is removed from the mother liquor by hydrogen sulphide, and the europium and gadolinium separated by further fractionation of the filtrate, the europium double nitrate being the first to crystallise from this solution (Demarçay, Compt. rend. 1900, 130,

1019, 1469; Urbain and Lacombe, ibid. 1904, 138, 627). This crystallisation process is a satisfactory method for obtaining pure europium, samarium, and gadolinium, and affords a means of separating quantitatively europium and samarium (cf. Eberhard, Zeitsch. anorg. Chem. 1905, 45, 374; James and Robinson, J. Amer. Chem. Soc. 1911, 33, 1363).

Europia (*Europium oxide*) Eu_2O_3, obtained from the purified double salt, shows no samarium spectrum, and only the strongest lines of gadolinium (Demarçay, Compt. rend. 1901, 132, 1482); it has a pale pink tint, but when produced by heating the sulphate at 1600°, the colour is somewhat deeper.

Europous chloride $EuCl_2$ is a colourless amorphous substance, forming a neutral solution in water, which oxidises at 100°:

$$12EuCl_2 + 3O_2 = 8EuCl_3 + 2Eu_2O_3$$
Europium sulphate $Eu_2(SO_4)_3,8H_2O$ forms pale-pink crystals, stable in air and dehydrated completely at 375° (Compt. rend. 1904, 138, 627).

The europium salts yield pale-pink solutions and in strong nitric acid they exhibit an absorption spectrum consisting of eight somewhat faint bands.

The spark spectrum is characteristic, and was first observed by Lecoq de Boisbaudran in that given by crude samaria, three very intense lines in the blue being ascribed by him to a new earth Z_{ζ}. The reversion spectrum shows the band $\lambda 615$ referred by de Boisbaudran to the earth Z_{ζ} (Compt. rend. 1893, 116, 674; 117, 199).

The most intense lines of the arc spectrum are very characteristic, and constitute a delicate test for europium, which can be thus identified in the crude oxides from monazite after removing the cerium (Eberhard, Zeitsch. anorg. Chem. 1905, 45, 374). The cathode phosphorescence spectrum exhibits the anomalous ray referred by Crookes to the 'meta-element' S_δ. Pure europia, however, give no phosphorescence spectrum unless diluted with some other earth. With lime in the proportion $Eu_2O_3 : 99CaO$, a red phosphorescence is observed, and similar effects are obtained on mixing europia with alumina or gadolinia. Mixtures with excess of the latter give a white, and with excess of europia a red phosphorescence (Urbain, Compt. rend. 1906, 142, 205, and Seventh Congress of Applied Chemistry, 1909, section 10, 94).

(Ultra-violet and arc spectra, v. Exner and Haschek, Sitzungsber. Wien. Akad. 1902, IIa, 3, 42, and Die Wellenlangen' der Bogenspektra, 1904).

Europium has been detected spectroscopically in the sun's chromosphere, in α-Boötis and in β-Geminorum (Lunt, Proc. Roy. Soc. 1907, A, 79, 118). G. T. M.

EUROSAMARIUM. An element detected by Eder, and occurring associated with europium and gadolinium in monazite (Sitzungsber. K. K. Akad. Wiss. Wien. 1917, IIa, 126, 473).

EUSCOPOL. Syn. for inactive scopolamine hydrobromide.

EUSOL. An antiseptic, used in surgery, consisting of a solution prepared by shaking up in 1 litre of water 25 grams of a mixture of equal weights of chloride of lime and boric acid, and filtering off the sediment; the solution

contains about 0·54 p.c. of hypochlorous acid, and 1·28 p.c. of calcium biborate.

EUSTÉNIN. Trade name for an addition product of theobromine-sodium and sodium iodide.

EUSYNCHITE v. VANADIUM.

EUXANTHIC ACID, EUXANTHONE, and **EUXANTHONIC ACID** v. INDIAN YELLOW.

EUXENITE. A rare-earth mineral consisting essentially of columbate and titanate of yttrium and erbium, with smaller amounts of uranium, thorium, cerium earths, iron, &c. Crystals are orthorhombic, but are very rare and indistinctly developed ; the mineral is more often massive, with a blackish-brown colour and a brilliant pitchy lustre ; sp.gr. 4·6–5·1 ; H. 6½. In appearance and character, it closely resembles several other rare-earth minerals, particularly polycrase, from which it differs in containing a lower ratio of $(Cb,Ta)_2O_5 : TiO_2$. It is occasionally found in the felspar quarries at several places in the neighbourhood of Arendal in Norway (v. W. C., Brögger, Die Mineralien der Südnorwegisschen Granit-Pegmatitgange, 1906) Also in the pegmatite veins of Madagascar, Cooglegong in Western Australia, South Sherbrooke in Ontario, &c Named from εὔξενος, friendly to strangers, in allusion to the several rare-earths it contains. L J. S.

EVAPORATION. The term ' evaporation ' is used in connection with technical or manufacturing operations where a liquid is converted into vapour, but in chemical manufactures it is generally limited to those processes where the object is to separate a liquid from a solid which is dissolved in it, or to separate a more volatile from a less volatile liquid. In cases where the liquid to be evaporated is one of the products of the process, and is collected by condensation, the process is known as DISTILLATION (q.v.). Where a solid substance contains water, not as water of crystallisation, and without presenting visible moisture or wetness, the process of removing this moisture under suitable circumstances is known as DESICCATION or DRYING (q.v.). The operation of evaporation, however, is conducted on the greatest scale in the generation of steam for steam engines, and in the production of steam generally for manufacturing purposes. Although more water is evaporated in connection with the steam engine than for any manufacturing processes, yet great quantities of steam are used as a convenient means of applying and distributing heat, especially when regulated and moderate temperatures are required. In such cases the heat is applied to the vessel to be heated by jacket spaces or through coils of pipes immersed in the liquid to be raised in temperature. Such applications are made in sugar and confectionery manufacture, and in distilleries, breweries, and dyeing, &c.

Water and many other liquids evaporate without the application of heat. A vessel of water freely exposed at the ordinary temperature of the atmosphere soon evaporates and disappears. This is due to the fact that water vapour has a sensible pressure at ordinary temperatures, and as gases and vapours freely diffuse throughout each other, any water placed with a free surface in a confined space continues to evolve and diffuse its vapour until the water vapour present in the whole space is at

the maximum pressure which corresponds with the temperature. Although evaporation occurs in this way without any application of increased temperature, yet heat is absorbed by the vapour formed from the liquid, and if the evaporation be rapid and be conducted under such circumstances that heat from surrounding objects is prevented from reaching the liquid, then its temperature will be greatly reduced. This fact is illustrated by the well-known lecture experiment of placing a shallow copper cup filled with ether upon a block of wood, and under it a drop of water. When air is blown upon the ether it rapidly evaporates and carries off so much heat from the copper that the water drop under it is frozen and the copper adheres to the wood. A liquid is said to be volatile when its vapour has a considerable pressure at ordinary atmospheric temperatures. At 20°, for example, the pressure of water vapour (or tension as it is somewhat inappropriately called) is 17·39 mm. mercury, whilst the pressure of ether vapour at the same temperature is 433·3 mm. and that of alcohol 44·5 mm. If the liquids be placed in atmospheres whose pressures could be kept at these points by artificial means, then these liquids would boil. As the evaporation under these circumstances is very rapid, relatively to the flow of heat to the liquid from surrounding bodies, if only atmospheric temperature be available, the heat is abstracted so quickly that many liquids freeze.

Advantage is taken of these properties for many purposes in the use of air currents passed over the surfaces of liquids to evaporate them without the application of other than natural heat. Reduced pressures are also applied to evaporate without heating or to reduce the temperature necessary in order to avoid chemical decomposition and also to produce cold mechanically.

Evaporation in steam boilers. The evaporative efficiency of the steam boiler has been more closely studied than that of any other type of evaporating apparatus, and the principles of the economical application of heat for evaporating are more completely known in this connection than in any other.

The leading types of steam boilers now in use for the purposes of motive power are as follows : Lancashire, Cornish, Locomotive multitubular, Marine multitubular, and Water-tube or tubulous types.

Obviously in an article of this character detailed description of the various types of boiler is uncalled for ; the reader is therefore referred to the numerous text-books existing on the subject, such, for example, as "Steam-Boiler Construction," by W. S. Hutton ; "Steam-Boilers, Their History and Development," by H. H. P. Powles ; "Steam-Boilers," by C. H. Peabody and E. F. Miller.

Evaporation in open vessels. In many chemical manufactures it is necessary to evaporate off water in which the substance, object of the process, is dissolved, and in such cases, when heat is to be applied, it is desirable to economise fuel to the greatest possible extent. The heat of waste gases is therefore used as much as possible. The method of applying heat varies considerably with the chemical nature of the substance dealt with, and choice of economical apparatus is often limited by the corrosive nature

of the liquid to be evaporated. In the process of concentrating oil of vitriol from the dilute acid, a series of shallow open lead pans receives the diluted acid and heat is applied below. The hot furnace gases are allowed to impinge upon the bottom of the vessel containing the weakest acid, and therefore requiring the greatest quantity of heat for evaporation, and as the gases cool they impinge upon the succeeding vessels of stronger and stronger acid, requiring less quantity of heat until the acid has become as concentrated as it is safe to trust to leaden vessels. Instead of this plan, in some cases the furnace gases are passed over the surface of the acid in order to heat it from above, and the volume of gases in motion removes the vapour as fast as it is formed. The advantage of surface evaporation arises not from the fact of its being economical, because liquids are heated with difficulty from above. The hot liquid in contact with the gases expands and has no tendency to cause convection currents, but rather remains stationary above the colder portions, and accordingly it is always advisable to heat from below when possible. In many processes, however, during evaporation, a deposit comes down and this, coating the bottom of the vessel, prevents the free contact of the metal with the liquid. The resistance to the passage of heat from the metal to the liquid is thereby much increased, and the bottom suffers rapid destruction from over-heating. In boilers using very hard water this is a fruitful source of trouble and danger.

When surface evaporation is resorted to, large surfaces are exposed in shallow tanks over which the flame and hot gases from a furnace are allowed to pass. The pans are covered in so that the radiant heat from the brickwork assists the action of the flame and hot gases. Arrangements of this kind are used in evaporating weak alum liquors, and the tanks are built up of bricks bound together with a cement composed of lime and alum shale. Sometimes an open pan is placed above the gases to contain the feed liquid and heat it in its progress to the evaporating pans.

Evaporation of brine. Brine is sometimes evaporated by allowing the liquor from the springs to flow over masses of twigs in such a manner as to expose very extensive surfaces to the action of air currents; by pumping over a succession of these surfaces it is gradually concentrated. When artificial heat is applied to the evaporation of brine, large shallow salt pans are used. They consist of flat quadrangular vessels of plate iron supported upon suitable brick walls, forming flues which distribute the heat from furnaces placed in the centre part under the vessel. The flames strike directly upon the bottom of the vessel, and the hot products of combustion are conducted outwards by flues leading to the stack or chimney. In this way they traverse the whole bottom surface of the evaporating pans. The pans are of great area, often 60 feet long by 30 feet wide. The water vapour is collected by a large conical hood and carried off by a separate chimney. The sides of the lower part of the cone are so constructed that they can be opened to admit air from the direction in which the wind is blowing. This assists the evaporation by carrying off the water

vapour generated and exposing the surface to a continual air current.

If heat enough to cause a liquid to boil be applied, an air current will not increase the evaporation, but will tend to diminish it by cooling the vessel containing the liquid; but when the liquid does not reach the boiling-point, the continuous removal of the atmosphere in contact with the liquid is necessary. If this be not done, then, so soon as the atmosphere has become saturated with the vapour, that is, so soon as the water vapour is present in quantity sufficient to produce the pressure which corresponds with the temperature of the liquid, the evaporation ceases.

It is a necessary condition of evaporation at temperatures less than the boiling-point, that the atmosphere into which the evaporation takes place should be continuously renewed, and it is advisable that the air into which the water evaporates should not be of lower temperature than the liquid. When the temperature of the air is lower than that of the liquid, the volume of vapour carried off is much reduced, as the air must be heated by the vapour before it is capable of carrying off the volume equivalent to the vapour pressure. Producer gas is used for evaporating the brine at Ischl salt works, and the operation is conducted in deep rectangular plate-iron vessels grouped together, and fed continuously by a system of distributing pipes.

Steam is much used to supply the heat required for evaporation, especially when the substances to be dealt with are of an easily decomposable nature if overheated. The heat is often applied to the vessel by means of a steam jacket, that is, the vessel is made double walled, and the interspace is utilised to receive the hot steam. When the temperature requires to be higher than 100°C., the jacket space is constructed to withstand pressure, and steam under boiler pressure is supplied, but steam is most commonly used at atmospheric pressure and applied to the liquid by passing through rows or coils of pipes immersed in it. The arrangement of these pipes varies, and in some cases they are so connected as to be capable of hinging out of the vessels for ready access and cleaning purposes.

Milk is now rapidly evaporated by spraying into heated air without raising the milk temperature to such a point as would cause chemical change.

Evaporation under reduced pressures. In the older processes of sugar manufacture, the sugar liquors were concentrated by the direct application of heat from a fire upon the vessels containing them, but the greatest difficulty was experienced in preventing decomposition when the solution became concentrated. To avoid this difficulty, the vacuum pan was introduced by Howard, and in various modified forms it is still used. The boiling-point of a liquid depends upon the pressure to which it is subjected, and by reducing the pressure the boiling-point is greatly reduced. The vacuum pan consists essentially of a globular copper vessel containing the sugar liquor, and having the lower portion steam jacketed, while steam also passes through a coil of pipe immersed in the liquid. The upper part of the vacuum pan carries a circular

steam dome or cylinder from which a pipe passes to a vessel intended to collect any liquor which may have primed over. From this vessel it is run back into the pan again. An air pump exhausts the apparatus and passes the steam to a condenser of usual construction. Fig. 1 shows a vacuum pan made by Messrs. Manlove, Alliot, & Co. The vacuum pan A is formed in two portions bolted together. It is fed with liquor from the vessel B by suitable cocks, the pipe connections a, b being arranged to equalise the pressure within the vessel, so that the flow may be towards A. The live steam is admitted at the valve C, and passes through coil D into the jacket E, from whence it discharges and drains by the pipe F. The cylindrical dome or cylinder G prevents any great priming, but any liquid which may find its way by the pipe H is caught in the cylinder I and returned to A by the pipe K. The pipe L leads to the air pump and condenser.
Fig. 1.

A thermometer placed in the upper part of the pan indicates the temperature of the operation, whilst a vacuum gauge or barometer column is used to show the pressure within. The boiling-point of the liquid at atmospheric pressure is about 250°F., and this is reduced to 150°F. by using the vacuum pan.

Fig. 2 shows a vacuum pan of modern construction, made by the Mirrlees Watson Co., Ltd., of Glasgow. In this vacuum pan, the liquor is heated in the vessel a by coiled steam pipes b, and also by reason of its passing upwards through small tubes c, through a steam chamber, d, the down flow of the liquor taking place through the central large tube e. In other respects, the operation of this vacuum pan is similar to that shown in Fig. 1.

Evaporation under reduced pressure by triple and multiple effect. It is evident that as a liquor becomes more concentrated the boiling-point rises, and in evaporating liquids liable to chemical change by overheating, the pressures under which boiling is effected must be arranged to keep the temperature within safe limits. In the case of sugar liquor this safe limit is 227°F. Steam at 5 lbs. per square inch above atmosphere has this temperature, and if it be applied to a pan containing a weak sugar liquor at atmospheric pressure, the liquor will boil.

Neglecting losses by radiation and like causes, the steam coming from it has the same amount of heat as was imparted to the liquor by the steam under slight pressure, and if it be

conducted to the coil and jacket of a second pan in which a slight vacuum is maintained, it will generate almost its own weight of steam at lower pressure and temperature, and so evaporate the water from the second pan. If the steam so generated be taken to the coil and jacket of a third pan, its heat can again be utilised to evaporate the liquor there, provided the vacuum is sufficient to allow it to boil. This process may be continued until the original heat of the steam supplied to the first pan is dissipated by conduction and radiation. This is the principle of the ' triple-effect ' apparatus, by which a great economy is effected in the amount of fuel needed to evaporate a given weight of liquor. The steam from one pan at higher pressure proceeds to the coil and jacket of the next, and the steam from the second proceeds to the coil and jacket of the third, the pressures within the pans proceeding in descending order as well as the temperatures.

Fig. 3 is an illustration of a triple-effect evaporator of the ' Hagemann ' type, constructed by the Mirrlees Watson Co., Ltd., for concentrating sugar. In this evaporator, the liquor is fed through an internal perforated pipe D at the bottom of the vessel A, and the flow of liquid from vessel to vessel is automatically regulated by traps E, the liquor passing through the vessels A, B, and C in turn, the reduction in pressure being so arranged that it is least in A, more considerable in B, and greatest of all in C, so that the boiling-points are lower in each succeeding vessel. The heating surface is obtained by means of a number of vertical tubes F, through which the liquor passes, these tubes being arranged in a steam or vapour space, G, divided by horizontal baffle plates H. The steam enters the steam space at the top above the upper baffle plate, and passes to the intermediate and lower spaces through apertures in the baffle plates slightly larger than the tubes which pass through them, the rush of steam through the openings removing the water of condensation from the surface of the tubes, and improving their efficiency. The upper part of each vessel acts as a separator, the vapour escaping, past a baffle J to prevent priming, through an outlet K either to the next effect or to the condenser.

In the Kestner ' climbing film ' evaporator, one complete section of which is illustrated in Fig. 4, vertical tubes are also used for the passage of the liquor, but they are fewer and of greater length than in the apparatus last described. Steam supplied through an inlet A to a jacket B causes ebullition of the liquor, supplied to a tank C, releasing a volume of vapour in the tubes D which occupies the central portion of each tube and carries up a film of the liquor on the internal surface. A fixed baffle E, by means of suitably shaped vanes, produces a whirling motion of the liquor and vapour mixture as it emerges into the separator F, whereby the liquor is thrown outwards and drawn off through an outlet G, and the vapour escapes, through a ' save-all ' H, by an outlet J. In another form the separator is placed at the bottom of the apparatus, the liquor, after passing through the ' climbing film ' tubes, being conducted thereto by a set of ' falling film ' tubes also within the steam jacket B.
Fig. 2.

Fig. 3.

Any number of sections as described may be connected to form a multiple effect apparatus, the liquor and vapour from the outlets G and J of one section being respectively led to the tank C and inlet A of the next.

FIG. 4.

The Yaryan evaporator. This ingenious evaporator is the invention of H. T. Yaryan, of Ohio, U.S.A., and it is now largely used in this country, the Continent, and America. It utilises evaporation under reduced pressures as with the triple effect and also multiple effect. It differs from other inventions of the same class in the method of applying heat to the liquid to be evaporated, whereby the liquid is heated in small quantities at a time, and is brought into very effective contact with the heating surfaces. Instead of using coils immersed in a liquid which is also heated by jacketed surfaces, the heat is applied by steam to the exterior surfaces of tubes, and the liquid to be evaporated is pumped within these tubes. The tubes are arranged in straight cylindrical drums, and pass from end to end, terminating in chambers with partitions so placed that when the liquid is pumped in at one end of a series it must pass through the whole series before escaping into the separating chamber. Fig. 5 is a section of

one drum of the evaporator, showing that the liquid is pumped in at one end, travels along in the direction of the arrows, and finally escapes with the steam which is generated into the separator. The tubes are divided into sections termed ' coils,' and each section consists of fine tubes coupled at the ends so as to form a continuous passage. The liquid and vapour pass from section to section in series, and so come into effective contact with the whole surface. As the liquid is pumped in it evaporates, and the steam produced carries it forward through the tubes, so that a mass of liquid and steam is brought in contact with every part of the whole heating surface, moving at a high velocity because of the steam generated, which has only the one direction of escape, that is, through the whole system of tubes in each towards the separator. The liquor under treatment issuing from the last set of tubes into the separator falls to the bottom, as shown in Fig. 5, and the vapour rising up flows in the direction of the arrow to the *catch all*, where any liquor entrained is caught during its passage through the number of small tubes with which this vessel is fitted,

FIG. 5.

and, striking against the end cover, falls to the bottom and is drained off into a receiver. This ensures dry vapour being passed on to the evaporating shell of the next vessel, where it in turn boils the liquor which is inside the tubes, and so on through the various effects until the vapour from the last vessel reaches the condenser. The advantages of this apparatus are its economical working and rapid flow of the liquor under treatment. Only a small quantity of liquid is in the apparatus at one time, and so it is exposed to heat for a much shorter period than in the ordinary vacuum pan, which is an important point. The apparatus avoids entirely the loss of colour which always occurs to some extent in the older vacuum pans because of the long period of time taken to evaporate the large quantity of liquid they contain, amounting in some cases to thousands of gallons. The Yaryan evaporator can be started very rapidly, as it contains but a small mass to be heated. At the same time, the details are arranged to permit of ready access to the tubes and ready cleaning. This is greatly assisted by the fact that the tubes are straight. Fig. 6 shows a quintuple-effect evaporator with its vacuum and auxiliary pumps in general use, for soda ash recovery in paper mills, caustic soda, caustic potash, meat extract,

distillery refuse, and other liquids readily amenable to concentration.

According to the patentees of the Yaryan apparatus, their double effect will evaporate

FIG 6.

16 lbs. of water for every pound of coal consumed under the boiler, 23½ lbs. in a triple effect, 30½ lbs. in a quadruple effect, assuming that the boiler is so constructed as to evaporate 8½ lbs. of water per pound of coal.

The Yaryan apparatus has, since its first introduction in 1888, been greatly improved in design and efficiency, and large sextuple-effect apparatus working on the Yaryan principle have been constructed by the Mirrlees Watson Co., Ltd., for the distillation of fresh water from salt water, producing from 25 to 350 tons per day of 24 hours, and also for use in the Solvay process of soda manufacture in Europe and America. Fig. 7 indicates the essential features of such an apparatus for the distillation of salt water. Salt water, previously warmed by being passed through heaters, is supplied by a pipe A to heating tubes in the lowest evaporator B_6, and thence is passed in succession by means of pipes c through heating tubes in the remaining evaporators. It has then reached boiling-point, and is circulated through the evaporating tubes of the first evaporator B_1, to which boiler steam is supplied by a pipe D. The mixture of liquor and vapour is conducted from the evaporators B_1-B_6, to the respective separators E_1-E_6, by pipes F, the outlets for the liquor and vapour from each separator to the next evaporator stage being by pipes G and H respectively. Concentrated brine is drawn off from the last separator E_6 by a pipe J, and the condensed fresh water passes from stage to stage by pipes K, and is finally drawn off through an outlet L.
In the Lillie type of evaporator the tubes are

FIG. 7.

also arranged horizontally, but the steam is passed through them and the liquor is allowed to fall over their external surfaces.

Evaporation in mechanical refrigerators. A separate class of mechanical refrigerators exists in which the cooling or refrigerating effect is produced by evaporation. Liquids used are ether, anhydrous ammonia, and anhydrous sulphur dioxide. In all of these the process of the machine is identical. The volatile liquid is

introduced into a chamber at a pressure at which it is liquid, and the vapour is rapidly withdrawn from the vessel by a pump. The rapid evaporation absorbs heat so quickly that the temperature falls and a brine or other liquid is cooled within a coil of pipes immersed in the liquid. By circulating this brine, the low temperature may be utilised for reducing the temperature of a cold store room or for producing ice.

The vapour drawn off by the pump is compressed and cooled by passing through tubes surrounded by water, and so becomes liquid again. It is then injected into the evaporating chamber again, so that the process is practically continuous, and but slight renewal of the volatile liquid is necessary to make up for small leakages.

The same principle is applied in Carre's freezing machine for freezing water. In this case the vapour is removed from the surface of the water by a pump and condensed by strong sulphuric acid. Ammonia is also utilised in another apparatus in solution in water for the same purpose. By alternate expulsion from the water and absorption, cold is obtained.

The rapid evaporation of liquid carbonic acid, air, and other bodies which are gaseous at normal temperatures and pressures, has also been used to produce low temperatures by liquefying the more permanent gases. D. C.
EVERNIC ACID and **EVERNINIC ACID.** Evernic acid, or *lecanoric acid monomethyl ether*, was first isolated by Stenhouse from the *Evernia prunasti* (Annalen, 68, 83), and has been found also by Hesse (Ber. 1897, 30, 366) to exist in the *Ramalina pollinaria* (*cf.* also Zopf, Annalen, 1897, 297, 271).

The lichen is extracted with diluted milk of lime, the extract neutralised with acid, the precipitate collected, dried, and digested with a little boiling alcohol. The hot alcoholic liquid, treated with its own volume of water, deposits crystals of evernic acid (Stenhouse).

Evernic acid crystallises in small colourless needles, m.p. 168°–169°, readily soluble in hot alcohol, and when boiled with solutions of the alkali hydroxides or baryta water, gives CO_2, orcinol, and *evernic acid*

$$C_{17}H_{16}O_7 + H_2O = C_9H_{10}O_4 + C_7H_8O_2 + CO_2$$

Ramalic acid suffers a similar decomposition.

Fischer (Ber. 1913, 46, 3253 ; and 1914, 47, 505) showed that when evernic acid was methylated by means of diazomethane, in ethereal solution, a neutral crystalline ester identical with trimethyl-lecanoric acid methyl ester was obtained, and he pointed out that, as the methoxy group in everninic acid is in the para-position to the carboxyl group, the structure of evernic acid must be :

CH₃—O—⟨CH₃⟩—CO—O—⟨CH₃⟩—COOH
            OH   OH

From this it follows that the isomeric ramalic acid (*v.* Ramalic acid) may be expressed as :

HO—⟨CH₃⟩—CO—O—⟨CH₃⟩—COOH
       OCH₃   OH

or HO—⟨CH₃⟩—CO—O—⟨CH₃⟩—COOH
        OH   OCH₃
* For descriptions of the Na, Ba, Ca, Cu, Pb, and Ag. salts of evernic acid, *cf.* Hesse (J. pr. Chem. 1915, [ii.] 92, 425).

Diacetyl-evernic acid $C_{17}H_{14}O_7Ac_2$ is a crystalline powder, m.p. 144°.

Everninic acid (orsellinic acid monomethyl ether) resembles benzoic acid in appearance, melts at 157°, and yields the ethyl ester
$$C_9H_9O_4(C_2H_5)$$
m.p. 72°. By digestion with hydriodic acid, everninic acid gives orcinol, CO_2, and 1 molecule of methyl iodide. According to Heinrich (Ber. 1904, 37, 1406), two formulæ are possible for everninic acid :

(1) ⟨CH₃ / COOH / OCH₃ / OH⟩   (2) ⟨CH₃ / COOH / OH / OCH₃⟩
Fischer and Hoesch (Annalen, 1912, 391, 347) have, however, shown that *orsellinic acid a-methyl ether*, prepared by them, and which has the structure (2), is identical with everninic acid.

This conclusion has been further substantiated by the synthesis of *everninic aldehyde*, m.p. 65°C. (and from it of everninic acid) (Hoesch, Ber. 1913, 46, 886), by the careful methylation of orcyl aldehyde with methyl sulphate, and 2N caustic soda in the presence of acetone. This when treated with an acetone solution of methylchlorocarbonate, yielded *methylcarbonato-everninic aldehyde*, needles, m.p. 77°C., and the latter, when oxidised with potassium permanganate, was converted into *methylcarbonato-everninic acid*, needles, decomposing at about 100°C., which on hydrolysis with N caustic soda solution yielded everninic acid. These changes may be represented thus :

HO—⟨CH₂ / CHO / OH⟩ → CH₃O—⟨CH₃ / CHO / OH⟩

→ CH₃O—⟨CH₃ / CHO / O·CO₂·CH₃⟩

→ CH₃O—⟨CH₃ / COOH / O·CO₂·CH₃⟩

→ CH₃O—⟨CH₃ / COOH / OH⟩

Hesse (J. pr. Chem. 1915, [ii.] 92, 425) has described the following derivatives of everninic acid :—

Acetyl everninic acid $C_9H_9O_4Ac$, colourless prisms, m.p. 111°C.

Nitro-everninic acid, orange-red needles, m.p. 195°C.

Dinitro-everninic acid $C_9H_8O_4(NO_2)_2H_2O$ golden-yellow needles, m.p. 87°C.—the potassium salt is very explosive.

Hesse's expression (J. pr. Chem. [ii.] 57, 253) of the isomerism of evernic acid and ramalic acid, and which was based upon the older formula of orsellinic acid, is as follows :
A. G. P. and A. E. E.

EVERNIIN *v.* GUMS.

EVODIA MELIÆFOLIA. This tree, belonging to the *Rutaceæ*, is found in China and Japan, where its bark is largely employed in dyeing and in medicine. It was formerly described by Loureiro as *Pterocarpus flavus*, but this error was eventually corrected by P. W. Squire (Pharm. J. 1888, [3] 18, 785), who showed it to be really *Evodia glauca*, which is synonymous with *E. meliæfolia*. By qualitative tests, Martin, Tokio (Arch. Pharm. 1898, 13, 337) and Squire (*l.c.*) suspected the presence of *berberine*, and this colouring matter was subsequently isolated by Perkin and Hummel (Chem. Soc. Trans. 67, 415).   A. G. P.

EVODIN $C_{17}H_{20}O_6$. A crystalline substance found in the fruit of *Evodia rutaecarpa*, used in China and Japan in medicine and perfumery. First isolated by Kermatzu by treatment of the dried fruits with benzene ; m.p. 285°. Insoluble in water, alcohol, ether, and light petroleum, slightly soluble in hot benzene, ethyl acetate, and chloroform, soluble in acetic acid and alkali solutions (*cf.* Asahina and Ishio, J. Pharm. Chim. 1916, [viii] 13, 53).

EXALGIN. Trade name for methyl acetanilide (*v.* SYNTHETIC DRUGS).

EXODIN *v.* SYNTHETIC DRUGS.

EXPLOSION, GASEOUS. Within recent years there has been an enormous increase in the extent to which the internal combustion engine has been utilised, and there are now many millions of h.p. at work on this principle. Gas engines using coal gas, producer gas, or blast-furnace gas, are now working for all powers up to 2000 h.p. per cylinder, and a large number of heavy oil engines are also in use. In addition, there are many thousands of petrol motors at work.

In internal combustion engines working on the constant volume cycle, the motive power is produced by the explosion of mixtures of inflammable gas or vapour and air in certain proportions, and the pressure produced by the explosion is utilised to propel the piston of an engine, as is done by the steam pressure in a steam engine.

Seeing that a proper understanding of the phenomena associated with gaseous explosions is necessary, not only for persons in charge of internal combustion engines, but also for those responsible for the safety of workers both in coal mines and in factories where explosive mixtures may be encountered or used, it is desirable first to consider generally the properties of such mixtures and the mode in which flame is propagated through them. At the outset, it should be recognised (1) that, under given conditions of temperature and pressure, the "*range of inflammability*" of mixtures of any particular combustible gas and air (or oxygen) may be strictly defined, so that all mixtures outside of certain 'lower' and 'upper' limits are non-inflammable ; (2) that the *ignition* of any given inflammable mixture at a particular pressure is determined by the attainment of a certain definable thermal (or electrical) condition at some point or region in it ; (3) that after ignition the speed and mode of propagation of flame through the mixture are usually capable of measurement or analysis by well-established experimental methods ; and (4) that when such a mixture is inflamed in a closed vessel, the maximum pressure attained on explosion may be accurately determined. But notwithstanding the truth of this statement, it is needful to warn the reader against errors involved in the loose employment of such terms as '*ignition temperature,*' '*speed of inflammation or flame propagation,*' '*pressure of explosion,*' etc , unless the concomitant physical circumstances are simultaneously defined.

A —IGNITION PHENOMENA.

Chemical change may be determined in a gaseous explosive mixture at a much lower temperature than is required to develop flame in it. Thus, for example, if electrolytic gas be heated in an enclosure to a temperature somewhat higher than 400°, the formation of steam can usually be detected after a lapse of a few days. On gradually raising the temperature the rate of interaction between the hydrogen and oxygen rapidly increases until at length a point would be reached when the rate at which heat is lost from the system (*e.g.* by conduction through the walls of the enclosure) is more than counterbalanced by the rate at which it is developed by the interaction. The reaction would then become self-propellant.

The temperature at which such autogenous (or self-propellant) reaction begins in a given gaseous mixture is usually termed its '*ignition temperature*' or '*ignition point,*' although it is not ordinarily a well defined physical constant, being dependent, for example, upon the manner in which heat is conveyed to the mixture. It is clear also that the ignition temperature, as thus defined, does not necessarily correspond with the appearance of flame in the mixture. There is, indeed, usually a definite '*pre-flame*' period, the duration of which can be controlled, and which varies considerably with the different gas mixtures. Only when a mixture is fired by adiabatic compression, and the pre-flame period is negligibly short, can its '*ignition temperature*' be regarded as a physical constant and determined with precision. In most cases the ignition temperatures assigned to a series of gas mixtures merely give an approximate index of their 'relative ignitibilities.'

The Determination of Ignition Temperatures. —Several experimental methods (of which three principal ones will be hereafter described) have been used to determine the so-called 'ignition temperatures ' of gases. The results naturally differ according to the details of the method adopted, and must therefore be carefully differentiated.

(1) A common method is to pass successive samples of a particular inflammable mixture into a vessel whose temperature is gradually raised until the lowest degree at which flame appears has been found. In this way the 'relative ignitibilities' of a series of gas-air mixtures may be determined, and for such purpose the method is a useful one. Thus, for example, one of us (R.V.W.) has recently determined by this method the 'relative ignitibilities' of a series of methane-air mixtures, expressed in each case as the lowest temperatures of the particular enclosure required to inflame each mixture, as follows :—

Per cent. Methane	6·0	7·0	8·0	9·0	10·0	12·0	13·0
Temperature of enclosure	695°	698°	701°	707°	713°	726°	73..

It may be noted, in passing, that the most ignitable of these mixtures is not the one (9·45 p.c. methane) which on combustion gives the greatest heat development per unit volume, but rather those containing a considerable excess of oxygen. The method does not, however, disclose the lowest temperature at which a given mixture can be ignited, because the walls of the heated vessel, by inducing chemical combination on their surface, retard the actual appearance of flame.

(2) A better method. (first employed by H. B. Dixon and H. F. Coward, Chem. Soc Trans. 1909, 98, 514), which to a large extent eliminates the effect of heated surfaces, consists in heating the combustible gas and the air (or oxygen) separately to a known temperature and then allowing them to mingle, increasing the temperature of each gas stream, *pari passu*, until their mixture results in flame. The '*ignition temperature ranges*' of some combustible gases, at atmospheric pressure, as determined by this method, are as follows :—

Combustible Gas	Ignition Range	
	In oxygen	In air
Hydrogen	580°–590°C.	580°–590°C.
Carbon monoxide	637°–658°	644°–658°
Cyanogen	803°–818°	850°–862°
Ethylene	500°–519°	542°–547°
Acetylene	416°–440°	406°–440°
Hydrogen sulphide	220°–235°	346°–379°
Methane	556°–700°	650°–750°
Ethane	520°–630°	520°–630°

These figures record for a given gas the lowest temperature at which any mixture of it with air or oxygen would inflame. But they afford no information as to the effect of varying the proportions of the gas and air.

(3) The temperature produced by the adiabatic compression of a gaseous explosive mixture within a closed cylinder may be accurately calculated from the fundamental gas laws, and this method has been successfully employed by H. B. Dixon and his co-workers for determining the 'ignition temperatures' of various mixtures of hydrogen and oxygen, as follows :—

Mixture	Ignition Temperature as determined by Adiabatic Compression
$2H_2 + O_2$	526°C.
$2H_2 + 2O_2$	511°
$2H_2 + 8O_2$	478°
$2H_2 + 16O_2$	472°

According to Dixon and Croft's determinations by this method of the ignition-points of mixtures containing electrolytic gas, whereas successive additions of hydrogen or nitrogen progressively raise the ignition temperature of the undiluted gas by regular increments, as would be supposed, successive additions of oxygen, on the other hand, lower it, as shown in the following table : —

THE IGNITION-POINTS OF MIXTURES CONTAINING ELECTROLYTIC GAS BY ADIABATIC COMPRESSION.

(By H. B. Dixon and J. M. Crofts, 1914.)

Electrolytic Gas, $2H_2 + O_2 = 526°$					
$+xH_2$		$+xN_2$		$+xO_2$	
$x=1$	544°	$x=1$	537°	$x=1$	511°
$x=2$	561°	$x=2$	549°	$x=7$	478°
$x=4$	602°	$x=4$	571°	$x=15$	472°
$x=8$	676°	$x=8$	615°		
$(526+18x)°$		$(526+11x)°$			

The observed raising effects of successive dilutions with hydrogen and nitrogen call for no comment, save that the relative greater effect of hydrogen, as compared with nitrogen, may be attributed to its greater thermal conductivity; but the lowering effect of oxygen is indeed puzzling, and its meaning can only be conjectured. Dixon and Crofts have suggested that it may be due either to the formation of some active polymeride of oxygen under the experimental conditions (which seems doubtful), or that the concentration of oxygen in some way or other brings about increased ionisation of the combustible gas This at once raises the larger question of whether or not ignition is a purely thermal problem, as until recently has generally been supposed.

Ignition by adiabatic compression is utilised in the Diesel oil engine, and in gas engine practice pre-ignition of the charge may take place during the compression stroke if too high a compression is employed. Knowledge of the degree of compression required to cause the ignition of a particular gaseous mixture is, therefore, of considerable industrial value.

Ignition by a Source of Heat of Short Duration.—This is a very common way of igniting explosive mixtures in everyday practice, although up to the present experimental data regarding it are very meagre. It will be realised that if the inflammation of a large volume of gas is attempted by rapidly heating a small portion of it, the size and duration of the source of heat employed, as well as its temperature, will be of importance, because the effectiveness of any means of ignition depends upon whether or not the volume of mixture first inflamed communicates by its combustion sufficient heat to the adjacent layer of mixture to inflame it in its turn. In general, the shorter the duration of the source of heat employed to ignite a given gas mixture, the higher must be its temperature. Unfortunately, until now this aspect of the question has been but little explored, but the point may be illustrated by some recent determinations of the '*relative ignitibilities*' of

mixtures of various gases with air expressed in the terms of the lowest temperatures at which a hot body of minute area must be raised in order to cause immediate ignition of the particular mixture to which it was momentarily applied. Such temperatures have obviously only an empirical interest.

Gas (Mixtures with air)	Minimum temperature of hot body required for immediate ignition by momentary contact
Hydrogen . . .	747°C.
Carbon monoxide . .	931°
Ethylene . . .	1000°
Coal gas . . .	878°
Petrol (Fraction 0-80°C.)	995°
Benzene . . .	1062°
Ether	1033°

Ignition by Electric Sparks.—It is still a matter of controversy whether ignition by means of an electric spark is a thermal phenomenon, or whether there is simultaneous ionization of the mixture by the spark, the ionization playing a necessary and important part in promoting the combustion of the gases. So far as the secondary discharge is concerned, ionization of the mixture between the electrodes undoubtedly precedes the passage of the discharge; and it is possible that this preliminary ionization may render the molecules more reactive than usual towards each other. It is known that the exposure of some gaseous mixtures to a source of intense ionization causes their combination at quite low temperatures. The point of controversy would, therefore, appear to be whether in the ignition of gaseous mixtures by an electric spark ionic rather than thermal phenomena predominate; whether, in fact, an electric spark is more effective as an ionizer than is a flame or a heated solid.

Insufficient experimental work has been done to enable a decision to be reached on this matter. The character of the phenomena of spark ignition seems to differ from that of the phenomena of ignition by the prolonged contact of a heated surface. Thus, the type of curve that can be constructed connecting 'igniting-current' or 'spark-energy' with percentage composition of mixtures of any given inflammable gas with air differs from the type of curve connecting ignition temperatures, as determined by the first method described, with percentage composition (*see* Fig. 1). It may be, however, that this difference is due to a large extent, if not entirely, to the short duration and small size of the electric spark; also that the rapidity with which flame can travel in a mixture away from the source of heat becomes of importance equally with the susceptibility of the mixture to ignition when the source of ignition is very small and lasts but a short time. It may be noted that the spark ignition curve in Fig. 1 is nearly the inverse of the speed-percentage curve for flame in methane-air mixtures described in the ensuing section of this article (*see* Fig. 2).

Limits of Inflammability.—If the whole volume of a gaseous mixture be raised to its ignition-temperature, as it is, for example, in the cylinder of a Diesel engine, it necessarily follows that the whole of it is inflamed. On the other hand, the introduction into a gaseous mixture of a small source of heat at a tempera-

ture considerably higher than the ignition-temperature of the mixture need not cause complete propagation of flame.

It is well known that when a flame is introduced into a mixture of an inflammable gas and air containing but little inflammable gas, a 'cap' or aureole is formed around the flame; and that this cap is larger the greater the proportion of inflammable gas present. The coalminer regularly uses this formation of a cap as an indication of the presence of firedamp in the workings of the mine. It has been observed also that in a current of gas and air, poor in combustible gas, passing a lamp flame or similar source of heat, the cap or aureole may become separated from the burning body by which it is originated and be carried along for a limited distance, giving a 'cloud' of flame. But unless this cloud were fed by some mixture richer in combustible gas than that in which it originated it would gradually die away. In a uniform mixture of gas and air the flame could only be carried on automatically through-out the extent of the mixture if the inflammable gas were present in quantity above what is termed the 'lower limit' of inflammability.

When a source of heat is introduced into a stagnant mixture of combustible gas and air, two things are necessary to ensure propagation of flame throughout that mixture, namely, (a) an adequate means of ignition, and (b) a sufficient proportion of inflammable gas.

Supposing that too small a proportion of combustible gas is present, only a small quantity of heat per unit volume of mixture is generated when the layer surrounding the initial source of heat is inflamed, and the products of combustion have to impart heat to a considerable volume of inert gases. The number of collisions between molecules of combustible gas and of oxygen that are chemically effective is therefore small. Such collisions, resulting in combination, will occur only in the neighbourhood of the initial source of heat around which an aureole will form of a size dependent on the nature and quantity of the combustible gas present.

As the proportion of combustible gas is increased a proportionately greater quantity of heat is evolved per unit volume of mixture, and a smaller quantity of inert gases is present to absorb it. At length a point is reached when the amount of heat contained in the products of combustion of any given layer is just sufficient to raise the adjacent layer to its ignition temperature. Flame is then propagated progressively throughout the mixture without any necessity for the continued presence of the source of heat which started the inflammation, and the mixture is said to 'inflame' or 'explode,' according to the rapidity of the propagation.

To ensure propagation of flame throughout the mixture, therefore, it is necessary for the initial source of heat to be of a volume, intensity, and duration sufficient to raise the layer of gases surrounding it to the ignition temperature of the mixture, and for the heat contained in the products of combustion of this first layer to be sufficient to raise the next layer to its ignition temperature, and so on. An inflammable mixture can be defined as a mixture in which flame can spread to any distance, independently of, and away from, the original source of ignition

In the case of mixtures of any particular combustible gas with air (or oxygen) there are, under given physical conditions, certain limits of composition within (but not outside of), which self-propagation of flame will take place after ignition has once been effected. These limits, defined in terms of the percentage of the combustible gas present, are usually referred to as the 'lower' and 'higher' limits of inflammability of the gas under the given conditions. For any particular gas they differ slightly with the position of the source of ignition, since the progress of the flame may be assisted or retarded by convection-currents dependent upon whether it has to pass in an upward or downward direction. For example, with mixtures of methane and air and of acetone vapour and air the limits, expressed as percentages by volume of the mixtures, are as follows for upward, downward, and horizontal propagation of flame:—

Lower limit

	Upward	Downward	Horizontal
Methane	5·40	6·00	5·40
Acetone vapour	2·15	2·35	2·20

Higher Limit

	Upward	Downward	Horizontal
Methane	14·80	13·40	14 30
Acetone vapour	9·70	8·50	9·50

The limits of inflammability of a number of gases and vapours, mixed with air at atmospheric temperature and pressure, are given in the table that follows. For all but hydrogen and carbon monoxide the criterion of inflammability adopted for the determinations was propagation of flame throughout a 2½-litre sphere, ignition being at the centre. The figures for hydrogen and carbon monoxide refer to upward propagation of flame.

Gas	Lower limit p.c.	Upper limit p.c.
Hydrogen	4·1	71·5
Carbon monoxide	12·5	73·0
Methane	5·6	14·8
Ethane	3·1	10·7
Propane	2·2	7·4
Butane	1·7	5·7
Pentane	1·4	4·5
Ethylene	3·0	22·0
Acetylene	3·3	52·3

Vapour	Lower limit p.c.	Upper limit p.c.
Benzene	1·5	5·6
Toluene	1·4	5·4
Ethyl alcohol	4·4	—
Methyl alcohol	6·5	24·0
Ethyl ether	2·0	5·0
Acetone	2·25	9·6
Carbon disulphide	4·2	—
Petroleum benzine	1·1	3·8
Gasoline	1·5	7·3

The Effect of Temperature.—From what has been said in the preceding paragraph, it is evident that the self-propagation of flame through a mixture is, in principle, dependent on the temperature that the portion of the mixture which is burning can impart to the portion which is about to burn, from which it follows that the higher the initial temperature of the mixture the less dependent is the propagation of flame upon the heat generated by combustion. Hence the effect of increasing the initial temperature of mixtures of an inflammable gas and air should be to widen the range of inflammability, lowering the lower, and raising the higher limit.

Thus it has been found experimentally that a progressive increase in the initial temperature of mixtures of methane and air from 20° to 700° caused a corresponding decrease in the amount of methane required to enable self-propagation of flame to take place from 6·00 to 3·25 p.c. (downward propagation). Similarly, the higher limit was raised gradually from 13·40 p.c. at 20° to 16·40 at 600°.

The Effect of Pressure.—As exemplifying the influence of the initial pressure of gaseous mixtures upon their limits of inflammability, the case of mixtures of methane and air may be cited. A reduction of the initial pressure, at 20°C., from 760 to 380 mm. has but little effect on the limits; but below a pressure of 300 mm. mercury the effect is marked, the limits narrowing rapidly until, at a pressure of 120 mm. no mixture of methane and air is capable of self-propagation of flame (downwards). On the other hand, an increase of pressure above 760 mm. slightly raises both the lower and the higher limit, the figures at 6 atmospheres being 6·40 and 14·05 p.c. of methane respectively, for downward propagation of flame.

The lower limit with mixtures of hydrogen and air, and of carbon monoxide and air, is also raised by increasing the initial pressure above 760 mm., but with these two gases the higher limit is lowered.

Mixtures of Inflammable Gases.—In the case of a mixture of inflammable gases such as coal gas, a general formula is available by means of which its limits of inflammability with air may be calculated if its composition, and the corresponding limits of the individual gases are known. If a, b, c, . . . are the relative proportions of its components, and A, B, C, . . . their respective limits of inflammability, then L, the limit for the mixed gases, is given by the equation:—

$$L = \frac{a+b+c+ \cdots}{\dfrac{a}{A}+\dfrac{b}{B}+\dfrac{c}{C}+ \cdots} \quad . \quad . \quad \text{(i.)}$$

This relationship holds both at the lower and the higher limit. It implies that if a limit-mixture with air of one inflammable gas is mixed in any proportion with a limit-mixture with air of another inflammable gas, a limit-mixture results.

It has been necessary to emphasize the fact that this formula refers to mixtures of combustible gases with air, for the reason that the presence of any considerable quantity of an uninflammable constituent, such as nitrogen, in the commercial gas would narrow the range of inflammability, just as the range for a pure gas is narrowed if the oxygen-content of the air is reduced.

The effect of Incombustible Gases.—The effect of a reduced oxygen-content of the 'air,' or of the presence of inert constituents in the 'combustible gas,' is more marked at the higher than at the lower limit. This is well illustrated

by determinations of the limits for mixtures of methane with 'atmospheres' containing different proportions of oxygen. These determinations afford an index of the general effect of 'inert' gases on the limits of inflammable gases in general when the actual data are not available; the effect of carbon dioxide is rather more pronounced than that of nitrogen.

Atmosphere		Methane—p.c.	
Oxygen	Nitrogen	Lower limit	Higher limit
20·90	79 10 (air)	5·60	14·82
19·22	80·78	—	12·93
18·30	81·70	—	11·91
17·00	85·00	5·80	10·55
15·82	84·18	5·83	8·96
14·86	85·14	6 15	8·36
13·90	86·10	6 35	7·26
13·45	86·55	6 50	6·70
13·25	86·75	No mixture capable of propagating flame.	

Speed of Propagation of Flame.—During the propagation of flame in any 'limit' mixture, a balance is struck between heat generated by combustion and heat employed in starting combustion, together with heat lost by conduction and radiation. Theoretically, therefore, provided that the amount of energy imparted to the system by the initial source of ignition is small, so that no appreciable impetus to the propagation of flame occurs near the source of ignition, flame should travel in a limit-mixture at a uniform speed This is found to be so in practice; the speed of the flame is slower in a limit mixture for downward than in one for upward propagation; but under either condition it is quite uniform throughout the extent of the mixture.

It is otherwise when the proportion of inflammable gas lies at some intermediate point between the limits; that is to say, when the mixture is such that one layer on burning is capable of imparting to it a temperature higher than the ignition-temperature of the mixture. The phenomena of propagation of flame in such mixtures are dependent in a marked degree upon the conditions under which ignition is effected, so that it is necessary when speaking of the propagation of flame through them to specify exactly those conditions.

When ignition of a mixture of combustible gas and air has been effected at the open end of a long tube which is closed at the other end, the flame can be propagated in two principal ways, namely, (a) by transmission (by radiation, conduction, and convection) of the heat developed by the burning of one layer of gas to the layer adjacent to it; and (b) by the transmission of a sufficiently high pressure.

According to the first mode of propagation, the flame travels along the tube at a uniform speed for a certain distance, and then develops vibrations, swinging backward and forward with oscillations of increasing amplitude. The mean speed of the flame during this vibratory movement, which comprises a series of compression and rarefaction waves, is usually greater than the speed of the uniform movement. According to the nature of the mixture, either the vibrations may continue to the end of the tube, or the flame may become extinguished

during a particularly violent vibration (e.g. during rarefaction). Or again, a sudden permanently greater enhanced speed of flame may be developed as the result of the second mode of propagation coming into play (during a compression).

During this second mode of propagation each layer of gas is compressed so suddenly that it is raised beyond its ignition temperature by the heat of compression, and in burning it compresses in turn the unburnt layer in front of it. As already stated, the speed of the flame during this mode of propagation is permanently enhanced; it is, in fact, the maximum speed attainable by the flame and is a physical constant for each mixture of gases. The phenomenon is termed the 'detonation wave.'

When ignition takes place at the closed end of a tube open at the other end, the flame travels at a rapidly increasing speed towards the open end. If the tube is long enough, the flame may eventually assume a vibratory character and the detonation-wave may be developed.

What has been said in this short summary refers only to mixtures of a combustible gas with air; mixtures with pure oxygen behave somewhat differently. With regard to the latter, it may be stated that, in general, (a) the preliminary period of uniform movement is shorter, (b) a rapid acceleration follows, and (c) this is immediately succeeded by the detonation-wave without any vibratory movement taking place.

Of the different phases in the propagation of flame in mixtures of gases, the two regarding which most information is available are the 'uniform movement' and the 'detonation wave.' Some further account of these will now be given.

The Uniform Movement.—The initial slow propagation of flame that takes place when an inflammable mixture at rest is ignited at a point, is usually regarded as controlled by the transference, by conduction, of the heat developed by the combustion of the mixture immediately surrounding the point of ignition, whereby successive contiguous portions of the mixture are raised in temperature until chemical action becomes rapid. The initial speed of propagation of flame in a given mixture away from the point of ignition should mainly depend, according to this view (a) on the conductivity for heat of the unburnt mixture, and (b) on the velocity with which a moderately heated layer begins to react chemically and so to rise gradually in temperature; or, in other words, on the rate of change of reaction velocity with temperature.

Under certain conditions, with all inflammable mixtures of gases and air at atmospheric temperature and pressure, the initial slow propagation of flame can be maintained at a uniform speed over a considerable distance of travel from the point of ignition. The conditions most favourable, or perhaps even necessary, to initiate and maintain this 'uniform movement' of flame are (a) that the inflammable mixture should be contained in a long straight tube open at one end and closed at the other; and (b) that ignition should be at the open end by a source of heat not greatly exceeding in temperature the ignition temperature of the mixture, and not productive of mechanical disturbance of the mixture. The speed of the uniform movement

then depends on the composition of the mixture (presumed to be at atmospheric temperature and pressure), and on the diameter of the tube in which it is contained.
With a tube of a given diameter the speed

Fig. 1.

of the uniform movement of flame in a mixture can be regarded as a definite physical constant for that mixture, and its measurement is of considerable value in enabling a judgment to be formed of the behaviour of the mixture under normal conditions of burning.
In Fig. 2 are shown speed-percentage curves for the uniform movement of flame in mixtures of some of the common combustible gases with air over the whole range of inflammability for each gas. All the measurements were made in a tube of 2·5 cm. internal diameter, so that they are strictly comparable one with another. Apart from the striking differences in the speeds obtainable in different gases displayed by this diagram, a noticeable feature of the curves is the fact that with each gas the maximum speed is obtained not, as might perhaps be expected, with the theoretical mixture for complete combustion, but over a range of mixtures containing an excess of inflammable gas.

The extent to which the speed of the uniform movement is affected by the size of the tube along which the flame travels has been determined for mixtures of methane and air. The results are recorded in Fig. 3. For all practical purposes it can be assumed that the speed of the uniform movement of flame in mixtures with air of gases other than methane will be affected to a similar degree, so that the absolute speeds of the flames in pipes 30, 60, and 90 cm. in diameter will be respectively about 2·5, 3, and 3·5 times as great as the speeds recorded in the 2·5 cm. tube (Fig. 2).

It should be noted that the uniform speeds of the flames in tubes of large diameter (greater than 10 cm. for methane-air mixtures) are not, strictly speaking, those of the ' uniform movement ' as previously defined, since they are not controlled solely by conduction of heat. A

Fig. 2.

second factor, namely, convection, comes into play when the tubes are large, and is responsible for the enhanced speed of flame.

Mixtures of Inflammable Gases.—It has been found that a similar expression to that used for calculating the limits of inflammability of mixed combustible gases can be employed to determine, with fair accuracy, the maximum speed of

uniform movement of flame for any complex gas mixed with air, from a knowledge of its composition and the maximum speeds of each of the components. The expression is :—

$$c = \frac{a+b+c+\cdots}{\dfrac{a}{S_a}+\dfrac{b}{S_b}+\dfrac{c}{S_c}+\cdots} \qquad \text{(ii.)}$$

in which S is the speed required; a, b, c . . . the proportions of the different simple constituents in the complex inflammable gas (coal-gas, for example); and S_a, S_b, S_c . . . the maximum speeds of flame in mixtures of the individuals with air.

Formula (i.) can be used also for determining the composition of the mixture of the complex

FIG. 3.

Methane in air, per cent

gas and air in which the speed of the uniform movement of flame will be greatest; and formula (ii.) for determining the speed of flame in the limit-mixtures, and (though with rather less accuracy) in the mixture containing the gases in theoretical proportions for complete combustion.

The value of these formulæ will be appreciated if reference be made to Fig. 2, wherein are recorded, for comparison with the simple gas-air mixtures, the speeds of the uniform movement of flame in mixtures of the composite gases $CH_4 + H_2$ and $3CH_4 + H_2$ with air as determined by actual measurement in a tube 2·5 cm. in diameter. It will be seen that the gas with the lower speed of flame and the smaller range of inflammability (methane) has the predominating influence in deciding the magnitude of these constants for the mixed gas

The Effect of Incombustible Gases.—In addition to restricting the limits of inflammability, the presence of an incombustible gas mixed with the combustible gas has the effect of reducing the speed of flame in any of the mixtures with air. This effect is illustrated in Fig. 4, which shows the speed-percentage

curves for the uniform movement of flame in mixtures of methane with nitrogen-oxygen mixtures containing less oxygen than air, the

Methane, per cent   FIG. 4.

curve for air-mixtures being given for comparison. This diagram shows also the effect of nitrogen in reducing the range of inflammability and establishes the fact, theoretically

deduci... ... the speed of travel of flame is the same ... ... limit-mixtures that comprise the same constituent gases. The experiments from which these curves are constructed were made in a tube 5 cm. in diameter, so that the speeds are not directly comparable with those recorded in Fig. 2.

B.—THE DEVELOPMENT OF 'DETONATION' IN GASEOUS EXPLOSIONS. THE EXPLOSIVE WAVE AND 'RETONATION'—RATIO OF EXPLOSION

It was in the year 1881 that Berthelot and Vieille, and independently also Mallard and Le Chatelier, announced the discovery of the rapid acceleration of the initial velocity of inflammation in the progress of gaseous explosions and the final attainment of the enormously higher constant velocity of the 'explosion wave.' Since that date, the phenomena associated with the development of 'detonation' and the propagation of the explosion wave has been extensively studied in this country by H. B Dixon and his co-workers.

Mallard and Le Chatelier devised a photographic method for investigating the initial phases of gaseous explosion, which consisted in recording on a sentitised plate, moving at a known velocity on a vertical plane, the movement of the flame as it travelled along a horizontal glass tube. A graph compounded of the two velocities was thus obtained.

H. B. Dixon's experimental method consisted in photographing the explosion flame travelling along a horizontal tube on a highly sensitive film rotated vertically with a constant high velocity (varying, however, between twenty-five and fifty metres per second in different experiments), the explosion tube being placed at such a distance from the camera that the size of the image was about one-thirtieth that of the flame. In this way it was found possible to analyse the progress of an explosion from its point of origin up to the final attainment of its maximum force and velocity in 'detonation.' The investigation also included the discovery of the wave of 'retonation,' which is thrown back through the still burning gases from the point where detonation starts (a phenomenon also discovered by Le Chatelier independently in 1900), of the effects of collision between two explosion waves, and of the passage of reflected waves through the hot products of explosion.

The phenomena associated with the development of an explosion in a gaseous mixture, fired in a closed tube by a spark passed between wires a few inches from the closed end, are very clearly shown in the photograph reproduced in Fig. 5 which is analysed in Fig. 6. This photograph was taken during an experiment in which carbon disulphide was exploded with a quantity of oxygen represented by the expression CS_2+5O_2. The flame in starting at the point o, sends out

invisible compression waves in both directions along the tube, which travel in advance of the flame with the velocity of sound through the unburnt gases, as represented by the dotted lines OM, ON in the diagram. The flame itself, travelling at first more slowly than the compression waves, traces the curves OA and OB. The compression wave ON, on reaching the closed end of the tube, is reflected back again as NC, and, on meeting the flame (which is still travelling in the direction OA), retards it, and passes thence through the hot and probably still burning gases as the visible wave CD. An instant later it overtakes at D the front of the flame, travelling in the direction OB, thereby accelerating it and increasing its luminosity in

FIG. 5.   FIG. 6.

consequence of the quickened combustion. The flame then continues to move forward with rapidly accelerated velocity until 'detonation' is set up at the point E. At this point a strongly luminous wave of compression EG (the "retonation wave') is sent backwards through the still burning gases, which, on reaching the near end of the tube, is reflected back again as GH. The detonation 'wave' EF passes onward through the mixture with its characteristic uniform high velocity and intense luminosity. Fig. 7 is a similar photograph showing the development of 'detonation,' and the phenomenon of 'retonation' in the case of mixture of cyanogen and oxygen $(C_2N_2+O_2)$ fired near the closed end of a tube.

Except in special circumstances (e.g. when it is reinforced by another reflected wave) the velocity of the retonation wave is always

inferior to that of detonation; thus Le Chatelier gives 2990 metres per second for the 'detonation wave' and 2330 metres per second for the 'retonation wave' in an equimolecular mixture of acetylene and oxygen. When, however, the 'retonation wave' is developed just at the closed end of a tube (e.g. when the explosive mixture is fired at such a distance from the closed end that 'detonation' is set up just as the flame arrives at the end) it may be reinforced by a reflected wave, in which case its velocity cannot be distinguished from that of a true 'detonation.'

The explanation of the intense luminosity of the retonation wave, and its higher velocity than sound through the exploded gases, is to be found in the fact that the combustion during the initial stages of an explosion is very much slower than when detonation has been set up. Under the extreme conditions of 'detonation' the temperature of each successive layer of the explosive mixture is suddenly raised to the ignition point by adiabatic compression, and it is probable that a large proportion of collisions between chemically opposite molecules are fruitful of change. The whole combustion is probably completed in an immeasurably short interval of time, as the result of a comparatively limited number of successive molecular collisions. But during the initial period of the explosion ('inflammation') not only is the flame propagated with a much slower velocity, but also the actual process of combustion is much more prolonged than in detonation, and at the moment when detonation is set up combustion is still proceeding in the layers of gas for some distance behind the flame-front. The 'retonation' wave, in passing backward through these layers, quickens this residual combustion, and is itself thereby rendered highly luminous. This interpretation is supported by the repeated observations of Dixon, that the collision of two flames, in neither of which 'detonation' has been determined, will frequently give rise to reflected waves more rapid and more luminous than the incident waves. There can be little doubt as to the important part played by reflected-waves in determining the violent shattering effects associated with gaseous explosions on a large scale.

The Explosion Wave.—Berthelot and Vieille, in announcing their discovery of the develop-

FIG. 7.

ment of detonation '(l'onde explosive')' in gaseous explosions, described it as 'une certaine surface régulaire, où se développe la transformation, et qui réalise un même état de combinaison, de température, de pressure, etc. Cette surface, une fois produite, se propage ensuite, de couche en couche, dans la masse tout entière, par suite de la transmission des chocs successifs des molécules gazeuses amenées à un état vibratoire plus intense en raison de la chaleur dégagée dans leur combinaison, et transformées sur place, ou, plus exactement, avec un faible déplacement relati, . . .' Such conditions are comparable with those of a sound wave passing through the gaseous mixture, with, however, the important difference that, whereas a sound wave is propagated from layer to layer with a small compression and a velocity determined solely by the physical condition of the vibrating medium, it is an abrupt change in chemical condition which is propagated in the explosion wave, and which generates an enormous force as it passes through each successive layer of the medium.

In their experimental work Berthelot and Vieille proved that the velocity of the explosion wave is independent of the length of the column of gas traversed, and of the material or diameter of the tube employed (at least above a certain small limiting diameter). It is also immaterial whether the tube is laid out straight, coiled round a drum, or even zigzagged. They also concluded that the velocity is independent of the initial pressure, but this is not strictly correct, as H. B. Dixon has since shown. The rate increases slightly with the initial pressure, attaining a nearly constant value at a pressure of about two atmospheres.

It must be understood that when detonation is once determined in a particular explosive mixture, the wave is propagated with constant velocity (i.e. for a given initial temperature and pressure), which velocity is indeed an important physical constant for the particular mixture. The following 'rates of explosion,' as determined by Dixon, may be considered as typical of the extremely high velocities attained:—

RATES OF EXPLOSION FOR MIXTURES FIRED AT 10° AND 760 MM.

Mixture	Metres per second
$2H_2+O_2$	2820
H_2+Cl_2	1729
$2CO+O_2$ (moist, sat'd at 28)	1703
NH_3+3O_2	2390
CH_4+2O_2	2322

In detonation, each successive layer of the explosive mixture is fired by compression, and the chemical change in the wave occurs under strictly adiabatic conditions. This means that the chemical action is more intense and of much shorter duration than during the initial phases of an explosion ('inflammation'); moreover, the pressures developed in the wave and the consequent shattering effects are much greater than in ordinary explosions. Thus, for example, in a mixture $2H_2+O_2$, fired at the ordinary atmospheric temperature and pressure, the initial velocity of the flame (i.e. during the short period of 'inflammation') is only 20 metres per second, and chemical action endures in each successive layer of the mixture for as long as

one-twentieth of a second. As soon, however, as detonation is set up, the flame travels forward with a constant velocity of 2820 metres per second, and the duration of chemical action in each successive layer certainly does not exceed $\frac{1}{50000}$ and possibly not much less than $\frac{1}{10000}$ of a second. Needless to say 'detonation' is not set up in a gas-engine cylinder; the terrific force developed in detonation would play havoc with the mechanism.

Dixon's photographic researches, already alluded to, have demonstrated beyond doubt the important *rôle* of 'compression waves' in determining detonation in explosive mixtures, and it is probable that the disastrous effect of colliery explosions are primarily due to the intensifying effects of reflected compression waves upon the burning mixture of gas and (or) coal dust and air.

In 1899 D. L. Chapman published a mathematical analysis of the explosion wave. Discarding Berthelot's sound-wave theory, which indeed had led to values for rates of explosion which were difficult to reconcile with facts, he regards the explosion wave as a wave of compression not in a homogeneous medium, but in a medium which is discontinuous in the vicinity of the wave-front. It is assumed (1) that the 'front' of the wave (i.e. from the unexploded gas to the point of maximum pressure) does not alter in character, or, in other words, that every portion of the wave travels with the same velocity; (2) that the velocity is the minimum consistent with (1); and (3) that at the point of maximum pressure the chemical change concerned in the propagation of the wave is complete. The unburnt gases immediately in

front of the wave are, of course, fired by compression, and the abrupt variation in the density and pressure of the medium is due to the chemical change. Chapman's formula for the velocity of the explosion wave in centimetres per second is—

$$V = \frac{2RJ}{\mu C_v{}^2}\left[\left\{(m-n)C_p + mC_v\right\}C_p t_0 + (C_p + C_v)h\right]$$

when R=the gas constant (1·985), J=the dynamical equivalent of heat (42+10⁶ ergs.), μ=the gram equivalents of the mixture exploded, n and m = the number of gaseous molecules before and after the chemical change in the wave, C_p and C_v=the mean specific heats of the products at constant pressure and volume respectively, h=the total heat generated in the wave, and t_0=the initial temperature (abs.) of the mixture exploded.

From the fact that the dilution of electrolytic gas $(2H_2+O_2)$ with oxygen lowers its rate of explosion a little more than a corresponding dilution with nitrogen, Chapman considers it improbable that there is any appreciable dissociation of steam in the wave. He assumes that the molecular heat of steam rises more rapidly with temperature than that of a diatomic gas, and that the molecular heats of oxygen, hydrogen, nitrogen, and carbon monoxide may for all practical purposes be considered as equal at any given temperature. Selecting some seventeen of Dixon's found rates of explosion, he has calculated by means of his formula the corresponding molecular heats and temperatures, arriving at the following results for Cv at intermediate temperatures by interpolation :—

Temperature	4300°	4000°	3700°	3400°	3100°	2800°	2500°
Cv steam	14·750	14·297	13·750	13·102	12·250	11·040	9·797
Diatomic gases	7·707	7·674	7·641	7·608	7·575	7·542	7·509

With the aid of this series of numbers he proceeded to apply his formula to the calculations of the rates of explosions of some forty other mixtures investigated by Dixon, finding in all cases close agreement between the found and calculated values, of which the following may suffice as examples :—

Mixture exploded	Products in the wave	Temp.	Rate of explosion Metres per sec.	
			Calculated	Found
$2H_2+2N_2O$	$2H_2O+2N_2$	3813°	2408	2305
$4H_2+2N_2O$	$2H_2O+2N_2+2H_2$	3077	2604	2545
$6H_2+2N_2O$	$2H_2O+2N_2+4H_2$	2612	2720	2705
$2H_2+2N_2O+2N_2$	$2H_2O+4N_2$	3077	2097	1991
$C_2H_4+2O_2$	$2CO+2H_2O$	4365	2619	2581
$C_2H_4+3O_2$	$2CO+2H_2O+O_2$	3882	2348	2368
$C_2H_2+O_2$	$2CO+H_2$	5029	3101	2961
CH_4+O_2	$CO+H_2O+H_2$	2772	2502	2528
$2CH_4+3O_2$	$2CO+4H_2O$	3764	2485	2470
$2CH_4+3O_2+N_2$	$2CO+4H_2O+N_2$	3513	2353	2349

A characteristic feature of detonation is the extremely short duration of chemical action and the subsequent rapid cooling of the products, as compared with ordinary combustion. Some

years ago, W. A. Bone and B. Lean found by a photographic method that the duration of luminosity in each successive layer of gas in the detonation of electrolytic gas is certainly less than $\frac{1}{1000}$ second, a much shorter interval of time than was required to shatter a tube of thin glass attached to the end of the explosion coil used. This tube, although invariably smashed by the force of the explosion, always appeared perfectly intact in the photograph. Dixon's subsequent photographic researches have demonstrated the abrupt suddenness with which the gases attain the maximum temperature in detonation, the intensity and short duration of luminosity, and the subsequent rapid cooling of steam in the wave, for, despite the instantaneous cooling of the products, there is less than 1 per cent. of the gases left uncombined after the wave has passed through electrolytic gas $(2H_2+O_2)$.

Influence of an Excess of an Inert Gas upon the Rate of Explosion of a particular Mixture.— It has been found experimentally that whereas an excess of nitrogen or oxygen retards the rate of explosion of a particular mixture, an excess of hydrogen actually increases it. Thus in the case of electrolytic gas, we have—

Mixture exploded				Rate metres per sec.
$2H_2 + O_2$	.	.	.	2817
$2H_2 + O_2 + 2H_2$	.	.	.	3268
$2H_2 + O_2 + 4H_2$	.	.	.	3527
$2H_2 + O_2 + 6H_2$	.	.	.	3532
$2H_2 + O_2 + O_2$	.	.	.	2328
$2H_2 + O_2 + 3O_2$	.	.	.	1927
$2H_2 + O_2 + N_2$	.	.	.	2426
$2H_2 + O_2 + 3N_2$	.	.	.	2055

The accelerating influence of an excess of hydrogen was for long an enigma, but it was perfectly explained when Chapman published his formula. It must, however, be understood that an excess of oxygen always has a somewhat greater influence than a corresponding excess of nitrogen by virtue of its relatively higher density

The Burning of Gaseous Carbon.- Of the many important facts brought to light during the course of Dixon's investigations none are of greater interest than those relating to the burning of gaseous carbon in the explosion wave, as illustrated by the case of cyanogen. In view of the fact that the molecular heat of combustion of cyanogen, when burnt completely to carbon dioxide, is 259·6 K.C.Us , whereas, if burnt to the monoxide, it would only be 123 K C Us., it might be expected that the rate of explosion for a mixture $C_2N_2 + 2O_2$ would be much higher than for $C_2N_2 + O_2$, if gaseous carbon is primarily burnt to carbon dioxide in the wave The exact opposite is the case, however, as the following results show —

Mixture	Products	Rate	
$C_2N_2 + O_2$	$2CO + N_2$	2728	metres per sec.
$C_2N_2 + 2O_2$	$2CO_2 + N_2$	2321	

Still more cogent is the evidence in favour of the initial formation of carbon monoxide in the wave, when the following figures are considered :—

	$C_2N_2 + O_2$	$C_2N_2 + O_2 + N_2$	$C_2N_2 + O_2 + O_2$
Rate	2728	2398	2321

The conclusion to be drawn from the preceding figures is that cyanogen is initially burnt to carbon monoxide and nitrogen in the wave itself, any excess of oxygen afterwards burning up the carbon monoxide as the gases cool down in the rear of the wave.

This conclusion was driven home by Dixon, in conjunction with Strange and Graham, by photographing on a sensitive film rotated at a speed of about 1500 metres per minute, the explosion flame in the case of the three mixtures (a) $C_2N_2 + O_2$, (b) $C_2N_2 + O_2 + N_2$, and (c) $C_2N_2 + 2O_2$. In each case the flame was photographed, after detonation had been set up, as it dashed past a glass window inserted into the lead explosion coil [2] The image obtained in the case of (a) showed an intensely brilliant flame (the explosion wave), slightly drawn out in tapering form ; in the case of (b), with nitrogen as diluent, the flame was less brilliant and somewhat more drawn out than in (a) but with (c) the flame, whilst no more luminous than in (b), was drawn out to great length, owing to the continued combustion of carbon monoxide in the rear of the wave The following diagram, Fig. 8 (approximately to scale), will convey an idea of the relative durations of the flames in the three cases :—

FIG. 8.

The Burning of Hydrocarbons in the Wave.— It was during the course of measurements of the rates of explosion of hydrocarbons with varying proportions of oxygen in 1891–92 that Dixon and his collaborators rediscovered facts (originally set forth by Dalton in his ' New System of Chemical Philosophy ') which finally disposed of the dogma that in a deficient supply of oxygen a ' selective ' burning of hydrogen occurs. Bone, in conjunction with Lean and Cain, found that when either ethylene or acetylene is detonated with its own volume of oxygen the ultimate products consist almost entirely of carbon monoxide and hydrogen.[1] The rates of explosion of hydrocarbon-oxygen mixtures, whilst they do not reveal the real mechanism of the combustion, show very clearly that,

as in the case of cyanogen, the carbon of a hydrocarbon is burnt to, the monoxide in the wave itself, the formation of the dioxide being an after-effect and taking place in the rear of the wave. In the cases of methane and acetylene the fastest rates are observed with equimolecular mixtures, whereas with ethylene the rate increases with the proportion of oxygen up to the limit $C_2H_4 + 2O_2$.

C.—THE PRESSURES PRODUCED IN GASEOUS EXPLOSIONS.

Many investigators, from the time of Bunsen's well-known experiments in 1867 onwards, have measured the pressures produced in gaseous explosions, with doubtless considerable success so far as what may be termed the mean effective

[1] *Vide* Lean and Bone, Trans. Chem. Soc. 1892, 61, 873, and Bone and Cain, *ibid.* 1897, 71, 26.

[2] Trans. Chem. Soc. 1896, 69, 759.

pressures are concerned. The explosion vessel employed by Bunsen was a stout glass tube 8·15 cm. long, 1·7 cm. internal diameter, and of 18 cc. capacity. It was closed by a suitable valve, the load on which could be adjusted until it was just lifted when the explosive mixture was fired by means of a powerful spark passed along the axis of the tube. Bunsen considered that the combustion would occur under adiabatic and 'constant volume' conditions, and he identified the rate of ignition of a particular mixture with that of the completion of chemical change. In calculating from his results the corresponding flame temperatures, he assumed the constancy of the specific heats of steam and carbon dioxide. Finding that the pressures recorded in the cases of electrolytic gas and of a mixture of carbon monoxide and oxygen in their combining proportions (namely, 9·5 and 10·1 atmospheres respectively) were somewhat less than one-half of those theoretically re-

quired on the above assumption, he concluded that in each case combustion had proceeded *per saltum*, owing to the supposed theoretical flame temperatures exceeding the limits at which steam and carbon dioxide respectively are completely dissociated. The problem was again attacked independently by Mallard and Le Chatelier in 1883,[1] and by Berthelot and Vieille in 1885.[2] The last-named fired various gaseous mixtures at atmospheric pressure in a spherical iron bomb, measuring the effective pressures by the movement of a light piston working against a spring in a tube attached to the bomb. In order to gain some information respecting the possible cooling influence of the walls upon the effective pressures recorded, three bombs of different capacities, namely, A. of 300 cc. B. of 1500 cc., and C. of 4000 cc, were employed. The results, expressed in each case as atmospheres in excess of the atmospheric pressure, were as follows :—

Bomb	A	B	C
Capacity in cm.³	300	1500	4000
Surface in cm.²	216	648	1200
Surface per unit volume	0·72	0·43	0·33
Diameter in cm.	6·0	14·2	21·7
Length of firing piece in cm.	6·3	5·3	6·3
Travel of flame before reaching the piston in cm.	9·1	16·3	24·8
	Atms.	Atms.	Atms.
Mixture exploded $2H_2+O_2$	7·41	9·69	9·80
$2CO+O_2$	9·29	9·93	10·21
CH_4+2O_2	13·94	14·81	16·31
$C_2N_2+O_2$	—	—	25·11
$C_2N_2+2O_2$	—	—	20·96
Time required for flame to travel from the firing piece to piston of indicator.			
Mixture $2H_2+O_2$	0·00104 sec.	—	0·00214 sec.
$2CO+O_2$	0·01286 sec.	—	0·01551 sec.

Perhaps the most notable feature about these results is the smallness of the difference between the pressures observed with bombs A and C in any particular case. These differences might at first sight be attributed to the (supposed) much smaller cooling influence of the walls of the bomb C as compared with bomb A, but if this were the true explanation the difference should be greater with the slow-burning $2CO+O_2$ mixture than with the fast-burning $2H_2+O_2$, whereas the opposite was the case. Moreover the fact that dilution of the mixture $2H_2+O_2$ with twice its own volume of nitrogen almost obliterated the difference between the pressures observed in the cases of bombs A and C (the ratio $\frac{pC}{pA}$ for the diluted being 0·95, as against 0·76 for the undiluted mixture) is all against the cooling theory. The more probable explanation is to be found in the fact that, owing to the much longer travel of the flame before it reached the piston of the indicator in bomb C as compared with A, the explosion would be in a more advanced phase of its development, and this would be most marked in the case of the fastest burning mixtures. Berthelot and Vieille assumed

that in the above experiments completion of the combustion synchronised with the attainment of maximum pressure, and attributed the marked disparity between the observed pressures (bomb C) and those calculated from the heats of combustion (on the assumption of adiabatic conditions) to a rapid increase in the specific heats of steam and carbon dioxide at high temperatures. They considered it improbable that dissociation phenomena play any conspicuous part in limiting the pressures attained.

Mallard and Le Chatelier (*l.c.*) who used a Bourdon gauge for measuring pressures and applied a 'cooling correction' to their results, arrived at practically the same conclusion as Berthelot and Vieille (Ann. Chim. Phys. [vi.] 4, 13) respecting both the increase of the specific heats of steam and carbon dioxide with temperature and the small if not negligible influence of dissociation. They calculated that the temperature of the flame when moist electrolytic gas is exploded in a closed vessel at atmospheric pressure is about 3350°, and that the mean molecular heat of steam at constant volume

[1] Annales des Mines, sec. viii. vol. 4.
[2] Ann. Chim. Phys. (vi.) 4, 13.

between 0° and 3350° is 16·6. In the case of the mixture $2CO + O_2$ they concluded that the molecular heat (C_g) of carbon dioxide rises to 13·6 at 2000°, above which temperature dissociation comes into play.

Dugald Clerk also made experiments with hydrogen-air mixtures in a large cast-iron vessel comparable in dimensions to the cylinder of a six-horse-power gas engine. It was a cast-iron cylinder truly bored out and the end covers turned, internal dimensions 7 inches diameter and 8¼ inches long, capacity 317 cubic inches. Upon the upper cover was placed a Richards indicator, in which the reciprocating drum had been replaced by a revolving one; the rate of revolution was adjusted by a small fan, a weight and gear giving the power. The cylinder was filled with the explosive mixture to be tested, the drum set in motion, the pencil of the indicator pressed gently against it, and the electric spark passed within the cylinder. The pressure of the explosion, acting upon the indicator piston, traced a line upon the drum which showed the rise and fall of pressure. The rising line traced the progress of the explosion, the falling line the progress of loss of pressure by cooling.

Fig. 9.

Fig. 9 shows the arrangement of the apparatus. Experiments with hydrogen and air mixtures gave the following results :—

MIXTURES OF HYDROGEN AND AIR (CLERK).

| Experiment | Mixture | | Max. pressure above atmosphere in lbs. per sq. inch. | Time of explosion | Max. temp. of explosion |
	H	Air			
			Temp. before explosion 16°. Pressure 14·7 lbs.(atmospheric)		
a	1 vol.	6 vols.	41	0·15 sec.	826° to 909°
b	1 vol.	4 vols.	68	0·026 sec.	1358° to 1539°
c	2 vols.	5 vols.	80	0·01 sec.	1615° to 1929°

The maximum temperatures were calculated on the two extreme assumptions of complete contraction and no contraction.

The curves of explosion from which these figures are deduced are given at Fig. 10.

The rate of cooling was comparatively slow; for instance, in all these experiments, at the end of 0·66 second from the beginning of explosion there still remains above 20 lbs. per sq. inch above atmospheric pressure. The explosion was followed by a very slow fall of pressure.

Calculating from these curves the total heat accounted for by maximum pressure, and allowing for loss of heat to the walls during time of

Vessel used 7 inches diam. and 8¼ inches long. Scale of indicator spring, 1 lb. = ¹⁄₁₄ inch.

FIG. 10.

explosion, as estimated from the falling curves, a great deficiency becomes evident.

Experiment	a	b	c
Heat of combustion of hydrogen present	100	100	100
Heat accounted for by maximum temperature and loss previous to its attainment.	55	70	54

Even with hydrogen and air mixtures the deficiency ranges from 30 to 46 p.c. It is remarkable that the deficiency at the temperature of about 900° is ·identical with that at about 1800° within the limits of error. It should be noted, however, that this method of allowing

for heat loss will probably give a low value, as no account is taken of the difference in the action of the walls on the rising and falling lines, nor of the possible difference in radiation.

In 1915 W. A. Bone and his collaborators published the results of experiments in which mixtures corresponding to (1) $2H_2+O_2+4N_2$; (2) $2CO+O_2+4N_2$, and (3) $CH_4+O_2+4N_2$, were exploded at an initial pressure of 50 atmospheres in a spherical bomb (capacity=275 c.c.) to which was attached a Petavel recording manometer with its optical accessories. The results of two typical experiments with each of the three mixtures are recorded in the following table :—

W. A. BONE'S PRESSURE EXPERIMENTS.

Mixture fired .	$2H_2+O_2+4N_2$		$CH_4+O_2+4N_2$		$2CO+O_2+4N_2$

Ratio p_m/p_i	8·0	8·0	5·35	5·6	8·3	8·4
Ratio p_f/p_i	0·575	0·575	1·049	1·034	0·832	0·837
Time required for attainment of maximum pressure in seconds	0 011	0 010	0·05	0·08 about	0·10	0·10

The pressure records which are reproduced in the following diagrams (Figs. 11, 12, and 13), in which pressures in atmospheres are plotted against time in seconds, prove conclusively the absence of any direct relation between the actual rate at which the potential energy of an

explosive mixture is transferred on explosion as sensible heat to its products and the magnitude of the chemical affinity between its combining constituents. This is hardly to be wondered at, seeing the extreme rapidity of chemical interaction at high temperature as compared with

FIG. 11.

the rate at which the liberated heat can be communicated to and uniformly distributed amongst the products by ordinary physical processes. Attention may be drawn to the extreme slowness of the cooling in each case after the attainment of maximum pressure; this has also been observed by previous workers in other similar cases of gaseous explosions. This was particularly marked in the case of the methane-air mixture, in which there was hardly any appreciable cooling during an interval of

0·22 seconds after the attainment of maximum pressure (in 0 08 sec), a circumstance which may be due in part to the combustion taking place in well-defined chemical stages, and in part also to the operation of the exothermic secondary interaction between carbon monoxide and steam during the cooling period. On the other hand, the curve for the hydrogen-air mixture, where the combustion to steam is a direct and comparatively simple transaction suggests that the attainment of maximum

pressure is succeeded by a period of gradual cooling uninfluenced by chemical combination.

It may be taken as the common experience of all investigators since Bunsen's day that the maximum effective pressures recorded when gaseous mixtures are fired in closed vessels are always considerably less than those calculated on the old assumption (now discarded) that the whole heat of combustion is communicated without loss to the products, and that the specific heats of the products do not vary with temperature. Another feature of the phenomenon is the very short time required for the attainment of maximum pressure relative to the subsequent cooling period.
The great disparity between the found and

Fig. 12.

'calculated' maximum pressures has been attributed by the various investigators, concerned to one or other of the following causes, namely :

1. *To the marked increase in the specific heats of steam and carbon dioxide with temperature.*

2. *To the fact that in ordinary gaseous explosions, where detonation has not been determined,* combustion is by no means instantaneous, and may not be completed within the period required for the attainment of maximum pressure. Sir Dugald Clerk put forward this suggestion as long ago as 1886 [1] in criticising the conclusions of Mallard and Le Chatelier respecting the great increase in the specific heats of steam and of carbon dioxide with temperature. He considered it highly

Fig 13.

probable that combustion extends far into the actual 'cooling period' in gaseous explosions (and hence the long drawn-out 'cooling curve'), so that the system loses a certain part of the heat of combustion before the chemical action is completed. This idea of a continued combustion finds support in H. B. Dixon's photographic researches, and chemists generally will concede its reality in any gaseous combination in which detonation is not determined. But to what extent it may be held to affect the pressures actually recorded by explosions is still a matter of conjecture.

3. *To loss of energy by direct radiation.*— Thus in the explosion of a mixture of hydrogen and oxygen it is conceivable that the *initial* action results in the formation of an intensely vibrating molecular complex from which steam, issues as the first recognisable product. Some experiments made in 1890 by Robert von Helmholtz (Beiblätter, 14, 589), showed that non-luminous hydrocarbon flames radiate about

5 p.c. of the heat of combustion of the gas, and more recent experiments by Callendar and Nelson show that the heat radiated from an ordinary non-luminous Bunsen flame may amount to between 15 and 20 p.c. of the total heat of combustion.

4. *To dissociation of products* (steam and carbon dioxide). In the case of two combining gases producing a dissociable product, it is clear that if the average temperature in the system reaches that at which dissociation begins the combustion must be delayed whilst heat escapes from the system by radiation and conduction. Qualitatively the partial dissociation of steam and carbon dioxide has been proved at temperatures which are certainly exceeded by those of explosion flames; but it may be urged that, inasmuch as all experiments upon dissociation have up to the present involved contact with hot solid surfaces, there is no positive evidence that the phenomenon would

[1] Proc. Inst. Civil Engineers, 85.

play any conspicuous part in an unconfined gaseous system. On the other hand, there is direct experimental evidence of the attainment of enormously high temperatures in the explosion wave, temperatures which would generally be considered as far beyond that of the initial, or perhaps even of the complete, dissociation of steam or of carbon dioxide. Moreover, the fact that the rate of explosion of electrolytic gas is retarded rather more by an excess of oxygen than by a corresponding excess of nitrogen is inconsistent with the supposition of any appreciable dissociation of steam in the explosion wave, and photographic records give no evidence of continued combination in the rear of the wave except where there are two or more chemical stages in the combustion.

Explosion of mixtures of coal gas and air.— Experiments were made many years ago by Clerk with mixtures of coal gas and air in the explosion apparatus already described, with the following results :—

GLASGOW COAL GAS AND AIR MIXTURES (CLERK).

		Temperature of gases before ignition, 18°. Pressure of atmosphere (14·7 lbs.)		
Experiment	Proportion of gas by volume	Maximum pressure in lbs. per sq. inch above atmosphere	Maximum temperature centigrade	Time of explosion
a	1/1·1	52	1047°	0·28 second
b	1/1·2	63	1265°	0·18 ,,
c	1/1·0	69	1384°	0·13 ,,
d	1/8	89	1780°	0·07 ,,
e	1/6	96	1918°	0·05 ,,

From these experiments, it will be observed that the greatest possible pressure exerted by a mixture of Glasgow coal gas and air at atmospheric pressure and temperature was 96 lbs. per square inch above atmosphere, the maximum pressure falling as dilution with air increased, while the time of explosion also increased. The shortest time of explosion was $\frac{1}{20}$ second, and the longest over $\frac{1}{2}$ second, at the end of 0·60 second from 30 to 35 lbs. per square inch pressure above atmosphere still remained in the vessel. It is very noticeable that, volume for volume, coal gas produced higher pressure than hydrogen.

Experiments with Oldham gas and air gave the following results :—

OLDHAM COAL GAS AND AIR MIXTURES (CLERK).

		Temperature of gases before ignition, 17°. Pressure of atmosphere (14·7 lbs.)		
Experiment	Proportion of gas by volume	Maximum pressure in lbs. per sq. inch above atmosphere	Maximum temperature centigrade	Time of explosion
a	1/15	40·0	806°	0·45 second
b	1/14	51·5	1033°	0·31 ,,
c	1/13	60·0	1202°	0·24 ,,
d	1/12	61·0	1220°	0·17 ,,
e	1/10	78·0	1557°	0·08 ,,
f	1/8	87·0	1733°	0·06 ,,
g	1/7	90·0	1792°	0·04 ,,
h	1/6	91·0	1812°	0·055 ,,
i	1/3	80 0	1595°	0·16 ,,

The greatest pressure produced by a mixture of this gas and air was 91 lbs. per square inch above atmosphere. Comparing these numbers with the Glasgow gas experiments, it appears that with $\frac{1}{10}$ vol. of Oldham gas present, the pressure attained was 0·5 lb. per square inch less, and the time of explosion is 0·31 second against 0·28 second with the same proportion of Glasgow gas. With $\frac{1}{8}$ of the two gases, Oldham was 5 lbs. less maximum pressure and 0·055 second against 0·05 second Glasgow.

In all these experiments the suppression of heat at the maximum temperature is very considerable, ranging from 50 to 60 p.c.

Experiments were also made by Clerk in the same vessel with mixtures previously compressed, and it is found that the pressures produced with any given mixture are proportional to the pressure before ignition—that is, with a mixture of constant composition double the pressure before explosion, keeping the temperature constant, doubles the pressure of explosion.

In 1900 Clerk made further experiments with London coal gas and air, with very complete precautions to ensure mixing, and with more accurate timing devices. The curves obtained with this apparatus are shown at Fig. 14, and the maximum temperatures and pressures, and time of explosion for the different mixtures, are as follows :—

EXPLOSION IN A CLOSED VESSEL (CLERK, 1900).
Mixtures of air with London coal gas.
Temperature before explosion 16°
Pressure before explosion . 14·8 lbs. per sq. in.

Mixture		Max. pressure above atmosphere in lbs per sq. inch	Temp. of explosion from observed pressure	Time of explosion
Gas	Air		°C.	sec.
1 vol.	12 vols.	4	—	—
1 ,,	11 ,,	58	1150	0·290
1 ,,	10 ,,	60	1155	0·305
1 ,,	9 ,,	65	1270	0·155
1 ,,	8 ,,	77	1475	0·087
1 ,,	7 ,,	80	1565	0 067
1 ,,	6 ,,	85	1660	0·055
1 ,,	5 ,,	87	1710	0·042
1 ,,	4 ,,	93	1830	0·045

J. E. Petavel has also made experiments on the explosion of coal gas and air compressed before ignition to pressures of over 1000 lbs. per square inch. Fig. 15 shows the diagrams obtained, with the particulars marked thereunder.

In all these experiments, it is clear that if the temperature be calculated from the maximum pressure of explosion, there is apparently a suppression of heat at a very considerable amount at maximum temperature, the amount being about 60 p.c.

Important experiments were also made by Prof. B. Hopkinson, of Cambridge University, who investigated the actual temperatures reached during explosions of coal gas and air in an explosion vessel of the form shown at Fig. 16 and found very large temperature variations at different parts of the vessel, and that the temperature differences existed after complete inflammation, quite independently of the local cooling effect of the walls of the vessel.

Explosion in a closed vessel, London gas, 1900 (Clerk).

He found that after the explosion of coal gas and air in the vessel, the distribution of temperature at the moment of maximum pressure was roughly as follows :—

Mean temperature (inferred from pressure) 1600°
Temperature at centre of vessel, thermometer B . . . . 1900°
Temperature 10 cm. (4 inch) within wall, thermometer C . . . 1700°
Temperature 1 cm. (0·4 inch) from wall, at end, thermometer D . 1100° to 1300°
Temperature 1 cm. (0·4 inch) within wall at side . . . . 850°

Half a second after maximum pressure, the distribution was as follows :—

Mean temperature (inferred from pressure) . . . . 1100°
Mean temperature, exclusive of layer 1 cm. thick at walls, determined by long platinum wire from B to D . 1160°
Temperature at centre of vessel, thermometer B . . . 1100° to 1200°

Here the temperature differences are much smaller than at the moment of maximum pressure. Hopkinson found that the explosion vessel is entirely filled with flame when the pressure reaches 70 lbs., although the maximum pressure attained later is 82 lbs. per square inch above atmosphere ; that is, maximum pressure is not attained until one-thirtieth of a second after the vessel is completely filled by flame. Hopkinson's experiments also distinctly prove that the highest temperature reached in the vessel is at the point of origin of the ignition, and is due to the compression of the gases which are first heated by explosion to about 1200°, and then compressed by the compression from the walls inwards, as the mixture near the walls inflames.

Explosion in gas-engine cylinders.—In all internal-combustion engines in general use at the present time, the mixture of fuel and air is compressed before ignition, the maximum temperature ranging from 1200° to 2500° ; while the temperature of the hot gases at the moment of opening the exhaust valve may be

about 1000°. Fig. 17 is a repro-
duction of an indicator diagram of
an internal-combustion engine work-
ing on the Otto cycle. The effect of
weakening the mixture is shown by
the different lines on the diagram.
The line *q* shows a diagram obtained
from a strong mixture; *b*, a diagram
from a slightly weaker mixture; and
c, a diagram obtained from a very
weak mixture. The effect of apparent
suppression of heat appears on the
gas-engine diagram as well as in the
diagrams obtained by explosion in
closed vessels at constant volume,
referred to above; and it is ex-
tremely important, for the purpose
of a correct theory of the internal-
combustion engine, to ascertain
exactly what takes place on ex-
plosion, and immediately after ex-
plosion of the mixture used; and a
complete knowledge of the thermal
properties of the working fluid and
its chemical composition at any instant during
the cycle is necessary.

In the normal gas-engine diagram, the
expansion line is at first usually considerably
above the adiabatic, showing that the whole of
the heat of combustion is not added before
maximum pressure, and that heat must be added
to the gases during a portion of the expansion,
to make up for the flow of heat through the
cylinder walls. If, however, the cooling on
expansion is too great, the expansion line may
fall below the adiabatic, although there is still
heat being added. The adiabatic expansion line
for any given mixture of gases depends on the
specific heat of the mixture, and therefore, in
order to determine what are the conditions as

FIG. 16.

Hopkinson's Explosion Vessel.

regards addition of heat, it is necessary to know
the specific heat or internal energy of the mixture
at any given temperature.

FIG. 17.

Clerk has investigated the properties of the
working fluid in the gas
engine itself, by a method
which allowed direct ob-
servation to be made upon
an actual charge taken
into the engine in the
ordinary operations of its
cycle. The method con-
sisted in subjecting the
whole of the heated pro-
ducts of combustion to
alternate compression and
expansion, within the
engine cylinder, while the
cooling proceeded, and
observing by the indicator
the successive pressure
falls from revolution to
revolution, together with
the temperature and pres-
sure rise and fall due to
the alternate compression
and expansion. The engine
was set to run at a given
speed, and after the
charge of gas and air had
been drawn in, compressed
and ignited, the exhaust
valve and inlet valve
were prevented from
opening, so that when
the piston reached the
Spherical enclosure capacity, 551·9 c.c   Temperature of enclosure : before firing,

Ratio $\frac{Maximum\ pressure}{Initial\ pressure} = 8\cdot8$.

FIG. 15.

Rise and Fall of Pressure during and after Explosion (Petavel).

end of its power stroke, the exhaust gases were retained within the cylinder, and compressed by the piston to the maximum volume, and again allowed to expand and again compressed, and so on. These operations gave a diagram as shown at Fig. 18. From this diagram, by determining the temperature fall due to work done on expansion, Clerk determined the apparent specific heat of the products of combustion, and found that for the gas-engine mixture there was a considerable rise of apparent specific heat with temperature, and it seemed probable that this was largely due to a real increase of the actual specific heat or internal energy of the gases at high temperatures. The experiments, however, could not differentiate between the possible effects produced by dissociation and real specific heat change. Further, the values obtained were subject to some uncertainty, due to the difficulty of apportioning heat loss between successive compression and expansion lines, and it is probable that the values are somewhat raised by some film phenomena, or by smouldering combustion, tending to keep the expansion line from falling as rapidly as it would otherwise do.

Work of the British Association Committee on Gaseous Explosions.—Owing to the great importance to the theory of the internal-combus-

tion engine of a complete understanding of the phenomena of gaseous explosions, the British Association appointed a committee for the purpose of investigating the whole matter, and although the work of this committee is not yet completed, very important results have already been obtained. These are set out in the Reports of 1908, Dublin; 1909, Winnipeg; and 1910, Sheffield. The committee regard it as proved that on the explosion of gaseous mixtures with air, the quantity of carbonic acid or steam dissociated at the temperature of the explosion is so small, that the suppression of heat cannot be due to this cause.

They also concluded that chemical equilibrium is complete within an extremely short period after inflammation at any point outside the influence of the walls, and that there is no time rate of combustion, such as will account for the apparent suppression of heat.

The committee have also made a very careful comparison of the specific heat found by Holborn and Henning by methods not depending on explosion, with the values found by explosion experiments, such as those of Clerk, Mallard, and Le Chatelier, and Langen. The results given in calories per gram-molecule for the internal energy calculated from 100° at temperatures of 800°, 1200°, 1600°, and 2000°, are as follows :—

| | 800° | | 1200° | | 1600° | 2000° |
	Clerk	Holborn and Henning	Clerk	Holborn and Henning	Langen	Langen
Air .	—	3570	—	5840	8760	11500
CO_2 .	—	6460	—	10880	17000	23300
H_2O .	—	4670	—	7930	14400	19900
Gas-engine mixture .	4250	3840	6900	6340	9800	13200
Ideal gas* .		3430		5400	7350	9300

* $C_v = 4.9$.

In this table, in order to reduce to foot-lbs., the figures should be multiplied by the factor 3.96.

FIG. 18.

Clerk diagram from engine at a brake load of 50 H.P. at 160 revolutions per minute.

The agreement between the figures by the two methods shows that the suppression of heat is very largely due to increase in the real specific heat at high temperatures.

It seems clear also that the cooling due to the walls of the explosion vessel will damp out a certain portion of the combustion, and thus give a certain time rate of combustion, so that all the heat is not actually evolved at the point of maximum pressure or maximum temperature. By arranging a moving piston so that the exhaust products can be collected, and immediately cooled at any instant during the expansion stroke, Clerk has shown from an analysis of the exhaust products that there is still some uncombined gas after the point of maximum temperature has been reached, even with strong mixtures.

The committee also consider that the apparent suppression of heat in explosion experiments, when temperature is calculated

from pressure, is partly due to under-estimation of the heat loss due to radiation. Callendar predicted that this would be the case from his experiments on the radiation from a Bunsen flame; and Hopkinson has shown that the total heat radiated during and after an explosion of a 15 p.c. mixture of coal gas and air amounted to over 22 p.c. of the whole heat of combustion.

W. A. B. and R. V. W.
